No controlled trials are available to guide therapy of MCTD, so that treatment is based on case series experience and conventional therapies that are known to be effective for manifestations of disease common to other CTDs (SLE, SSc, PM/DM). Since the clinical course of disease in MCTD is variable, therapy should be individualized to address specific organ involvement and disease severity. Most clinical manifestations of MCTD, with the exception of Raynaud phenomenon, are steroid responsive. Low-dose glucocorticoids, nonsteroidal antiinflammatory drugs, hydroxychloroquine, or combinations of these medications are used for early nonaggressive disease. Vasodilating drugs are used for Raynaud phenomenon, with nifedipine the most common. High dose systemic corticosteroids, methotrexate, or cytotoxics may be added for more severe disease, particularly organ threatening disease.

PAH may require treatment with the same classes of drugs used to treat idiopathic PAH (prostacyclin analogues, endothelin receptor antagonists, phosphodiesterase type 5 inhibitors—see Chapter 72 for management of PAH). PAH can be fatal but is not always progressive and sometimes resolves.[179,191] Multiple case reports in adults[179,187,192] and children[191,193,194] also report successful treatment of PAH with immunosuppressive therapy (corticosteroid and CYC), considering the PAH as part of a "disease flare." Heart and lung transplantation is an option for end-stage PAH.

## Prognosis

MCTD is considered incurable and outcomes are variable depending on organ involvement; however, most children have a favorable prognosis. Ten years mortality is reported to be 16%–28% in adults and 7.6% in children.[191] Deaths are most often due to rapid-onset pulmonary hypertension in adults[179] and infection in children.[191]

# Sarcoidosis

Sarcoidosis is a chronic multisystem disorder of unknown etiology affecting mostly young adults and rarely children.[195–197] It is characterized by noncaseating epithelioid cell granulomas, which have a predilection for thoracic lymph nodes and lung tissue. Children with sarcoidosis commonly have disease manifestations similar to adults with sarcoidosis, with bilateral hilar lymph adenopathy (BHL) with or without parenchymal infiltrates. At least half of adult cases will resolve spontaneously within 2 years without any specific therapy. However, progression of lung disease to pulmonary fibrosis and uveitis to blindness are two potential long-term morbidities that call for careful consideration for treatment and follow-up of the sarcoidosis patient.

Early onset sarcoidosis (EOS), with symptom onset at the age of 4 years or younger and a unique phenotype of skin rash, uveitis, arthritis, and absence of lung disease, was previously described to be a rare presentation of sarcoidosis.[198] However, it is now believed that EOS is the sporadic form of Blau syndrome, a familial autoinflammatory disease with autosomal dominant inheritance caused by mutations in the NOD2/CARD15 gene.[199,200] With increasing recognition of EOS, previously unidentified visceral involvement, including interstitial pneumonitis, has now been reported.[201] EOS tends to present to the pediatric rheumatologist and will not be discussed further in this chapter. However, the pulmonologist should consider genetic causes in the differential diagnosis of sarcoidosis in young children and familial cases.

## Epidemiology

The incidence of sarcoidosis varies by geographic location, race, and age, but usually develops before the age of 50 years and peaks in incidence between 20 and 39 years. The highest incidence of disease has been reported in northern European countries (5–40 cases per 100,000 people)[202,203] and among black Americans (35.5 cases per 100,000 compared with 10.9 per 100,000 in white Americans).[204] The incidence in children is less well described but is generally felt to be much lower than in adults. Data from the Danish national patient registry show an overall incidence of 0.29 per 100,000 children-years (15 years of age and younger) compared with the overall Danish incidence of 7.2/100,000 person-years.[205] Incidence in children increases with age and peaks at 1.02 per 100,000 in the 14–15-year-old age group.[205] In the two largest American pediatric case series from Virginia[206] and North Carolina,[207] 75% of children with sarcoidosis were black, and most were over the age of 10 years. Males and females are equally affected. There is some familial clustering of cases, but no inheritance pattern has been established.[208,209]

## Etiology and Pathogenesis

The etiology of sarcoidosis remains largely unknown; however, a variety of environmental, occupational, and genetic risk factors have been associated with the disease.[197,210] Current models of pathogenesis suggest that an exaggerated TH-1 immune response to unidentified antigen(s) in individuals who are genetically susceptible leads to granuloma formation in many different organs.

The mycobacterium tuberculosis catalase-peroxidase protein has been identified as a potential sarcoidosis antigen,[211,212] and several associations of sarcoidosis with MHC-2 alleles have been described.[196]

Granulomatous lesions are the hallmark of sarcoidosis, and they may occur in any organ of the body. These are typically noncaseating, which distinguishes them from the necrotizing granulomatous lesions of tuberculosis and GPA. The granulomas consist of tightly organized collections of predominantly CD4$^+$ T lymphocytes and mononuclear phagocytes (epithelioid cells, macrophages, and multinucleated giant cells). The epithelioid and giant cells may contain Schaumann or asteroid inclusion bodies. In the lung, most granulomas are located in the perilymphatic areas, including near bronchioles, in the subpleural space and the perilobular spaces (Fig. 58.9). In more mature granulomas, fibroblasts and collagen may encase the ball-like cluster of cells. Special stains for fungi and mycobacteria are negative. The granulomatous lesions usually heal with preservation of lung parenchyma; however, in 20%–25% of patients, fibroblasts proliferate at the periphery of the granuloma and produce fibrotic scar tissue.

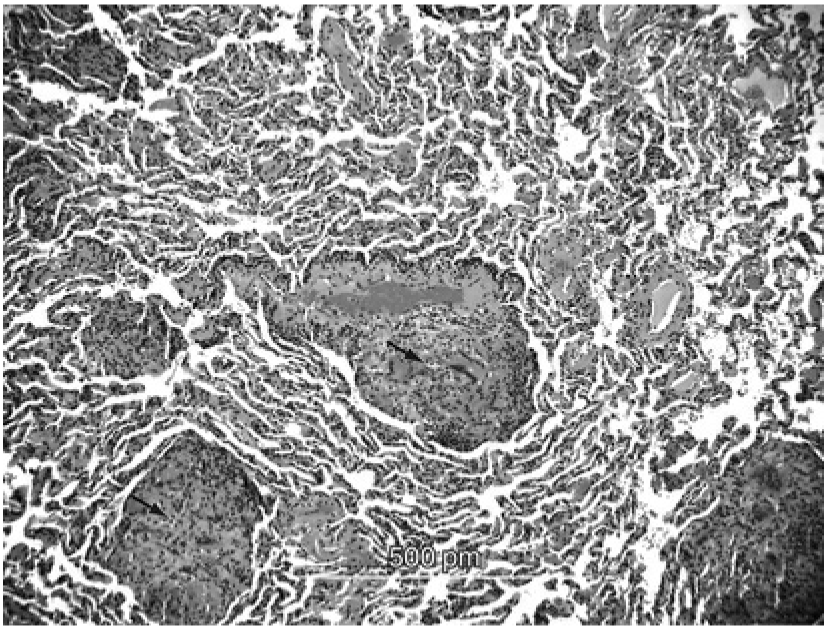

**FIG. 58.9** Biopsy of the apex of the left lung from a 15-year-old African-American boy with a history of skin

lesions, bilateral ankle swelling, a painful red eye, and lung infiltrate (see Fig. 58.10). Biopsy shows nonnecrotizing interstitial granulomas *(arrows).* Special stains for acid-fast bacillus and fungi were negative, as were stains for vasculitis. Similar results were found on biopsy of axillary lymph nodes.

## Clinical Manifestations

Children older than 8 years of age tend to present with similar clinical manifestations as adults, with pulmonary findings predominating.[213] Granulomatous lesions may occur in any organ, but the lungs, lymph nodes, eyes, skin, and liver are the most commonly involved. Occasionally joints, bone, spleen, central nervous system (neurosarcoidosis), heart, or kidneys are involved. Nonspecific and often minor symptoms of general malaise, weight loss, fatigue, and fever are common. Other symptoms are related to local tissue injury caused by granulomas and hence depend on the organs involved. Cough, dyspnea with exertion, and chest pain are common symptoms of lung involvement.[205,214,215] Common skin lesions include papules, plaques, nodules, changes in old scars, erythema nodosum, hyperpigmented lesions, and hypopigmented lesions. Lupus pernio, erythroderma, and ichthyosis are less common skin lesions in children. Central nervous system involvement may present with headache, seizures, cranial nerve palsies, motor signs, hypothalamic dysfunction, and hydrocephalus.[216] Physical exam findings may include peripheral lymphadenopathy, eye changes, skin rashes, hepatosplenomegaly, abnormal chest sounds, neurologic deficits, and parotid gland enlargement. Cardiac disease is rare but may present with heart block, arrhythmias, or dilated cardiomyopathy. Asymptomatic patients may be identified by routine screening chest radiographs. Löfgren syndrome, a triad of acute arthritis, BHL, and erythema nodosum, is a common presentation in 9%–34% of adults[217] but is less common in children.[205] A diagnosis of sarcoidosis should prompt a slit-lamp exam of the eye to look for asymptomatic uveitis, since blindness is one of the described morbidities of sarcoidosis.

Frequent laboratory abnormalities include increased erythrocyte sedimentation rate, anemia, hypergammaglobulinemia, cutaneous anergy (>40% of adults), hypercalciuria (19%–30%), hypercalcemia (8%–12%), eosinophilia, leukopenia, and increased angiotensin-converting enzyme (ACE; 60%–80%). Rheumatoid factor is occasionally positive (14% of adults).

## Pulmonary Involvement

Pulmonary involvement occurs in more than 90% of adult[217] and pediatric[218] cases, commonly affecting the intrathoracic lymph nodes and the pulmonary parenchyma (Fig. 58.10). Presenting symptoms of pulmonary sarcoidosis may include dyspnea, wheezing, and cough. Physical examination of the chest may be normal or include crackles and wheezing. Radiographic findings have classically been categorized as Stage 0 = normal radiograph; Stage I = BHL; Stage II = BHL with parenchymal infiltrates; Stage III = parenchymal infiltrates without BHL. Some authors also define pulmonary fibrosis as Stage IV disease. A population-based Danish pediatric study found that 10% of children present with stage 0 disease, 71% with stage I, 8.3% with stage II, and 8.3% with stage III disease. Parenchymal infiltrates may be nodular, fibrotic, or alveolar, and tend to occur in the upper lobes. Recently, a French multicenter study group demonstrated that parenchymal lung abnormalities occurred on chest HRCT imaging in 95% of children with normal (stage 0) CXR.[213] Classic HRCT parenchymal abnormalities at disease presentation are similar in children and adults,[219] and consist of widespread micro-nodules and nodules in a perilymphatic distribution (peribronchovascular), with nodular pleural thickening and thickening of interlobular septae, as well as hilar and mediastinal lymphadenopathy. Nodules may coalesce into areas of consolidation with air bronchograms, bronchiectasis, and bronchiolectasis. Areas of ground-glass attenuation may also be present. Pulmonary fibrosis with honeycombing occurs in 20%–25% of sarcoidosis patients, but only after years of disease activity.[195] Pulmonary function tests may be normal, particularly with stage 0 or I disease. The most common abnormality is a restrictive pattern with a reduction in DLCO, and occasionally an obstructive pattern may be seen.[195,213–215]

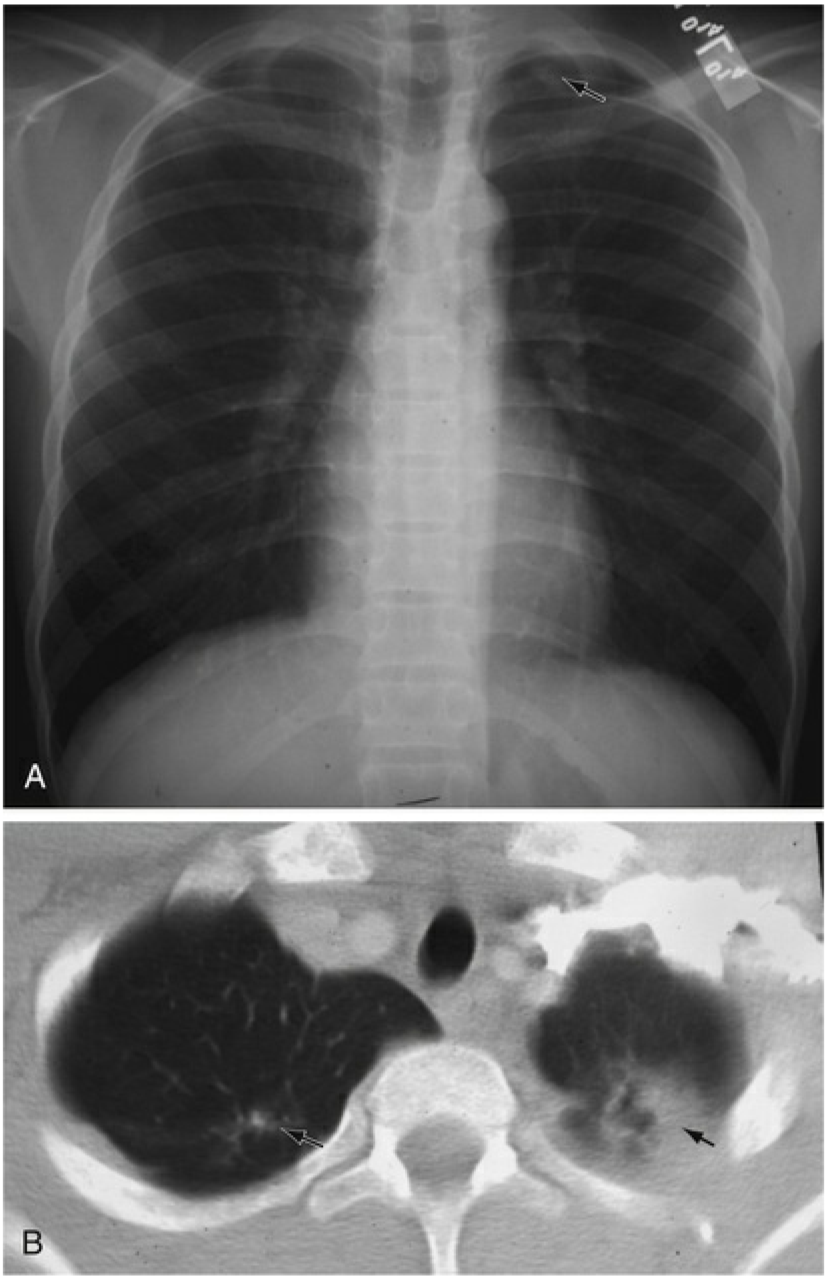

**FIG. 58.10** (A and B) Chest radiograph (A) from the adolescent described in Fig. 58.9 that shows an 8-mm density in the left lung apex *(arrow).* Chest computed tomography image (B) shows parenchymal opacifications in the lung apices *(arrows)* and axillary adenopathy on the right (not shown). The patient was diagnosed with sarcoidosis after lung and axillary lymph node biopsies revealed typical sarcoid granulomas (see Fig. 58.9).

Airway involvement is well described in adults with sarcoidosis.[220] Airway changes are best appreciated with bronchoscopy: these include specific changes of waxy yellow mucosal nodules and nonspecific changes such as erythema, edema, granularity, and cobblestoning of airway mucosa and bronchial stenosis, typically in the lobar and segmental bronchi. In our experience, these typical airway lesions may also be observed in children with sarcoidosis (Fig. 58.11). Airway hyperreactivity is well documented in adult studies and is associated with the presence of visible airway involvement on bronchoscopy.[221] Pediatric laryngeal sarcoidosis, presenting with symptomatic supraglottic edema, has been described in multiple case reports, including several where the disease was isolated to the larynx.[222]

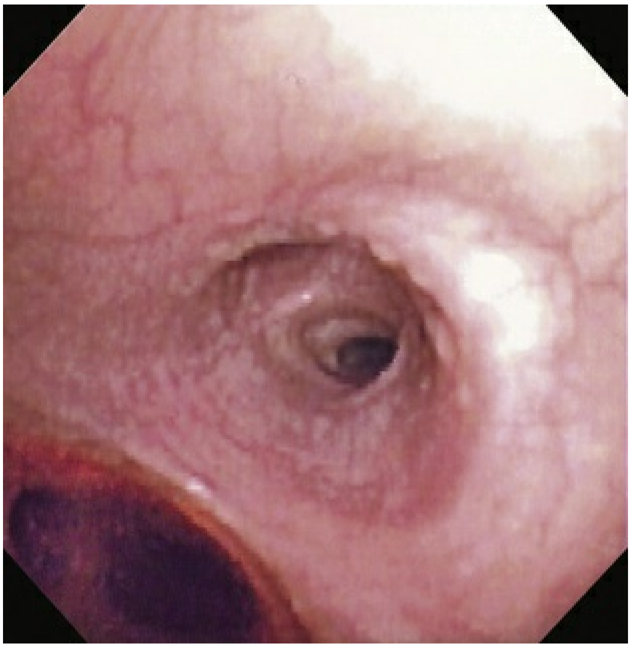

**FIG. 58.11** Bronchoscopy picture of sarcoid airway: right upper lobe (RUL) airway involvement with hypervascularity and waxy nodules.

Progression of granulomatous lung lesions to pulmonary fibrosis and end-stage lung disease may be a fatal complication of pulmonary sarcoidosis. Pulmonary disease may also be complicated with the development of bronchiectasis and chronic infections, including development of an aspergilloma in damaged tissue. Hemoptysis may occur secondary to bronchiectasis or aspergilloma development.[217]

## Diagnosis

Box 58.2 describes the clinical evaluation that should be considered for a patient with suspected sarcoidosis. Diagnosis is established when typical clinical features are supported by a tissue biopsy showing noncaseating granulomas. One must also be careful to exclude other causes of noncaseating granulomas, including immunodeficiency syndromes (especially chronic granulomatous disease and common variable immune deficiency), fungal and mycobacterial infections, berylliosis, ulcerative colitis (UC), and GPA. Any organ that is involved and accessible may be used for a tissue diagnosis. Whole body positron emission-computed tomography (PET-CT) may help localize inflammatory activity and biopsy sites.[223] In children, biopsies are often performed from peripheral lymph nodes, skin lesions, salivary glands, lung lesions, and the liver.[215] It is generally accepted that young adults presenting with Löfgren syndrome do not require a biopsy to confirm the diagnosis.[195] The Kveim-Siltzbach test is no longer used as a diagnostic test in routine clinical practice, and ACE levels have poor sensitivity.

### Box 58.2

### Clinical Evaluation for the Patient With a Suspected Diagnosis of Sarcoidosis

#### Initial Evaluation

Complete history and physical exam, including careful examination of lungs, peripheral lymph nodes, skin, eyes, parotid glands, liver, spleen, nervous system, and joints
Chest radiograph, both posteroanterior and lateral views
Pulmonary function tests, including spirometry, lung volumes, and DLCO
Tuberculin skin test

Biopsy of affected organ, with special stains and culture of specimen
Electrocardiogram
Complete blood count with white cell differential, erythrocyte sedimentation rate, serum calcium, creatinine, alkaline phosphatase, alanine, and aspartate aminotransferases
Serum level of angiotensin-converting enzyme (if elevated, may be useful to monitor patient compliance)
24 hour urine collection for calcium:creatinine ratio
Complete ophthalmologic evaluation (slit-lamp, tonometric and funduscopic)
Other tests as indicated for assessment of involved organs (e.g., MRI with gadolinium and cerebral spinal fluid analysis if central nervous system involvement)
Consider referral to pediatric rheumatologist for comanagement of disease depending on local experience
Consider genetic analysis for CARD15 mutations, especially if young or no pulmonary involvement

## Follow-Up Monitoring (Every 3 Months Initially, and for at Least 3 Years After Discontinuation of Therapy)

Assessment for decline in physiologic function based on initial organ involvement (for lung involvement follow chest radiograph and pulmonary function tests)
Tests to monitor side effects of therapy (e.g., bone densitometry and blood pressure for steroid use, semiannual eye exam for hydroxychloroquine use)
Further testing as indicated if new symptoms or physical findings develop

*MRI,* Magnetic resonance imaging.

---

When mediastinal nodes or lung tissue are the obvious site for biopsy, several options for tissue diagnosis exist. Transbronchial lung biopsy (TBLB) has a relatively high yield (40%–90% sensitivity) in adults with at least stage I disease, but there are no data on its utility in children.[195] In one adult study, endobronchial biopsy (EBB) in addition to TBLB was safe and increased the diagnostic yield of bronchoscopy by 20%. When abnormal airway mucosal lesions were visualized, 75% of EBB were positive, while only 30% of EBB specimens were positive in those with normal appearing airways.[224] If TBLB does not yield a diagnosis, which occurs in about 58% of unselected adult patients,[225] surgical biopsy of mediastinal nodes or peripheral lung lesions is the next step.[195] Hilar and mediastinal nodes may be assessed with mediastinoscopy, or alternatively with the newer and minimally invasive technique of endobronchial ultrasound-guided transbronchial needle aspiration (EBUS-TBNA), which has been reported to have a sensitivity of 71%–85% for diagnosing sarcoidosis.[225–227] Although technical issues limit the application of this technique in younger children, EBUS-TBNA has been reported to be successful in the diagnosis of sarcoidosis in a 13-year-old with BHL as well as hypercalcemia, nervous system, and eye involvement.[228] CT-guided transthoracic fine needle aspiration with core needle biopsy may also be used as an alternative to surgical biopsy to access peripheral pulmonary infiltrates in centers with sufficient experience.[229]

BAL cell profiles are not specific for sarcoidosis, but they may help narrow the differential diagnosis. However, BAL shows a lymphocytosis in greater than 85%; neutrophils are normal or low except in late disease; and CD4:CD8 ratio is increased (opposite to findings in ILD associated with connective tissue diseases) in 50%–60%. BAL cell profile is not helpful in monitoring disease progression or response to therapy.[195,215]

## Treatment

The decision to treat pulmonary sarcoidosis is often difficult, as disease will spontaneously remit in many patients. If therapy is needed, corticosteroids are the mainstay. Efficacy data on treatments for pulmonary sarcoidosis are mainly based on adult data, which are well summarized in two Cochrane reviews.[230,231] Limited observational data from a pediatric cohort suggest similar outcomes of corticosteroid therapy in children.[215] Indications for treatment of lung disease are generally based on data about the natural history of spontaneous remission of different forms of lung disease: stage 1 60%–80%, stage II 50%–60%, and stage III 30% remit.[195,197,217]

The following criteria should prompt consideration for corticosteroid treatment:

1. Pulmonary sarcoidosis: Worsening pulmonary symptoms, deteriorating lung function, progressive radiographic changes (worsening of interstitial opacities, cavitation, progression of fibrosis with honeycombing, development of pulmonary hypertension).
2. Cardiac, neurologic, ocular, renal involvement, or hypercalcemia, even with mild symptoms, because fatal arrhythmias, blindness, and renal failure may develop.
3. Severe debilitating symptoms from any organ involvement.

Therapy is not indicated in asymptomatic children with stage one or two pulmonary disease with normal or mildly abnormal lung function. However, stage 3 disease needs to be followed closely, as adult data suggest that the majority do not resolve, it may progress to pulmonary fibrosis, and most patients will require therapy in the future.[195,230] The limited pediatric data support this concept.[214,215,218]

Corticosteroid therapy is typically started at a relatively high dose (1 mg/kg per day depending on severity of disease) for 4–6 weeks and then tapered. A response to therapy is usually seen within 6–12 weeks of initiation of therapy with improvement in symptoms, pulmonary infiltrates, and lymphadenopathy on imaging, and variable improvement in pulmonary function. Steroid therapy typically needs to be continued for 12–18 months in order to prevent relapse of disease. Relapses are treated with increasing doses of corticosteroids. Alternative immunosuppressive and/or cytotoxic therapies may be added if disease is steroid-resistant or as steroid-sparing agents in relapsing disease; however, data on the efficacy of these agents are very limited.[231] Low-dose methotrexate is the most commonly used alternative therapy, which has been shown to have a steroid-sparing effect in one adult randomized controlled trial[232] and in a small case series of children.[233] Hydroxychloroquine has been reported to be successful in treating patients with hypercalcemia and neurological involvement.[234,235] Infliximab, a tumor necrosis factor inhibitor, has a strong pathophysiological basis for use, but side effects of therapy are a concern, and randomized controlled trials do not support its routine use. It has been shown to have limited efficacy in severe pulmonary disease refractory to steroid therapy.[236] Lung transplantation has been reported to be successful in many young adults with end-stage lung disease[237] and candidate selection criteria specific to sarcoidosis have been published.[238]

## Prognosis

In adults, spontaneous recovery occurs in about two-thirds of patients with sarcoidosis within 2 years of diagnosis without therapy. Another one-third to one-half of patients is treated with corticosteroids, and most improve with treatment, but relapse occurs in many when the drug is tapered or discontinued. The clinical course is chronic or progressive in 10%–30%, and fatalities occur in 1%–5% of patients, typically due to progressive pulmonary fibrosis or central nervous system or cardiac involvement.[195] Limited long-term pediatric outcome data from the United States,[239] France,[215] and Denmark[218] suggest that most children with sarcoidosis also have a good prognosis, as most have a complete recovery. Chronic active disease with impaired lung function occurs in a small proportion and there are few deaths (mainly patients with neurosarcoidosis). Population-based data from Denmark is particularly informative for white children with sarcoidosis, showing that in 46 Danish children identified between 1979 and 1994, after a median follow-up time of 15 years, 78% of children showed complete recovery, 11% had chronic active disease with multiorgan involvement and impaired lung function, and 7% died of their disease.[218] Newer cohort data from France, which identified 41 children of mainly Afro-Caribbean and sub-Saharan ethnicity and 1.5–5 years of follow-up, presented a less favorable outcome, with less than half of children in remission at 5 years.[213] The French children had a more severe disease presentation with multiorgan involvement and all but one patient requiring systemic steroid therapy at disease presentation. These observations are concordant with adult data that show that African-American race is a risk factor for more severe disease.[240,241] Pulmonary involvement may lead to progressive pulmonary fibrosis and end stage chronic lung disease; this seems to be more likely with stage III pulmonary disease at the onset in both adults and children.[195,218,239] Eye involvement may lead to blindness.

Löfgren syndrome (i.e., BHL, erythema nodosum, fever, and polyarthritis) has an excellent prognosis with greater than 85% spontaneous remission rates within 6–12 months.[195] Clinical factors associated with a worse prognosis in adults include black race, hypercalcemia, lupus pernio, splenomegaly, pulmonary infiltrates on chest radiograph (stage II and III disease), chronic uveitis, cystic bone lesions, nasal mucosal sarcoidosis, neurosarcoidosis, cardiac involvement, and low family income.[195,241] In children, where prognostic data are much more limited, erythema nodosum has been associated with a good prognosis,[218] while the increased number of organs involved is associated with relapses,[213] and central nervous system involvement has been associated with fatalities.[218]

# Childhood Vasculitides

Vasculitis is defined as the presence of inflammation in a blood vessel. Vasculitis syndromes are generally named according to their clinical manifestations, the size and type of blood vessels involved, and the pathologic features found within the vessel walls.[242] Clinical manifestations and epidemiological features are different in childhood vasculitides compared with adult vasculitides.[97] A pediatric classification scheme has been developed by the European League against Rheumatism and the Paediatric Rheumatology European Society, which includes classification criteria for the more common childhood vasculitis syndromes (Table 58.4).[243–245] The clinical presentation of vasculitis depends on the size of the vessel involved. When predominantly large- or medium-sized vessels are affected, arterial insufficiency to the affected organ results in infarction, necrosis, and end organ dysfunction. Smaller vessel (arterioles, venules, capillaries) inflammation may result in leakage of blood into the tissues. In the lung, this causes diffuse alveolar hemorrhage (DAH), which is characterized by diffuse alveolar infiltrates and a drop in hemoglobin with or without hemoptysis. Other clinical features suggestive of vasculitis are associated acute glomerulonephritis, pulmonary-renal syndrome, ulcerating or deforming upper airway lesions, cavitary or nodular disease on chest imaging, tracheobronchial stenosis, palpable purpura, arthritis, uveitis, and systemic symptoms including weight loss, fatigue, and fever.

## Table 58.4

### Nomenclature of Childhood Vasculitis and Associated Pulmonary Involvement

| Classification Category | Pulmonary Involvement |
|---|---|
| LVV | |
| ■ Takayasu arteritis | Rare: Pulmonary arteritis[317,318] |
| MVV | |
| ■ Childhood polyarteritis nodosa | Rare: Isolated case reports of pulmonary arteritis in adults[319,320] |
| ■ Kawasaki disease | ■ During acute phase cough is common and chest radiograph changes occur in 15%[321]<br>■ Unresolving pneumonia is a rare presentation of disease[322] |
| SVV | |
| AAV | |
| ■ GPA (previously Wegener's)[a] | Almost universal: upper and/or lower airways and/or parenchymal (see text) |
| ■ EGPA[a] (previously Churg-Strauss syndrome) | Nonfixed pulmonary infiltrates in 85%; prior history of asthma almost universal (see text) |
| ■ MPA[a] | Pulmonary hemorrhage in 30%–50% and may have clinical presentation identical to idiopathic pulmonary hemosiderosis (see text) |
| Immune complex SVV | |
| ■ Henoch-Schönlein purpura (IgA vasculitis) | Rarely may have pulmonary hemorrhage[323] |
| ■ Antiglomerular basement membrane disease | Pulmonary-renal syndrome[324] but rare in children[325] |
| VVV<br>■ Behçet's disease | Infrequent (1%–8%); pulmonary artery aneurysms, hemoptysis, thrombi reported in adults[326] |
| SOV | Isolated pulmonary capillaritis[246,a]<br>Isolated pulmonary arteritis case report[327] |

| | |
|---|---|
| Vasculitis associated systemic disease | (SLE, SSc, others—see Table 58.2) |
| Vasculitis associated with probably etiology (infection, malignancy, and drugs, including hypersensitivity vasculitis) | Rarely may have pulmonary hemorrhage or thrombosis |

[a] ANCA associated vasculitides that commonly have pulmonary involvement.

Table includes only childhood vasculitides with reported pulmonary involvement.

*AAV*, ANCA-associated vasculitis; *EGPA*, eosinophilic granulomatosis with polyangiitis; *GPA*, granulomatosis with polyangiitis; *IgA*, immunoglobulin A; *LVV*, large-vessel vasculitis; *MPA*, microscopic polyangiitis; *MVV*, medium-vessel vasculitis; *SLE*, systemic lupus erythematosus; *SOV*, single-organ vasculitis; *SSc*, scleroderma; *SVV*, small-vessel vasculitis; *VVV*, variable vessel vasculitis.

Pulmonary involvement has been reported in association with most vasculitis syndromes; however, clinically significant pulmonary involvement occurs mainly with vasculitis associated with antineutrophil cytoplasmic antibody (ANCA).[246] ANCA-associated vasculitis (AAV) syndromes are characterized by necrotizing vasculitis of small vessels, frequent pulmonary and renal involvement, and a paucity of immune deposits in the blood vessel wall. The major clinicopathologic variants of AAV syndromes with frequent pulmonary involvement are GPA (formerly Wegener's), microscopic polyangiitis (MPA), eosinophilic granulomatosis with polyangiitis (EGPA, formerly Churg-Strauss), and isolated pulmonary capillaritis (IPC; Table 58.5). MPA is recognized mainly as a rare pauci-immune small vessel vasculitis of adults involving the skin, joints, kidneys, and lungs, but it may present in childhood and is often (10%–30%) associated with pulmonary hemorrhage.[247,248] It is distinguished from GPA by the presence of high titers of antimyeloperoxidase (MPO)–ANCA and the absence of granulomatous inflammation pathologically. It may present initially to the pulmonologist as a case of idiopathic pulmonary hemosiderosis, which on lung biopsy is proven to be IPC, with the subsequent development of pauci-immune glomerulonephritis.[249] MPA is discussed in detail in Chapter 58. EGPA is a small-vessel vasculitis that is exceedingly rare in children, and most of the published literature is limited to single case reports.[250–252] It is characterized by fever, peripheral eosinophilia, migrating pulmonary infiltrates, and anti-MPO-ANCA antibodies in patients with concomitant severe atopic asthma or allergic rhinitis. Sinusitis, skin, neurologic, and cardiac involvement are also common, while renal disease is uncommon.[253,254] In the largest pediatric case series report of 117 children with new diagnoses of AAV from 30 different North American centers from 2004 to 2008, two children had EGPA compared with 76 with GPA and 17 with MPA.[251]

### Table 58.5

### Small Vessel Vasculitides With Frequent Pulmonary Involvement

| | GPA | MPA | EGPA | IPC |
|---|---|---|---|---|
| Common presenting features | Epistaxis, saddle nose deformity, dyspnea, cough, pulmonary nodules, constitutional symptoms | Necrotizing crescenteric glomerulonephritis (pauciimmune), marked constitutional symptoms | Severe asthma, chronic rhinosinusitis, peripheral blood eosinophilia, migrating chest infiltrates, constitutional symptoms | Anemia, diffuse alveolar infiltrates with or without hemoptysis |
| Frequency of pulmonary involvement | >80% | ~30%–60% | 70%–90% | 100% |
| Typical pulmonary manifestations | Nodules with or without cavities, tracheobronchial stenosis, DAH | DAH | Asthma, patchy pulmonary infiltrates, rarely DAH | DAH |
| Autoantibody status | 85%–90% PR3-ANCA+ | 50%–75% MPO-ANCA+ | 0%–25% MPO-ANCA+ in children; 35%–50% MPO-ANCA+ in adults | 0–?[a] |
| Other organ involvement | Kidney, skin, ocular, MSK, nervous system, heart | Kidney, skin, MSK, bowel, cardiac, ocular | Kidney, skin, cardiac, GI, CNS, mononeuritis multiplex, skin | None at initial presentation, but may evolve into MPA with kidney disease |

[a] IPC cases ($n = 12$) reported in literature to date all ANCA negative but ANCA+ cases may have been classified as MPA and MPO-ANCA+ idiopathic pulmonary hemosiderosis cases are reported.

*CNS*, Central nervous system; *DAH*, diffuse alveolar hemorrhage; *EGPA*, eosinophilic granulomatosis with polyangiitis; *GI*, gastrointestinal; *GPA*, granulomatosis with polyangiitis; *IPC*, isolated pulmonary capillaritis; *MPA*, microscopic polyangiitis; *MPO-ANCA+*, myeloperoxidase-antineutrophil cytoplasmic antibody positive; *MSK*, musculoskeletal; *PR3-ANCA+*, proteinase 3-antineutrophil cytoplasmic antibody positive.

Stimulator of interferon genes (STING)–associated vasculopathy with onset in infancy (SAVI) is a rare inherited autoinflammatory disease that should be suspected in infants who present with skin vasculitis changes and ILD.[255] The differential diagnosis for DAH and pulmonary-renal syndrome includes ANCA-associated vasculitides, Goodpasture syndrome, SLE, thromboembolic disease, and infections, and is discussed separately in Chapter 61. The remainder of this section will focus on GPA, as this is the most common vasculitis syndrome presenting to the pulmonologist, and it may initially present with isolated airway or lung involvement.

# Granulomatosis With Polyangiitis

## Epidemiology

Vasculitis is rare in children. One English survey of family clinicians estimated an annual incidence of 53.3 per 100,000 children less than 17 years of age, with Henoch-Schonlein purpura and Kawasaki disease being the most common vasculitides. All other primary vasculitides, including ANCA-associated vasculitides, had an incidence together of 0.24 per 100,000.[97] Population-based studies of GPA from America and Norway specifically suggest that incidence is less than 1 per million in children, and the disease incidence peaks in the fourth to sixth decades of life.[256,257] The multicenter ARChiVe (A Registry for Childhood Vasculitis: e-entry) study suggests that GPA accounts for most (65%) new pediatric AAV cases. The GPA patients had a median age of diagnosis of 14.2 years (range 4–17 years), 69% were Caucasian, and 63% were female.[251]

## Pathogenesis

The etiology of GPA is largely unknown; however, the almost universal presence of ANCA and response to immunosuppressive therapy provide strong rationale for an autoimmune basis.

Many recent studies examining the effects of ANCA-neutrophil and neutrophil-endothelial cell interactions have provided evidence supporting a pathogenic role for ANCA. ANCA are directed against the neutrophil granule components proteinase 3 (PR-3-ANCA) and MPO-ANCA. ANCA interact with these target antigens on cytokine-primed neutrophils. This causes neutrophil activation and interaction with endothelial cells via multiple signaling pathways. The end result is tissue inflammation and damage as the neutrophils migrate through the endothelial cells and undergo respiratory burst, and degranulation with release of toxic products. Failure of adaptive immune system regulation mechanisms results in a loss of self-tolerance, so that T-helper and B cells also assist in this autoantibody reaction.[258] The histopathology of all AAV is hence marked by necrotizing vasculitis of the small blood vessels without immune complex deposition (i.e., pauci-immune vasculitis). GPA is distinguished among the AAV by the anti-PR-3-ANCA specificity and by the presence of granulomas (Fig. 58.12).

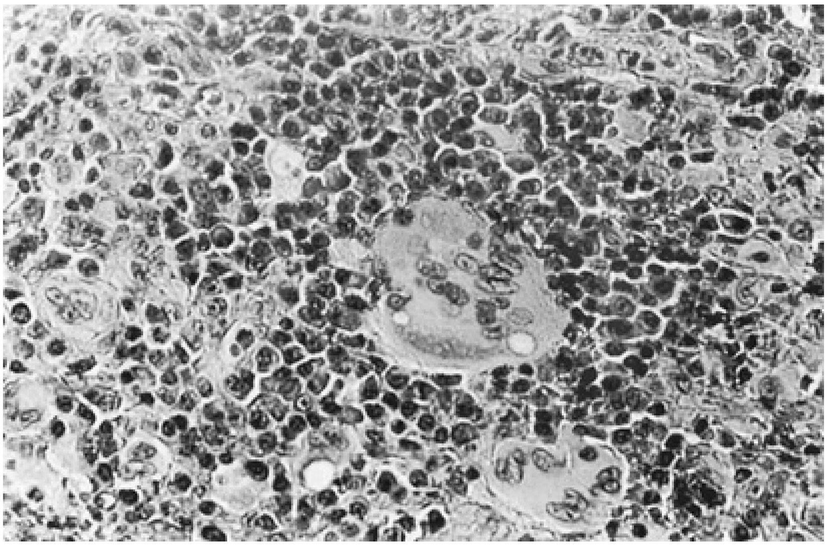

**FIG. 58.12** Photomicrograph of a lung biopsy from a patient with granulomatosis with polyangiitis showing a dense pleomorphic infiltrate, numerous mononuclear cells, scattered neutrophils, and several giant cells. This aggregate of cells would be considered a granuloma.

What is still poorly understood is why and how ANCA develop in the first place. It has long been recognized that some drugs and infectious agents may trigger the development of ANCA and a clinical syndrome of secondary vasculitis, which is similar to the clinical presentation of primary vasculitis.[259] Some studies have suggested a triggering role for infections, particularly bacteria colonizing the upper airway such as *Staphylococcus aureus*.[260] This has led to a clinical trial investigating the role of prophylactic cotrimoxazole in preventing GPA relapses.[261] In addition, other autoantibodies have recently been described as having a potential role in the disease pathogenesis, including lysosomal membrane protein 2[262] and antiendothelial cell antibodies.[263]

## Clinical Manifestations

Four large pediatric case series describe the typical clinical presentation of GPA with a triad of upper airway, lower respiratory tract, and renal disease manifestations.[251,264–266] Symptom onset is most often insidious, with dyspnea or chronic cough along with constitutional symptoms, but it may also be dramatic, presenting with pulmonary hemorrhage, upper airway obstruction, or renal failure. The median interval from symptom onset to diagnosis is 2.7 months (range 0–49 months).[251] Most children present with multiorgan involvement. The most frequent presenting features are constitutional (fever, malaise, fatigue, weight loss; 89%); pulmonary (80%); ear, nose, and throat (80%); and renal (75%). Less commonly eyes (37%), skin (35%), gastrointestinal (42%), musculoskeletal (57%), and nervous system (25%) may be involved.[251] In a series of 25 patients from Toronto, Canada, 16% experienced venous thrombosis associated with antiphospholipid antibodies during the disease course.[266] Case reports describe involvement of the heart, spleen, and pituitary gland. Contrary to the adult experience, limited GPA without renal involvement is uncommon in children. Laboratory abnormalities include elevated white blood cell counts, normochromic normocytic anemia, thrombocytosis, elevated erythrocyte sedimentation rate or C-reactive protein level, abnormal urinalysis with proteinuria, hematuria and red blood cell casts, and elevated serum creatinine. ANCAs are present in 89% of children with cytoplasmic immunofluorescence staining pattern (cANCA) in 86%, and 68% positive for anti-PR3,[251] which is comparable to serology results in adults with GPA.[267]

## Pulmonary Involvement

Presenting pulmonary symptoms include dyspnea or chronic cough in over half of children.[251,265] Hypoxia requiring oxygen therapy is present in 19%.[251] Hemoptysis may signal necrotizing mucosal airway involvement or DAH. Symptoms of dyspnea with hoarseness and stridor suggest subglottic stenosis. Subglottic stenosis has been reported in one series to occur with higher frequency in pediatric onset GPA compared with adults[264]; hence this feature has been included in the new EULAR/PReS classification criteria.[244,245] Frequent upper airway findings include sinusitis, nasal septal ulceration or perforation, otitis media, mastoiditis, hearing loss, oral ulcers, and nasal cartilage damage, characteristic of long-standing disease, with resultant saddle-nose deformity (which must be distinguished from the diagnosis of relapsing polychondritis). About half of children will have abnormalities on chest radiographs. The most common findings are nodules followed by fixed infiltrates. Cavitations, mediastinal lymphadenopathy, pleural effusions, and pneumothoraces may also occur. Chest CT is more sensitive in detecting small nodules and ground-glass abnormalities than plain radiography. The largest case series ($n = 18$) of chest CT findings in children with GPA showed pulmonary involvement in 90% of newly diagnosed patients with nodules (90%), ground-glass opacification (52%), and air space opacification (45%), the predominant findings. Nodules tended to be multiple (69% had more than five nodules), greater than 5 mm in diameter, and cavitating in 17% (Fig. 58.13). Air-space opacification usually correlated with clinical evidence of pulmonary hemorrhage.[268] Chest CT findings in children were similar to findings in adults, except that the frequency of identified bronchial narrowing seems to be lower in children (6.7%) compared with adults (59%; Figs. 58.14 and 58.15).[268,269] Sinus CT may be useful to identify upper airway involvement, particularly sinus opacification and bony destruction. Pulmonary function test abnormalities are seen in 42%, and these may show obstructive or restrictive defects, depending on the tissues involved.[251,270]

**FIG. 58.14** (A–C) Fifteen-year-old teen with GPA presenting with a hoarse voice, hemoptysis, weight loss, and antineutrophil cytoplasmic antibody positive serology. (A) Soft tissue radiograph of neck shows narrowing of trachea at level of seventh cervical vertebrae. (B and C) computed tomography scan of neck shows severe stenosis of the upper trachea (15 mm in length and narrowing to a diameter of 4 mm [B] from 14 mm [C] above the stenotic area) secondary to circumferential soft tissue thickening. Stenosis improved with pulse steroid therapy and local airway laser ablative therapy.

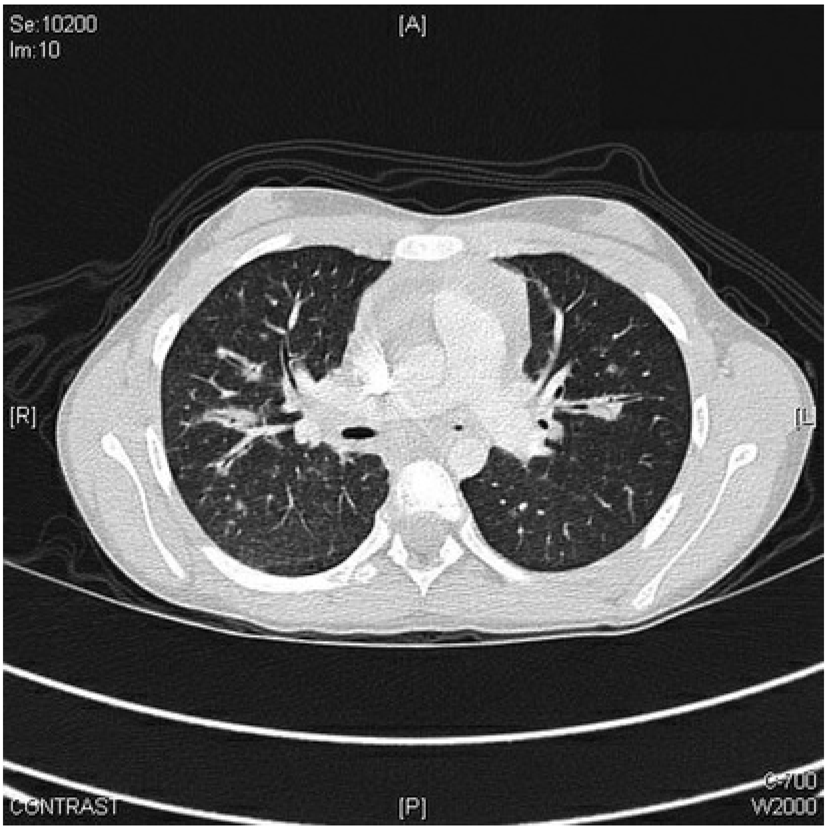

**FIG. 58.15** Nine-year-old girl with granulomatosis with polyangiitis presenting with hemoptysis and antineutrophil cytoplasmic antibody+. Computed tomography scan shows pericardial effusion, diffuse bilateral irregular peribronchial soft tissue thickening, and an 11-mm nodular-like mass surrounding the left mainstem bronchus causing pinhole narrowing; no cavitary lesions present.

It is important for the pulmonologist to recognize the bronchoscopy findings of GPA, as these may provide the first clue to the diagnosis for a child presenting with nonspecific symptoms of cough (Fig. 58.16). Mucosal erythema, edema, ulceration, hemorrhage, cobblestoning, nodules, polyps, submucosal tunneling, synechial bands, and airway stenosis have all been described in airways from the oropharynx down to the bronchi, in case series that include mostly adults and a few children.[270–273] Endobronchial findings are nonspecific, as similar findings may be encountered with infections and sarcoidosis.

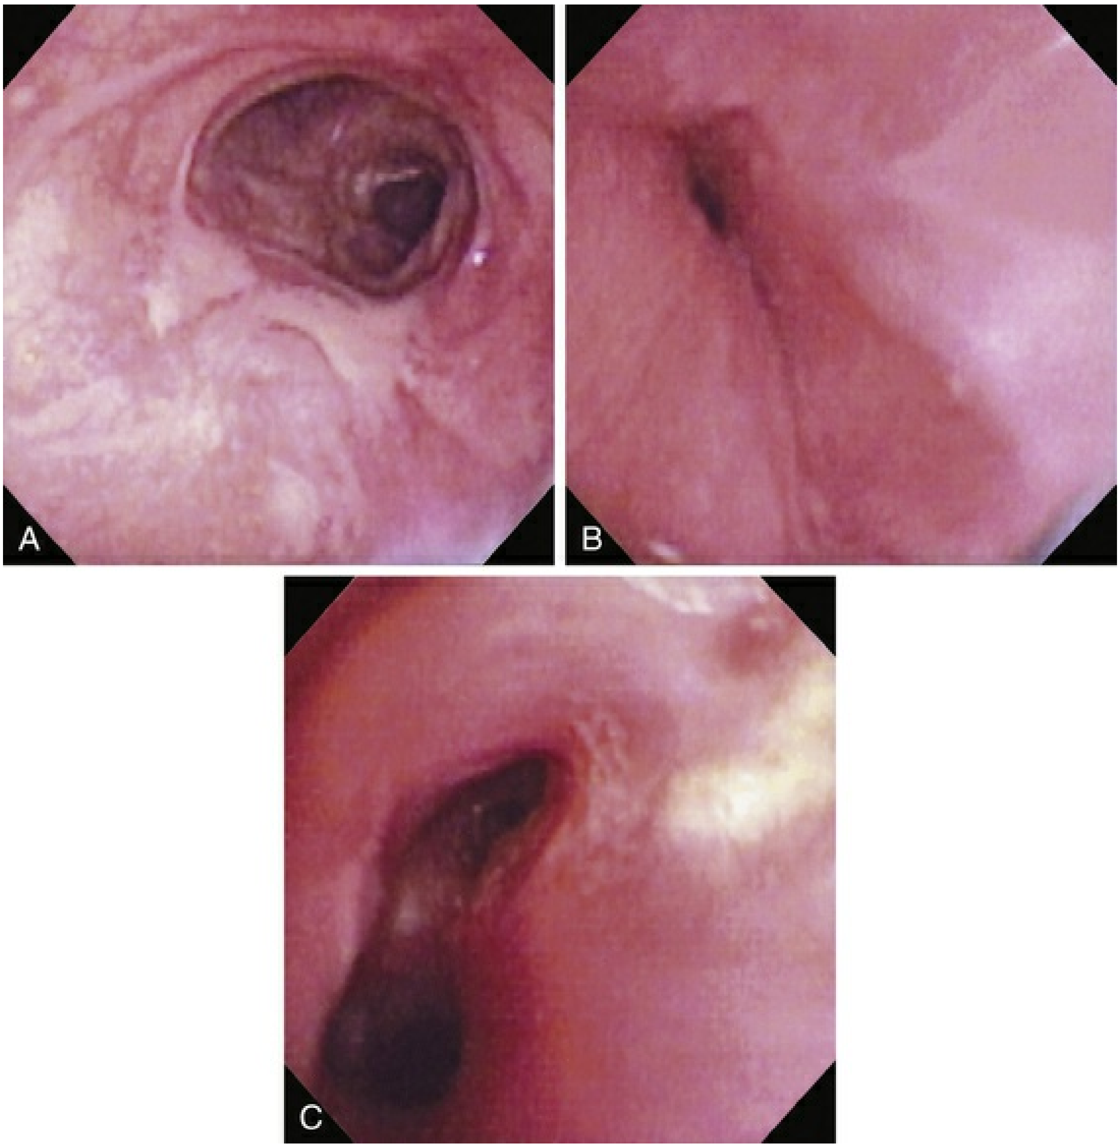

**FIG. 58.16** Bronchoscopic photographs of the airways of a 15-year-old teenager diagnosed with granulomatosis with polyangiitis (A) Main carina showing mucosal erythema. (B) Left main stem bronchus showing pinhole stenosis. (C) Left secondary carina showing erythematous friable mucosa.

## Diagnosis

The diagnosis of GPA is based on a combination of clinical findings (e.g., pulmonary-renal syndrome), supportive serology (i.e., anti-PR-3 ANCA positive), and characteristic histopathology (pauci-immune granulomatous inflammation of predominantly small to medium sized blood vessels or pauci-immune glomerulonephritis).

If GPA is suspected, it is important to examine the urine and to obtain chest and sinus imaging to rule out asymptomatic renal or upper and lower respiratory tract disease. The differential diagnosis often includes infections (especially mycobacterial, fungal, or helminthic infections in addition to common viral and bacterial causes), other causes of pulmonary-renal syndrome (other ANCA-associated vasculitides, SLE, MCTD, Goodpasture syndrome), sarcoidosis, UC with pulmonary involvement, malignancy, and chronic granulomatous disease. Renal biopsy has a high yield for identifying pauci-immune glomerulonephritis if there are urinary abnormalities. Diseased upper respiratory tract tissues (e.g., ears, nose, sinuses, trachea) and endobronchial airway lesions offer relatively noninvasive access for tissue diagnosis, but often have low yields for diagnosis. Lung biopsy yield may also be low, since disease is often patchy, but open lung biopsy procedures may offer a better yield than less invasive fine needle aspiration or transbronchial techniques.

## Treatment

Historically, standard treatment for GPA at diagnosis is a combination of glucocorticoids and CYC. This therapy has changed GPA from a rapidly fatal disease to a manageable chronic illness with frequent relapses in most adult and pediatric cases.[274,275] CYC may be used as a daily oral therapy or pulse intravenous therapy, which results in a less cumulative dose and is the preferred dosing regimen in children. Disease remission may be maintained, with low-dose weekly methotrexate or daily azathioprine.[276] Methotrexate may also be effective in inducing remission when the disease is localized or has milder manifestations, and renal disease is not a concern.[277] Rituximab, a monoclonal antibody against B cells, has been effectively used for severe refractory disease that does not respond to conventional cytotoxic therapy and has emerged as an excellent option for both induction phase treatment and maintenance phase treatment to prevent disease relapse. Rituximab has been shown to be not inferior to CYC for induction phase treatment for AAV in new onset disease and disease flare, and is superior for those with PR3-ANCA+.[278,279] In maintenance phase treatment, patients on rituximab therapy had fewer major relapses compared with azathioprine.[279]

Obstructing airway lesions, including tracheal and bronchial stenosis, may not respond to cytotoxic therapy. These lesions should be managed by a specialized airway team with expertise in the area. They may require intralesional injections of glucocorticoids, endoscopic dilatation, stent placement, or tracheostomy.[270–273] Intralesional corticosteroids may be most effective when used before other surgical interventions, which may result in scarring.[280]

Patients with GPA are at increased risk of infection due to the immunosuppressive therapy they are receiving, as well as the presence of vulnerable damaged tissues.[281] Prophylaxis against *pneumocystis jiroveci* pneumonia is recommended while receiving CYC[282] and should be considered for children receiving high dose corticosteroids with methotrexate, and those receiving rituximab.[283]

## Prognosis

GPA was almost universally fatal in both adults and children at an average of 5 months after diagnosis prior to the advent of cytotoxic therapy.[274,275] With current induction therapy, over 90% of patients are expected to respond partially or completely; however, about half will relapse within 5 years.[274] Fatalities reported in children are due to lung disease or sepsis,[264] while malignancy, renal failure, and cardiac disease are additional reported causes of death in adults with GPA.[274] Long-term morbidity may result from persistent airway obstruction, renal insufficiency, or treatment-related side effects, including cystitis, infertility (due to CPA), cataracts, glaucoma, vertebral compression fractures, and growth effects (due to steroids).[264,266,274]

# Other Systemic Inflammatory Diseases With Significant Pulmonary Involvement

SS is a chronic inflammatory autoimmune disorder that is characterized by lymphocytic infiltration of the exocrine glands. It is often associated with other CTD, including JIA, SLE, SSc, and JDM. The classic symptoms are keratoconjunctivitis sicca (dry eyes) and xerostomia (dry mouth), along with a high prevalence of ANA, RF, anti-Ro, and anti-La antibodies. SS is very rare in children, with most major pediatric rheumatology centers only reporting a few cases. There is a lower frequency of sicca symptoms and higher frequency of parotitis with childhood onset compared with adult onset SS.[284–286] Pulmonary involvement occurs in up to 75% of adult patients, but is usually mild and nonprogressive.[287–289] Dryness of the airways resulting in “sicca” cough occurs in up to half of adult patients. Small airways obstructive disease and airway hyperreactivity are also common and are thought to be caused by lymphocytic inflammation around the bronchioles and bronchi (follicular bronchiolitis). ILD occurs infrequently, usually with the histopathological changes of LIP, a finding generally not seen with other CTDs in the absence of SS.[290,291] Chest radiograph changes include diffuse reticular or reticulonodular infiltrates and bronchiectasis, while CT scan may have a variety of additional findings, including ground glass attenuation, subpleural nodules, and cysts.[288] Pulmonary hypertension responsive to steroid and CYC therapy has also been reported in a 9-year-old child with SS.[292] Prognosis is generally very good, but a poor outcome may occur from progression of LIP to lymphoma in adults.[293]

Inflammatory bowel disease (IBD), including Crohn disease (CD) and UC, is commonly associated with extraintestinal manifestations but only very rarely (<1%) associated with clinically significant pulmonary disease.[294,295] Subclinical pulmonary involvement is probably common, as latent pulmonary function abnormalities have been demonstrated in a case series of children with CD[296] and adults with both CD and UC[297,298] who have no respiratory symptoms and normal chest radiographs. The main abnormality is a reduction in DLCO that tends to be worse during active disease. Children with CD have also been demonstrated to have bronchial hyperreactivity.[299] The etiology of these pulmonary function abnormalities is likely secondary to a subclinical airway or alveolar inflammatory process, as BAL samples in CD show hypercellularity with lymphocytosis.[300–302]

Symptomatic lung disease associated with IBD has been reported in two large case series[303,304] as well as multiple case reports, and is summarized well in recent reviews.[295,305] Bronchiectasis is the single most common disorder described in adults, although a range of rare pulmonary manifestations have been reported, including tracheal stenosis, colobronchial and ileobronchial fistulae, chronic bronchitis, BO, BOOP, granulomatous pulmonary nodules (including necrobiotic[306]), ILD, pulmonary vasculitis, and pleural effusions.[295,307] Descriptions of pulmonary disease in children with IBD are limited to isolated case reports of granulomatous and necrobiotic nodules, BO, and BOOP in CD,[308–311] and vasculitis, BOOP, and ILD in UC.[312–314] High-resolution CT findings include air trapping with mosaic perfusion pattern, tree-in-bud appearance, bronchiectasis, and multiple pulmonary nodules.[304] Pulmonary involvement in IBD usually responds to corticosteroid therapy, with systemic therapy for more severe or interstitial disease and inhaled therapy for mild airways disease.[305] Infliximab therapy (monoclonal antibody to tumor necrosis factor alpha) has been used successfully in children with granulomatous lung disease.[310] The differential diagnosis for pulmonary manifestations associated with IBD must also include drug induced disease (especially hypersensitivity pneumonitis associated with sulfasalazine[315] and mesalamine[316]), opportunistic infection, malignancy, and thromboembolism. When significant lung disease and IBD coexist, consideration should also be given to distinguishing between CD and sarcoidosis or UC and GPA, as these diseases may have striking similarities; however, management strategies may differ.[295]

# Clinical Approach to Diagnosis and Management of Pulmonary Involvement in the Systemic Inflammatory Diseases of Childhood

The clinical presentation of pulmonary involvement is highly variable. The most common presentation for ILD is slowly progressive dyspnea with or without a dry cough. Dyspnea due to

ILD must be distinguished from the dyspnea due to muscle weakness, deconditioning, thromboembolic disease, and cardiac causes. Patients may also present with pleuritic chest pain. Infection and drug toxicity must always be considered in the differential diagnosis of pulmonary involvement.

Following a detailed history and physical examination, pulmonary function testing may be very helpful for further elucidating the type of pulmonary involvement. Patterns of pulmonary function impairment are suggestive of certain diagnoses (Table 58.6). Abnormal pulmonary function tests are best followed up with HRCT. The anatomical distribution of pulmonary involvement varies with the type of disease (see Table 58.2). Patterns of HRCT findings have been much better described and correlated with pathological changes in the adult literature; however, some generalities can be extrapolated to the pediatric population. Ground glass densities generally correlate with parenchymal lung disease, while peribronchovascular changes and air trapping correlate with airways disease. Pleural inflammation is manifested as pleural thickening with effusion.

## Table 58.6

## Patterns of Pulmonary Function and Gas Exchange Impairment in Lung Disease Associated With Systemic Inflammatory Conditions

| | Pattern of Ventilatory Impairment | Diffusing Capacity for Carbon Monoxide | Gas Exchange Characteristics |
|---|---|---|---|
| Chest wall restriction (muscle weakness or chest wall deformity) | Restrictive defect with low MIPS/MEPS[a] (especially with associated muscle weakness) and low peak flow in more severe disease | Preserved until severe loss of volume | With severe disease, hypoventilation results in hypercapnia and hypoxia with normal a-A gradient[b] |
| Pulmonary fibrosis | Restrictive defect | Reduced | With severe disease, hypoxia at rest |
| Bronchiectasis | Obstructive defect | Preserved until severe end stage disease | With end-stage disease, hypoxia at rest |
| Diffuse alveolar hemorrhage | Variable—often restrictive | Increased if hemorrhage is recent[c] | During active bleeding, hypoxia, often profound with a wide a-A gradient[b] |
| Pulmonary | Normal pulmonary function tests | Reduced | Hypoxia at rest even with |

| | | | |
|---|---|---|---|
| vascular disease | | | moderate pulmonary hypertension |
| Mixed disease: Pulmonary fibrosis and muscle weakness | Restrictive defect, often severe | Less reduced than expected for degree of restrictive defect | Hypoxia at rest or with exercise is frequent |

[a] MIPS/MEPS = maximal inspiratory pressures and maximal expiratory pressures as measured at the mouth opening.

[b] a-A gradient = alveolar-arterial oxygen gradient.

[c] Within past 24–36 hours.

Bronchoscopy with BAL may be very helpful for distinguishing autoimmune lung disease from opportunistic infection, alveolar hemorrhage, and cancer. BAL cytology patterns may suggest specific disease etiologies, although the use of BAL for monitoring CTD-ILD is still investigational. There may also be characteristic airway changes of GPA or sarcoidosis noted during bronchoscopy, and EBB may yield additional diagnostic information (see previous disease sections in this chapter).

Lung biopsy is reserved for a small subset of patients where a diagnostic dilemma remains, despite investigation utilizing previously suggested modalities. If lung biopsy is required, it is best to do so expeditiously before clinical deterioration of the patient makes it too risky or even impossible to undertake. It may be needed to rule out an opportunistic infection or to confirm a diagnosis of inflammatory lung disease that will require a change in the management strategy, particularly the addition of a cytotoxic or biologic agent with potential significant side effects.

Occasionally patients present with sudden onset of new respiratory symptoms and progression to respiratory failure can occur rapidly. Multiple etiologies of disease need to be considered as the potential cause of acute respiratory deterioration (Table 58.7). Prompt recognition and treatment of the cause of respiratory symptoms in this scenario may be lifesaving.

## Table 58.7

**Causes of Acute Respiratory Deterioration in Children With Systemic Inflammatory Diseases**

| Etiology | Distinguishing Features |
|---|---|

| | |
|---|---|
| Infection | Fever, tachypnea, change in cough, increase in sputum volume, change in sputum color, malaise, new areas of consolidation on chest imaging. May be difficult to distinguish from disease flare. |
| Air leak: pneumothorax or pneumomediastinum | Sudden onset of chest pain or shoulder tip pain and dyspnea, tracheal shift in the presence of tension pneumothorax, absence of fever and cough, more common in dermatomyositis/polymyositis |
| Upper airway obstruction | Stridor and dyspnea of subacute onset caused by progressive tracheal circumferential soft tissue thickening in GPA |
| Acute pneumonitis or pleuritis | Fever, new nonproductive cough and/or chest pain, dyspnea, basal coarse crackles on chest exam, hypoxia, diffuse interstitial infiltrates on chest imaging, more common in lupus and JIA |
| Diffuse alveolar hemorrhage | Anemia, tachypnea and hypoxemia, hemoptysis usually absent, diffuse alveolar infiltrates on chest imaging, more common with ANCA + serology and lupus |
| Pulmonary embolus | Sudden onset chest pain, dyspnea, hypoxemia, no change in chest radiograph or rounded or wedge shaped opacity with apex directed to hilum, more common with hypercoagulable states like lupus |
| Progression of chronic lung disease | End-stage lung disease prior to deterioration, absence of fever or viral prodrome, rapid increase in dyspnea and oxygen need over a period of 1–2 weeks, mild (or no) changes on chest imaging out of keeping with severity of symptoms |
| Cardiac dysfunction | Low blood pressure, poor perfusion, may have wheezing, signs of left or right heart failure, cardiomegaly and/or pulmonary venous congestion on chest imaging, abnormal electrocardiogram |

*ANCA*, Antineutrophil cytoplasmic antibody; *GPA*, granulomatosis with polyangiitis; *JIA*, juvenile idiopathic arthritis.

End with Key Messages in a box (Box 58.3).

**Box 58.3**

## Key Messages in the Approach to Pulmonary Involvement in the Systemic Inflammatory Diseases of Childhood

Pediatric pulmonologists must work closely with the rheumatologist to diagnose and manage lung disease associated with systemic inflammatory diseases of childhood.

The differential diagnosis of respiratory symptoms includes generalized muscle weakness, deconditioning, cardiac disease, thromboembolic disease, opportunistic infection, and drug toxicity effects, as well as inflammatory lung disease.

Recognize that pulmonary disease may sometimes be the predominant initial presentation of a systemic inflammatory disease.

Specific inflammatory diseases are associated with probable patterns of pulmonary involvement (see Table 58.2).

Pulmonary function testing, including measurement of lung volumes and diffusing capacity for carbon monoxide, are helpful in refining the differential diagnosis, measuring the severity, and following the progression of lung disease (Table 58.6).

Bronchoscopy may reveal recognizable airway abnormalities associated with specific conditions (e.g., granulomatosis with polyangiitis and sarcoidosis).

Bronchoalveolar lavage is helpful in ruling out infection, and the cytology count may also help refine the differential diagnosis of lung disease.

High morbidity and possible mortality are associated with pulmonary involvement of some systemic inflammatory diseases; hence it is important to diagnose and treat early.

Pulmonary involvement may require specific drug therapies for some diseases (e.g., cyclophosphamide for vasculitis).

Most treatment protocols in pediatrics are extrapolated from results of clinical trials in adult patients.

Early identification of pulmonary involvement may lead to application of new therapies, including biologic agents and therapies for pulmonary arterial hypertension.

## 59

# Lung Injury Caused by Pharmacologic Agents

*Marianna M. Henry MD, MPH, Terry L. Noah MD*

Numerous drugs can cause pulmonary or pleural reactions in children. The most frequent offenders are chemotherapeutic agents used in the treatment of childhood neoplasms (Table 59.1), although toxic effects of other agents are increasingly recognized (Table 59.2).[1,2] Diffuse interstitial pneumonitis and fibrosis constitutes the most frequent clinical syndrome. Hypersensitivity lung disease, noncardiogenic pulmonary edema, pleural effusion, bronchiolitis obliterans, and alveolar hemorrhage are also encountered.

### Table 59.1

### Cytotoxic Drugs Used in Cancer Therapy

| | Incidence (%) | Mortality (%) | Clinical/Pathologic Syndromes |
|---|---|---|---|
| Bleomycin | 2–40 | 1–10 | IP/PF, H, P Eff, EP |
| Cyclophosphamide | ≤1 | 40 | IP/PF, PE, B, AH |
| Chlorambucil | [a] | ≤50 | IP/PF |
| Busulfan | 2–43 | [b] | IP/PF, P Eff, AH |
| Melphalan | [a] | ≤60 | IP/PF |
| Carmustine (BCNU) | 10–30 | 15–90 | IP/PF |
| Methotrexate | 8 | 1 | IP/PF, H, PE, P Eff |

| | | | |
|---|---|---|---|
| 6-Mercaptopurine | [a] | [b] | IP/PF |
| Cytosine arabinoside | 13–28 | 50 | IP/PF, PE, BOOP, DMD |
| Gemcitabine | [a] | [b] | IP, B, PE, ARDS |
| Fludaribine | 9 | [b] | IP/PF |
| Procarbazine | [a] | [b] | H |
| Hydroxyurea | [a] | [b] | H |
| Paclitaxel | 4–9 | 0 | H |
| Docetaxel | 73 | 0 | H, IP, decreased $DL_{CO}$ |
| Gefitinib | 1 | 33 | IP |
| Imatinib | [a] | [b] | P Eff, PE |
| Cetuximab | 1 | [b] | IP |
| Interleukin-2 | >50 | 0 | PE, P Eff |
| ATRA | 5–27 | 5–29 | IP, P Eff, PE, AH |

[a] Infrequent case reports.

[b] Unknown.

*AH,* Alveolar hemorrhage; *ARDS,* acute respiratory distress syndrome; *ATRA,* all-*trans* retinoic acid; *B,* bronchospasm; *BOOP,* bronchiolitis obliterans organizing pneumonia; *DMD,* diffuse micronodular disease; *EP,* eosinophilic pneumonitis; *H,* hypersensitivity lung reaction; *IP,* interstitial pneumonitis; *PE,* pulmonary edema (noncardiogenic); *P Eff,* pleural effusion; *PF,* pulmonary fibrosis.

## Table 59.2

## Noncytotoxic and Other Drugs

| | Recorded Cases or Incidence | Mortality | Clinical/Pathologic Syndromes |
|---|---|---|---|
| Nitrofurantoin | >500 adult<br>>10 pediatric | 8% (chronic exposure) | H, IP/PF, B, AH, P Eff, BOOP, GIP |
| Sulfasalazine | >50 adult | [a] | H, EP, IP/PF, BOOP, FA, B |
| Mesalazine | >40 adult<br>8 pediatric | [a] | H, EP, IP/PF,G |
| Diphenylhydantoin | >5 adult<br>>5 pediatric | 0 | H, B, BOOP |
| Carbamazepine | >10 adult<br>>10 pediatric | 0 | H, IP/EP, B, BOOP |
| Levetiracetam | 2 adult<br>1 pediatric | 0 | IP |
| Minocycline | >50 adult and adolescent | [a] | EP |
| Penicillamine | >40 adult<br>1 pediatric | 50% (AH, BO) | H, DA, BOOP, AH |
| Leflunomide | >40 adult | 20% | IP, DAD |
| Azathioprine | >15 adult<br>1 pediatric | 12% | H, AH, IP, DAD, BOOP |
| Amiodarone | 5%<br>4 pediatric | 10%<br>50% for ARDS | H, EP, IP/PF, BOOP,P Eff, AH, ARDS |
| HMG-CoA reductase inhibitors (statins) | >15 adult | 25% | H, IP/PF |

| | | | |
|---|---|---|---|
| Pegylated interferon | [b] | 7% | IP |

[a] Unknown.

[b] Infrequent case reports.

*ARDS,* Adult respiratory distress syndrome; *AH,* alveolar hemorrhage; *B,* bronchospasm; *BO,* bronchiolitis obliterans; *BOOP,* bronchiolitis obliterans organizing pneumonia; *DA,* diffuse alveolitis; *DAD,* diffuse alveolar damage; *EP,* eosinophilic pneumonia; *FA,* fibrosing alveolitis; *G,* granuloma, nonnecrotizing; *GIP,* giant cell interstitial pneumonia; *H,* hypersensitivity lung reaction; *IP/PF,* interstitial pneumonitis/pulmonary fibrosis; *PE,* pulmonary edema; *P Eff,* pleural effusion.

Although some drug-induced pulmonary damage is reversible, persistent and even fatal dysfunction may occur. Lung reactions occasionally are temporally remote from exposure to chemotherapeutic agents. Depending on the agent involved, the reaction may or may not be dose related. The mechanism of toxicity is thought to be direct injury to lung cells in most cases, but immunologic and central nervous system-mediated mechanisms seem to play a role in the toxicity of certain agents. Identified risk factors associated with cytotoxic drug therapy vary, but they include cumulative dose, age of patient, prior or concurrent radiation, oxygen therapy, and use of other toxic drugs. Most reactions to noncytotoxic drugs appear to develop idiosyncratically. When patients are treated with combinations of potentially toxic drugs or with a toxic drug plus irradiation to the chest or high concentrations of oxygen, as is common in the treatment of childhood cancers, specific offenders often cannot be identified. There is little if any evidence that children are more susceptible to drug-related pulmonary injury, and in fact, they may be less susceptible to some agents such as bleomycin.

The clinical presentation of drug-induced lung disease often includes fever, malaise, dyspnea, and nonproductive cough. Radiologic studies almost always demonstrate diffuse alveolar and/or interstitial involvement. Segmental or lobar disease, particularly if unilateral, should suggest another diagnosis. Abnormal pulmonary function, indicative of restrictive or obstructive disease, may be found before appearance of roentgenographic lesions. Chest computed tomography (CT) may also provide early evidence of parenchymal abnormalities,[3] and hypoxemia is an early and clinically important functional consequence. Pathologic features do not distinguish between most drugs and most often consist of interstitial thickening with chronic inflammatory cell infiltrates in the interstitial or alveolar compartment, fibroblast proliferation, fibrosis, and hyperplasia of type II pneumocytes, which contain enlarged hyperchromatic nuclei.[4] With hypersensitivity reactions, the interstitial infiltrate includes substantial numbers of eosinophils. Interstitial pneumonitis can be part of the multisystem syndrome known as “drug-induced hypersensitivity syndrome/drug rash with eosinophilia and systemic symptoms” (DIHS/DRESS).[5] Other diagnoses, such as infection, pulmonary hemorrhage, lung disease related to an underlying disorder, and radiation damage must be considered in patients with suspected drug-induced lung injury. Bronchoalveolar lavage (BAL) is increasingly utilized to provide microbiologic and cytologic information essential to differential diagnosis and as a tool to begin to identify disease markers and potential pathogenic mechanisms.[6]

Practical criteria for diagnosing drug-induced lung disease have been suggested by Kubo and colleagues.[7] These include (1) history of ingestion of a drug that is known to induce lung injury, (2) clinical manifestations have been reported to be induced by a drug, (3) other causes of clinical manifestations have been ruled out, (4) improvement of clinical manifestations after drug discontinuation, and (5) exacerbation of clinical manifestations after resuming drug administration.

## Cytotoxic Drugs Used in Cancer Therapy

Survivors of childhood cancers have often been exposed to multiple cytotoxic agents with potential lung toxicity, in addition to radiation, and are thus at increased risk for long-term pulmonary complications from these agents.[8] Compared to children without a cancer history, leukemia and lymphoma survivors are at increased risk for hospitalization for pulmonary-related reasons (relative risk [RR], 8.1; 95% confidence interval [CI], 3.9–16.8).[9] A recent review by the Children's Oncology Group Guideline Task Force on Pulmonary Complications recommended that health care providers following such children should receive a standardized cancer treatment summary from their oncologist to assess risk for pulmonary complications and that pediatric cancer survivors who received bleomycin, or who are subsequently undergoing general anesthesia for procedures, should have lung function monitored.[10] A cohort of 5000 survivors of childhood cancers, using the Children's Oncology Group Long-Term Follow-Up (COG-LTFU) Guidelines, underwent rigorous screening with pulmonary function tests (PFT), and abnormalities were present in 84%.[11]

## Bleomycin

Bleomycin is a mixture of peptide antibiotics obtained from *Streptomyces verticillus.* Its major use in children is in the treatment of Hodgkin disease and other lymphomas. Because of the high frequency of pulmonary reactions and the utility of bleomycin for generating animal models of lung fibrosis, this agent has been studied more thoroughly than others. Pulmonary damage develops in two distinct patterns, most commonly progressive fibrosis and uncommonly an acute hypersensitivity reaction.

Pulmonary disease secondary to bleomycin occurs in as many as 40% of patients receiving the drug,[12] and a recent systematic review identified bleomycin exposure (along with alkylating agents) as a significant risk factor for long-term pulmonary toxicity.[13] Forty-one percent of childhood cancer survivors treated with bleomycin had abnormal spirometry (obstructive changes) in a cross-sectional analysis, although only 9% were symptomatic.[14] Multivariate analyses of follow-up data from the multicenter Childhood Cancer Survivor Study indicate that use of bleomycin is significantly associated with lung fibrosis (RR 1.7), bronchitis (RR 1.4), and chronic cough (RR 1.9) ≥5 years postdiagnosis.[15] Bleomycin-induced pneumonitis may be diagnosed years after its use, as reported in a 15-year-old girl who had received bleomycin as an infant for yolk sac carcinoma.[16] Significant lung damage rarely occurs in adults at cumulative doses less than 150 mg. When more than 283 mg/m$^2$ is administered, 50% of adult patients develop severe pneumonitis.[17] Pulmonary damage is more severe in elderly than in young patients and in those with reduced glomerular filtration rate.[12] Slow intravenous administration results in less lung disease than intramuscular injection or intravenous bolus. The combination of radiotherapy or high inspired oxygen concentrations and bleomycin produces more lung injury than either alone. Pulmonary toxicity associated with relatively small quantities of bleomycin has been reported during combination drug therapy,[18] and pediatric sarcoma or Hodgkin disease patients receiving bleomycin have increased risk for radiation pneumonitis.[19]

Pulmonary injury due to bleomycin occurs by direct injury to cells as well as by secondary immunologic reactions. Direct toxicity may be mediated by oxidant injury, either through the production of reactive oxygen metabolites or through inactivation of antioxidants. Data supporting this mechanism include the findings that pretreatment of rodents with antioxidants, or upregulation of the antioxidant gene transcription factor Nrf2, can reduce subsequent bleomycin-induced pulmonary fibrosis.[20–22] Additionally, bleomycin may directly induce senescence or apoptosis of type II epithelial cells.[23–25] Bleomycin also generates production of inflammatory mediators by lung cells,[26–31] and inflammatory cells may participate in further oxidant and proteolytic damage to lung cells.[32] Bleomycin promptly increases collagen synthesis by fibroblasts, an effect which may be mediated by transforming growth factor-β.[33] Anti-inflammatory agents, antioxidants and, specifically, nebulized heparin or urokinase can inhibit bleomycin-induced lung damage in animal models.[34,35] Gunther and colleagues[36] have reported complete abrogation of bleomycin-induced pulmonary fibrosis in rabbits using nebulized heparin or urokinase.

Bleomycin-induced lung disease can begin insidiously, and asymptomatic patients may have decreases in arterial oxygen saturation and carbon monoxide diffusing capacity ($DL_{CO}$). As the illness progresses, there is a decline in vital capacity and total lung capacity, which is characteristic of restrictive lung disease. In both interstitial pneumonitis and hypersensitivity lung reactions, patients typically present with a dry hacking cough and dyspnea; these signs occur only on exertion in mild cases, but profound respiratory distress accompanies advanced illness. Fever suggests a hypersensitivity reaction. Physical examination reveals tachypnea and fine crackles. Chest radiographs in symptomatic patients most commonly demonstrate diffuse linear densities. A widespread reticulonodular or alveolar pattern may also be seen. Chest CT is more sensitive for detection of early interstitial disease, and in animal models, chest CT findings correlate well with pathologic changes.[37,38] Biopsy specimens usually reveal interstitial pneumonitis, fibrosis, and extensive alveolar damage with hyperplasia of type II cells, which are most prominently in subpleural and basilar regions.

Patients receiving bleomycin should be monitored by serial determinations of $DL_{CO}$. Chest CT may also be useful for monitoring progression of disease, although the radiation exposure from this source cannot be ignored.[38] Therapy of bleomycin-induced pneumonitis consists largely of supportive measures. Withdrawal of the drug at the onset of toxicity must be considered. Careful monitoring of oxygen therapy to avoid excessive exposure is imperative.[39] Although the inflammatory cell element resolves substantially with therapy, much of the fibrotic damage is irreversible. Treatment with bleomycin is a significant predictor of long-term respiratory symptomatology and pulmonary function decrements in survivors of Hodgkin disease.[40] Use of steroids is controversial, but reversal of severe toxicity has been documented in some patients after use of high-dose steroids.[41] In the few patients exhibiting hypersensitivity reactions or eosinophilic pneumonitis with bleomycin,[42] corticosteroids have a definite role.

## Alkylating Agents

### Cyclophosphamide

Cyclophosphamide is widely used in the treatment of leukemias, lymphomas, and nonmalignant illnesses. Although pulmonary toxicity is uncommon, it does produce severe and even fatal lung damage.[43,44] Data from the Childhood Cancer Survivor Study indicate a significantly increased long-term risk for supplemental oxygen requirement, recurrent pneumonia, chronic cough, dyspnea on exertion, and bronchitis.[15] Frankovich and colleagues[45] reported a series of 34 children who underwent autologous bone marrow transplant for relapsing Hodgkin disease and were treated with cyclophosphamide in combination with etoposide and either carmustine, chloroethylcyclohexylnitrosourea, or irradiation. Fifteen of these patients developed lung injury syndromes including interstitial pneumonitis, acute alveolitis, diffuse alveolar hemorrhage, acute respiratory distress syndrome (ARDS), and bronchiolitis obliterans. Four of the patients died of pulmonary complications. In this series, a history of atopy was associated with pulmonary complications.

Cyclophosphamide appeared to result in greater pulmonary toxicity than fludarabine in one pediatric series when either agent was combined with busulfan for prehematopoietic cell transplantation conditioning.[46] Experiments in rodents indicate that, as for bleomycin, both oxidant and inflammatory or immune mechanisms are involved in cyclophosphamide lung toxicity.[47–50] Acute IgE-mediated systemic reactions have been reported, including angioedema and bronchospasm. Cyclophosphamide also may predispose to toxicity when medications such as bleomycin, azathioprine, and carmustine are used subsequently.

Little is known regarding the relationship of dose, duration, and frequency of administration to the appearance of parenchymal disease in humans, although cytotoxicity appears to be dose-related in rats.[48] Pulmonary reactions have occurred following total doses between 0.15 and 50 g. Pulmonary disease may begin during cyclophosphamide therapy or weeks to years after.[51,52] A striking feature in pediatric cases has been chest wall deformity secondary to failure of lung growth during the adolescent growth spurt.[52] Subacute dry cough and dyspnea herald the onset of pulmonary toxicity; and then malaise, anorexia, and weight loss follow.[51,53] Physical examination reveals tachypnea and diffusely diminished breath sounds. Chest roentgenograms may show diffuse bilateral infiltrates, sometimes with pleural thickening, and pulmonary function testing reveals hypoxemia and restrictive lung disease. Biopsy and postmortem specimens show interstitial fibrosis, alveolar exudates, and atypical alveolar epithelial cells.[51,53] Withdrawal of the drug, supportive therapy, and corticosteroids are recommended treatment.

## Chlorambucil

Chlorambucil is used in the treatment of leukemias, some lymphomas, nephrosis, and inflammatory conditions such as sarcoidosis.[54] Several reports indicate that the drug produces pulmonary toxicity, albeit rarely. Little is known concerning the dose or duration of therapy necessary to produce lung damage. Patients develop cough, dyspnea, fatigue, and weight loss that appear 6 months to 3 years after initiation of therapy and progressively worsen.[55,56] Physical examination reveals tachypnea and fine bibasilar crackles. Chest roentgenograms demonstrate diffuse interstitial infiltrate, and pulmonary function tests indicate restrictive lung disease accompanied by a defect in $DL_{CO}$. Histopathologic findings are similar to those associated with busulfan and cyclophosphamide therapy.[55,56] Although improvement with discontinuation of the drug and corticosteroid therapy has been reported,[57] progression of disease may occur.[55]

## Other Alkylating Agents

*Busulfan* (Myleran) is used to treat chronic myelogenous leukemia, which occurs occasionally in childhood, and in some preparative regimens for bone marrow transplantation. Four percent of adult patients undergoing long-term treatment with this drug develop interstitial pneumonitis and fibrosis.[58] Mertens and colleagues[15] reported increased long-term risk for supplemental oxygen requirement and pleurisy after busulfan treatment. As with chlorambucil, pulmonary injury is usually not evident for many months after initiation of treatment, and radiation and previous cytotoxic therapy are risk factors.[59] The clinical syndrome is similar to that produced by the other alkylating agents,[58] and the treatment consists of discontinuation of busulfan. Efficacy of corticosteroids is unproven, but a carefully monitored trial is indicated because of the poor prognosis.

An increase in incidence of alveolar hemorrhage has been reported when *etoposide* (VP-16) was added to a regimen of busulfan and cyclophosphamide for bone marrow transplantation; toxicity in this study was largely confined to patients who had been given prior chest radiotherapy.[60] However, Quigley and colleagues[61] found that in children, preparative regimens for bone marrow transplantation that included busulfan were associated with preservation of pulmonary function compared to regimens using other combination high-dose chemotherapeutic regimens or total body irradiation.

*Melphalan* is used primarily in the treatment of multiple myelomas and hence is employed infrequently in pediatrics. Although overt toxicity is unusual, frequency of epithelial changes and fibrosis at autopsy may be as high as 50%.[62] Bronchial epithelial cell proliferation has been an unusual finding. Otherwise, the pathologic changes are typical for alkylating agents and may be reversible with discontinuation of the drug.[63]

## Nitrosoureas

### Carmustine

Carmustine, also called bis-chloroethylnitrosurea (BCNU), is a synthetic antineoplastic compound, and its major use is in the therapy of lymphomas and gliomas. The incidence of BCNU pulmonary toxicity is quite variable; 20%–30% of treated patients develop some lung disease.[64,65] The total dose administered, duration of therapy, and preexistence of lung disease are the most accurate predictors of pulmonary toxicity. Most patients with symptomatic respiratory disease have received large cumulative doses (>777 mg/m$^2$). When the cumulative dose exceeds 1500 mg/m$^2$, there is a 50% probability of lung disease. Patients with toxicity also appear to have received the drug over a shorter period, irrespective of the total dose given. The onset of pulmonary symptoms has been noted between 30 and 371 days after institution of therapy, sometimes after BCNU has been discontinued. Young patients are reportedly at greater risk, but this may be the result of relatively higher doses and increased numbers of therapy cycles because of greater general tolerance. Mertens and colleagues[15] reported a significant risk for supplemental oxygen requirement among children ≥5 years status post BCNU or *lomustine* (CCNU) treatment. A study of 73 children with high-grade glioma treated with the combination of BCNU, cisplatin, and vincristine reported that seven children developed interstitial pneumonitis, which was fatal in six children.[66] Radiation therapy may be synergistic. In adult patients, female gender and combination with cyclophosphamide have been identified as risk factors for pulmonary complications.[65,67]

Patients with BCNU pulmonary toxicity exhibit much the same clinical picture as that described for bleomycin.[64] Histologic findings are also similar. In a study of eight patients who underwent lung biopsy 12–17 years after treatment with BCNU, there was electron microscopic evidence of ongoing endothelial and epithelial damage, suggesting long-term toxic effects of the drug.[68] One of these patients died with pulmonary hypertension due to interstitial fibrosis. The disease is fatal in approximately 15% of those affected.

Therapy is essentially supportive. Corticosteroids are often administered concomitantly with BCNU for brain tumors and afford no protection from subsequent pulmonary toxicity. However, corticosteroids may offer some benefit in the treatment of early stages of acute disease. Thymidine has been used as a biomodulator to protect from BCNU pulmonary toxicity in patients with malignant melanoma and may act via modulation of DNA repair enzymes in normal tissue.[69] In a rat model, metallothionein attenuated BCNU toxicity via antioxidant effects.[70]

## Antimetabolites

### Methotrexate

Methotrexate (4-aminopteroylglutamic acid) is a folic acid antagonist used in the treatment of several childhood malignancies, notably leukemias and osteogenic sarcoma as well as nonmalignant conditions such as rheumatoid arthritis and psoriasis.[71,72] The lung inflammation induced by methotrexate appears to be linked to activation of the p38 mitogen-activated protein (MAP) kinase signaling pathway with subsequent cytokine activation.[73] Prevalence rates of 0.3%–11.6% have been reported for pulmonary toxicity due to methotrexate, but ascertainment of its effects is complicated by the frequent use of combination therapy and the tendency of underlying diseases such as rheumatoid arthritis to also cause lung disease.[72] No correlation has been found between lung toxicity and dose of methotrexate, and pneumonitis may occur remotely.

The clinical features of methotrexate lung toxicity are consistent with a hypersensitivity pneumonitis.[74] Disease usually begins with a prodrome of headache and malaise and is then followed by dyspnea and dry cough. Pleuritic pain is rare, and fever may also occur. Physical examination reveals tachypnea, diffuse crackles, cyanosis, and occasionally skin eruptions. Hypoxemia is observed in 90%–95% of patients, and mild eosinophilia has been reported in 41%.[72] Few reports have documented pulmonary function changes but decreased $DL_{CO}$ may occur.[75] Lung function testing in a series of children with juvenile rheumatoid arthritis who received methotrexate showed a similar incidence of abnormal function, including $DL_{CO}$, to a control population not receiving methotrexate.[76] The most common abnormalities on chest radiographs are bilateral interstitial infiltrates or mixed interstitial and alveolar infiltrates. Lung biopsy in adults reveals interstitial pneumonitis with lymphocytic and sometimes eosinophilic infiltrates, bronchiolitis, and granuloma formation consistent with a hypersensitivity reaction, although type II alveolar cell hyperplasia typical of cytotoxicity has also been found.[77,78] BAL fluids typically show lymphocytosis with variable CD4/CD8 ratios and moderate neutrophilia.[79,80]

Diagnosis of methotrexate-induced pneumonitis is difficult because this condition may mimic other diseases. Pulmonary infection must be excluded, particularly if high-dose methotrexate is used or if the underlying disease is associated with immunosuppression. Therapy consists of withdrawal of the drug and administration of corticosteroids, but the latter has not been analyzed in controlled trials. Treatment with folinic acid (leucovorin rescue) does not prevent methotrexate lung toxicity,[72] and the outcome is usually favorable with clinical improvement preceding radiographic and pulmonary function improvement.[72,81] However, two fatal outcomes in arthritis patients with a history of lung toxicity suggest that retreatment should be avoided after recovery from methotrexate lung injury.[82]

## 6-Mercaptopurine, Cytosine Arabinoside, and Gemcitabine

Scattered case reports have linked pulmonary dysfunction to 6-

*mercaptopurine* and *cytosine arabinoside* (also known as *Ara-C*). In addition, an autopsy study of patients who had leukemia and who received cytosine arabinoside within 30 days of death demonstrated significant pulmonary edema for which there was no obvious other explanation in most instances. An adult patient receiving low-dose cytosine arabinoside (20 mg/m$^2$ per day) and recombinant human granulocyte-macrophage colony stimulating factor (GM-CSF) developed ARDS on day 12 and died 40 days after initiation of therapy.[83] It has recently been reported that 5 of 22 pediatric patients receiving Ara-C (1.0–1.5 g/m$^2$ per day) for treatment of acute myelogenous leukemia developed pulmonary insufficiency secondary to noncardiogenic pulmonary edema. The outcome was fatal in 3 of 5 patients.[84] Bronchiolitis obliterans organizing pneumonia (BOOP) developed in an adult patient with chronic myelogenous leukemia after treatment with Ara-C in combination with interferon alpha, and the condition resolved after discontinuation of these agents.[85] Chagnon and colleagues[86] described a series of six young adults with acute myelogenous leukemia who developed fever and diffuse micronodular lung disease associated with high-dose Ara-C. *Gemcitabine,* a similar drug in structure and metabolism to Ara-C, has been associated with ARDS in three patients.[87] These authors reported that corticosteroids and diuretics were helpful, but two of the three patients died. Gemcitabine has also been associated with dyspnea, bronchoconstriction, and nonspecific pneumonitis, particularly in Hodgkin disease patients also treated with bleomycin.[88] The nucleoside analog *fludaribine,* used in treatment of lymphoma and chronic lymphocytic leukemia, is associated with steroid-responsive interstitial disease in 9% of cases.[89]

## Other Cytotoxic Agents

*Procarbazine, VM-26, and vinca alkaloids* (vinblastine and vindesine) have been associated with pulmonary injury, but in all cases, other agents may have contributed. Three of five young adults treated with a regimen of vinblastine, doxorubicin, bleomycin, and dacarbazine for Hodgkin disease, and granulocyte colony stimulating factor (G-CSF) to increase neutrophil counts developed pulmonary toxicity in one report.[18] G-CSF may thus potentiate the lung toxicity of these agents. Reactions to procarbazine have been of the hypersensitivity type. *Hydroxyurea* has been reported to induce severe, corticosteroid-responsive, hypersensitivity pneumonitis.[90] *Paclitaxel* is a plant-derived taxane agent that has been used against a broad range of tumors, including breast, ovarian, lung, head, and neck cancers; and it has been associated with a high frequency of hypersensitivity pneumonitis reactions. Lung biopsy has shown interstitial pneumonitis, and BAL fluid has shown eosinophilia and lymphocytosis with a depressed CD4/CD8 ratio.[91] In a 5-year review of a series of cancer patients who received monthly paclitaxel infusions, the incidence of hypersensitivity reactions was 4%, and pretreatment with dexamethasone, diphenhydramine, and $H_2$-blockers was effective in preventing recurrence.[92] Interstitial pneumonitis is more common when paclitaxel is combined with radiation therapy[93] and has been reported in association with a paclitaxel-eluting coronary artery stent.[94] *Docetaxel,* a semisynthetic taxane, has been proposed as a safer alternative but has also occasionally been associated with severe hypersensitivity reactions or corticosteroid-responsive interstitial pneumonitis.[95–97] For example, a series of asymptomatic adult cancer patients who received docetaxel monotherapy for nonlung cancers had a small but significant drop in lung function post treatment.[98] *Oxaliplatin* appeared to cause cryptogenic organizing pneumonitis in a 30-year-old being treated for colorectal cancer and has been associated with fatal diffuse alveolar damage in adults.[99,100]

## Epidermal Growth Factor Receptor/Tyrosine Kinase Inhibitors

*Gefitinib* is an inhibitor of the tyrosine kinase activity of the epidermal growth factor receptor (EGFR), and it inhibits the growth of human cancer cell lines expressing EGFR in preclinical studies. In an irradiated rat model, gefitinib treatment augmented lung inflammation but attenuated fibrotic lung remodeling due to the inhibition of lung fibroblast proliferation.[101] In clinical trials in patients with nonsmall cell lung cancer, gefitinib was associated with development of interstitial lung disease in about 1% of patients, and about one third of cases of gefitinib-associated interstitial lung disease have been fatal.[102,103] Patients presented with acute dyspnea with or without cough or fever at a median of 24–42 days after starting treatment. Another tyrosine kinase inhibitor, *imatinib,* is used in treatment of chronic myelogenous leukemia and has been associated with pleural effusion and pulmonary edema in a small number of cases.[104] *Cetuximab* is a monoclonal antibody that specifically binds to EGFR and inhibits its downstream signaling. In a series of 2006 patients with colorectal cancer in a prospective multicenter registry, ranging in age from 18 to 80 years, 1.2% developed diffuse interstitial pneumonitis due to cetuximab.[105] Such drugs targeting specific molecular pathways are likely to be increasingly used in cancer treatment, as well as pulmonary fibrosis, in the future.[106,107]

Interleukin-2 (IL-2) has been used as an antitumor factor that stimulates lymphokine-activated killer (LAK) cell and natural killer cell activity, and it is sometimes given in combination with LAK cells. Although a number of systemic side effects such as fever and hypotension are seen, its major toxicity appears to be a vascular leak syndrome characterized by fluid retention, peripheral edema, ascites, pleural effusion, and pulmonary edema.[108] This syndrome has been described in children with acute lymphocytic leukemia (ALL) treated with IL-2.[109] Infusion of IL-2 in cancer patients has resulted in increased alveolar-arterial oxygen gradients and decreased forced vital capacity (FVC), forced expiratory volume in 1 second ($FEV_1$), and $DL_{CO}$.[110,111] A retrospective review of chest radiographic abnormalities in 54 patients with metastatic cancer receiving IL-2 revealed that 52% developed pleural effusions, 41% developed pulmonary edema, and 22% developed focal infiltrates. While most changes resolved by 4 weeks after therapy, residual pleural effusion was sometimes seen, primarily in patients receiving IL-2 by intravenous bolus rather than by continuous infusion.[112] Lung histopathology in rodents that received high doses of IL-2 showed widespread mononuclear and eosinophilic infiltration of parenchyma, increased lung weight, and endothelial damage.[113] Mechanisms implicated are increased generation of oxygen free radicals, activation of complement by IL-2, and injury mediated by tumor necrosis factor (TNF)-$\alpha$.[114–116] Rapid recovery from toxic effects of IL-2 followed withholding of treatment in most cases.[111]

All-*trans* retinoic acid (ATRA), a vitamin A derivative with multiple regulatory activities in the lung, is effective as induction and maintenance chemotherapy for acute promyelocytic leukemia (APL). Its major toxicity is a syndrome including fever, weight gain and peripheral edema, respiratory distress, interstitial infiltrates, pleural and pericardial effusions, hyperleukocytosis, intermittent hypotension, and acute renal failure. Chest CT shows small, irregular parenchymal lung nodules and pleural effusions.[117] The incidence of ATRA syndrome was 26% in a large series of APL patients followed prospectively,[118] and among patients developing ATRA syndrome, mortality was 2% including a 4-year-old child. Mean duration of therapy before the syndrome appeared was 11 days with a range of 2–47 days. Nicolls and colleagues[119] reported an 18-year-old with APL who developed diffuse alveolar hemorrhage 15 days after starting ATRA. Lung histology in patients who died of ATRA syndrome showed differentiation of APL cells, endothelial cell damage, and leukocyte infiltration.[118] ATRA may upregulate TNF receptors on lung cell lines.[120] In a murine model of APL, ATRA increased lung and heart expression of chemokines macrophage inflammatory protein 2 (MIP-2) and keratinocyte-derived cytokine (KC), suggesting that proinflammatory cytokines play a role.[121] Treatment for ATRA syndrome consists of prompt initiation of corticosteroids. Tallman and colleagues[118] used dexamethasone 10 mg/day and found that the syndrome resolved rapidly in most patients, even if ATRA was continued. In addition, these authors suggested that ATRA may be safely restarted in most patients once the syndrome has resolved. The cis-retinoic acids used for the treatment of neuroblastoma have not been associated with lung toxicities.

# Noncytotoxic and Other Drugs

## Nitrofurantoin

Nitrofurantoin is an antimicrobial agent used for prophylaxis of urinary tract infections. Significant pulmonary reactions are relatively common, and more than 500 cases have been reported, including children (see Table 59.2).[122–128] Pulmonary reactions occur in two distinct clinical patterns. In the more common acute presentation, patients report abrupt onset of fever, cough, and dyspnea within hours to 2 weeks after initiation of therapy. Alveolar hemorrhage has been described in two patients.[129,130] Rash and flu-like symptoms may occur. Diffuse fine crackles and, rarely, wheezes are noted. Bilateral interstitial or alveolar infiltrates with or without pleural effusions are characteristically present, although chest radiographs may be normal. Physiologic abnormalities include hypoxemia, evidence of a restrictive ventilatory defect, and a reduced $DL_{CO}$. Eosinophilia, leukocytosis, and an elevated sedimentation rate may accompany the reaction. Symptoms and chest radiographic abnormalities usually resolve within several days after withdrawal of the drug. Pulmonary histopathology of the acute syndrome has not been well defined, as patients improve rapidly, making biopsy unnecessary.

In the less common chronic presentation, patients develop insidious onset of cough, dyspnea, and chest pain after months to years of nitrofurantoin therapy.[131,132] Fever may be present, and a lupus-like syndrome has also been reported.[126] Crackles are heard, and diffuse interstitial infiltrates are present on chest radiographs. Pleural effusion is less common than in the acute reaction. Physiologic abnormalities are similar to those found in the acute reaction but are often more severe. Eosinophilia, positive reactions for antinuclear antibodies, and elevated gamma globulin and hepatic enzymes are often found, and significant concurrent hepatic toxicity has been reported.[133] Pulmonary histopathology typically reveals interstitial pneumonitis with variable fibrosis, and chest CT findings vary but may show ground glass opacities.[131,132] Desquamative interstitial pneumonia, BOOP, and giant cell interstitial pneumonia have also been reported on long-term nitrofurantoin therapy.[128,134–137] Treatment includes withdrawal of the drug and supportive measures. Corticosteroids have been used with apparent benefit; however, controlled studies to evaluate efficacy are not available. Resolution of symptoms, physiologic dysfunction, and radiographic abnormalities require weeks to months and may be incomplete. Approximately 8% of adult cases with the chronic syndrome are fatal.

The findings of eosinophilia, elevation of sedimentation rate, and positive antinuclear antibodies support a role for immunologic mechanisms of injury.[138] The drug may also damage the lungs by promoting production of toxic oxygen species.[139–141]

## Sulfasalazine and Mesalazine

Sulfasalazine, a combination of 5-aminosalicylic acid and sulfapyridine, is used primarily in the treatment of inflammatory bowel disease. Adverse reactions occur in approximately 20% of recipients, but pulmonary reactions are uncommon; 50 cases were identified in the most comprehensive review.[142–147] Diagnosis can be challenging, because inflammatory bowel disease is at times associated with lung disorders including bronchitis, BOOP, bronchiectasis, nonspecific interstitial pneumonitis, and granulomatous lung disease.[148–152] Patients experiencing drug-related illness report acute onset of fever, cough, dyspnea, and chest pain 1 month to several years into therapy; and fine crackles are usually present. Hypoxemia, eosinophilia, obstructive and occasionally restrictive pulmonary function patterns, and bilateral alveolar densities have been noted. Cytology from BAL fluid has no consistent pattern of cell predominance. Histopathologic lesions include interstitial pneumonitis with or without fibrosis, eosinophilic pneumonia, fibrosing alveolitis, and bronchiolitis obliterans with or without a component of organizing pneumonia. Discontinuation of the drug usually results in resolution of symptoms and radiographic abnormalities in several weeks to months. Corticosteroids may accelerate improvement, although effectiveness is not well established. At least five fatalities have been reported.[146] The mechanism of toxicity is unknown.

Therapy with mesalazine or 5-aminosalicylic acid, an alternative for inflammatory bowel disease that is related chemically to sulfasalazine, has also been associated with pulmonary toxicity; more than 40 cases have been described, including children.[153–157] Symptoms typically include fever, cough, dyspnea, and chest pain recognized 1–6 months into therapy. Eosinophilia is often present peripherally and may be present in BAL fluid. Bilateral densities are present on chest radiographs, and CT scans may show patchy infiltrates, ground glass opacities, or lung nodules. Eosinophilic pneumonia, interstitial pneumonitis, and nonnecrotizing granulomas have been observed on lung biopsy. Symptoms and radiographic changes usually resolve when therapy is discontinued. Consideration of corticosteroid therapy has been suggested in patients with severe disease and those not responding to discontinuation of the medication.

## Diphenylhydantoin, Carbamazepine, and Levetiracetam

The anticonvulsant agents diphenylhydantoin, carbamazepine, and levetiracetam have been associated rarely with acute pulmonary disease as part of a generalized hypersensitivity reaction, including the syndrome of drug reaction with eosinophilia and systemic symptoms (DRESS).[5,158–164] Clinical manifestations include fever, cough, dyspnea, and rash occurring typically 2–8 weeks after initiation of therapy. Facial swelling and lymphadenopathy may be prominent. Crackles and, rarely, wheezes are heard; bilateral interstitial or alveolar infiltrates, sometimes with hilar adenopathy, are seen on chest radiographs. Associated findings include eosinophilia, elevated liver enzymes, hypoxemia with a restrictive pattern of lung function, and reduced $DL_{CO}$. Cell counts from BAL fluid reveal lymphocyte predominance, and lung biopsy typically shows interstitial pneumonitis, possibly with mild fibrosis, and rarely BOOP.[165,166] Ventilatory failure has been described.[166] Rapid improvement occurs over days to weeks, following discontinuation of the drug, although manifestations may linger with multisystem involvement. Resolution may be hastened by corticosteroid administration. Carbamazepine hypersensitivity has been associated with transient pan-hypogammaglobulinemia[167] and has been implicated in the occurrence of interstitial pneumonitis/eosinophilic pneumonia in an adolescent with cystic fibrosis (CF) on immunosuppressive therapy following lung transplant.[168] Levetiracetam has been associated with biopsy demonstrated diffuse interstitial lung disease in a child.[169]

## Minocycline

Multisystem hypersensitivity with a prominent component of skin rash has been associated with minocycline, often in a pattern consistent with DRESS. More than 50 cases have involved the lung, often in adolescents and young adults treated for acne.[5,170–175] Eosinophilic pneumonia has been suggested by the finding of excess eosinophils in blood and BAL fluid or on lung biopsy. Minocycline-associated lupus has been well described. Infrequently, significant organ dysfunction with or without lung involvement has been reported including hyperthyroidism or hypothyroidism, renal failure, hepatitis, sometimes in an autoimmune pattern, and, rarely, myocarditis.[176–178] Withdrawal of the drug typically prompts improvement, although resolution may require months. Corticosteroids may accelerate improvement and have been used in combination with immunosuppression for autoimmune hepatitis. Hypersensitivity to doxycycline has been implicated in a single case involving respiratory failure.[179]

## Penicillamine

Penicillamine, a chelating agent, is commonly used to treat Wilson disease, cystinuria, and lead poisoning and, occasionally, rheumatoid arthritis and primary biliary cirrhosis. A conclusive association of this agent with lung disease is problematic, because similar lung disorders occur in underlying diseases.[180,181] More than 40 cases of penicillamine-associated lung disease are reported, and these cases are primarily in patients with rheumatoid arthritis.[182,183] Several patterns have been described: diffuse alveolitis, hypersensitivity pneumonitis, alveolar hemorrhage with or without associated acute glomerulonephritis (similar to antiglomerular basement membrane disease [Goodpasture syndrome]), and obstructive airway disease characterized pathologically as bronchiolitis obliterans. Duration of therapy before onset of symptoms tends to be short in patients with hypersensitivity reactions (<2 months), intermediate with diffuse alveolitis and bronchiolitis obliterans (3–19 months), and prolonged with alveolar hemorrhage (7 months to 20 years, but typically 2–7 years). Cough and dyspnea develop progressively over several weeks but may begin abruptly in hypersensitivity reactions with hemoptysis. Crackles and, occasionally, wheezes are present. Elevation of erythrocyte sedimentation rate, increased serum IgE, and eosinophilia may be noted. Chest films show diffuse alveolar or interstitial infiltrate, hyperinflation alone, or no changes. Hypoxemia and severe obstructive lung disease are usually identified in patients with bronchiolitis obliterans or restrictive disease in those with alveolitis or hypersensitivity disease. Discontinuation of the drug and corticosteroid therapy is warranted in most cases. Diffuse alveolitis and hypersensitivity pneumonitis generally improve using this approach, although some patients have residual lung disease. Response to corticosteroids alone has been disappointing in most cases of bronchiolitis obliterans and alveolar hemorrhage. Addition of azathioprine or cyclophosphamide in combination with plasmapheresis has been beneficial in several patients with Goodpasture-like syndrome and in a single patient with bronchiolitis obliterans.[183–186]

## Leflunomide

Leflunomide, an immunomodulatory drug that inhibits pyrimidine synthesis in activated lymphocytes that is used in treatment of rheumatoid arthritis and other autoimmune disorders, has been associated rarely with significant lung injury.[187–203] Injury appears to be more likely in those with underlying interstitial lung disease.[200–203] Presentation typically includes acute onset of cough and dyspnea 12–20 weeks after its introduction (occasionally after its discontinuation) with crackles on exam and bilateral patchy densities on chest radiograph. Ground glass and reticular/interstitial densities are identified on chest CT. The most common histologic abnormalities are diffuse alveolar injury and interstitial pneumonia. Leflunomide should be stopped when injury related to the drug is suspected. Because of its long half-life, some have advocated treatment with cholestyramine, although the benefit of cholestyramine is uncertain.[203,204] Steroid therapy has been recommended; however, effectiveness is unclear. Mortality of nearly 20% has been described.

## Azathioprine

Azathioprine, an immunosuppressive agent used in a variety of conditions including inflammatory bowel disease, autoimmune disorders, and following solid organ transplant, has been implicated rarely in lung injury.[205–213] Fever, cough, shortness of breath, and hypoxemia typically develop within weeks to months of onset of therapy in association with infiltrates on chest imaging. Hemoptysis and a clinical pattern of ARDS have been described and restrictive lung disease and reduced $DL_{CO}$ observed. Histologic patterns identified in the lung have been consistent with hypersensitivity, interstitial pneumonitis, diffuse alveolar damage, and BOOP. Treatment consists of discontinuation of the drug with or without corticosteroids. Most improve relatively quickly, but progressive deterioration and death have occurred in about 12%.

## Other Immunomodulatory Agents

Drugs targeting or modifying immune pathways are increasingly used for a variety of chronic inflammatory diseases and after transplantation. Most information on pulmonary toxicities of these agents is from adult literature. *Rituximab,* a monoclonal antibody against CD20 expressed on B lymphocytes has been associated with interstitial pneumonitis, including a fatal case in a 10 year old status-post renal transplant.[214,215] Rituximab-associated lung injury (RALI: ground-glass lesions on CT, negative bronchoscopy with BAL and deficit in $DL_{CO}$) was described in two adolescents with nephrotic syndrome, 14 and 40 days following a single rituximab infusion.[216] Infusion of *alemtuzumab* (Campath), a humanized monoclonal antibody against CD52 expressed on all lymphocytes, as well as some natural killer (NK) cells and monocytes, was associated with severe bronchospasm responsive to steroids in an adult with chronic lymphocytic leukemia.[217] *Cetuximab,* an anti-EGFR monoclonal antibody, caused dyspnea with infusion in 13% of adult colorectal cancer patients.[218] *Trastuzumab,* a humanized monoclonal antibody against the EGFR, has become standard treatment of HER2-expressing breast cancer. Acute interstitial pneumonitis developed after its infusion in a 56-year-old.[219]

*Infliximab* (Remicade) is a TNF-$\alpha$ inhibitor used in treatment of rheumatic and inflammatory bowel disease at all ages. Acute interstitial pneumonitis and respiratory failure has been reported in association with infliximab.[220,221] The calcineurin inhibitor *tacrolimus* has been associated with interstitial lung disease in adult rheumatologic patients, where it is often seen in the setting of preexisting chronic lung disease and has a high mortality.[222] Chronic use of *sirolimus* (rapamycin), an immunosuppressive agent used as an alternative to calcineurin inhibitors, has been associated with interstitial pneumonitis or BOOP in adults after renal transplant[223] and children following hematopoietic stem cell transplant.[224] Standard treatment for hepatitis C in children and adults is a combination of *pegylated interferon* and ribavirin. Interstitial pneumonitis with 7% mortality was reported in adult patients treated with peg interferon $\alpha$-2β for hepatitis C.[225]

## Amiodarone

Amiodarone, a benzofurane derivative with Class III antiarrhythmic activity, is used in the treatment of serious ventricular and supraventricular tachyarrhythmias.[226,227] Pulmonary toxicity is one of the most significant complications of therapy and develops in about 5% of patients.[227–231] Most affected patients have been adults; however, lung toxicity has been reported in at least four children.[232–235] The risk of lung toxicity appears to be dose related; for example, approximately 5%–15% of patients who take ≥500 mg/day and 0.1%–0.5% of those who take up to 200 mg/day develop drug-related lung disease.[230] Onset of symptoms is often insidious, but symptoms can be acute and rapidly progressive with alveolar hemorrhage or the development of ARDS.[236] Risk for ARDS may be increased by exposure to high concentrations of inspired oxygen, cardiothoracic surgery, or iodinated contrast media.

In the more common subacute presentation, patients insidiously develop nonproductive cough, dyspnea on exertion, weight loss, weakness, and in some instances, pleuritic chest pain and fever, usually during the first year of therapy. Approximately one-third of the patients have an acute onset of symptoms more consistent with hypersensitivity pneumonitis. Chest examination reveals tachypnea, crackles and, occasionally, a pleural friction rub. Physiologic abnormalities include hypoxemia, restrictive lung disease, and impaired diffusion. Predominance of cell type on cytology of bronchoalveolar fluid is variable.[237] Diffuse or asymmetrical interstitial or alveolar infiltrates are typically present on chest x-rays. Chest CT shows bilateral involvement with ground-glass or reticular opacities often in the upper lobes or periphery of the lung bases, wedge-shaped consolidations, or nodules and may show pleural effusion or thickening.[227,238]

Amiodarone interferes with movement of phospholipid across intracellular membranes and reduces phospholipid catabolism by inhibition of lysosomal phospholipase.[239] The drug accumulates in structures such as macrophage lysosomes, leading to the recovery of ‘foamy’ macrophages in BAL fluid that are indicative of “amiodarone effect” (not toxicity) and may accumulate in type II pneumocytes and interstitial cells, interfering with gas exchange and causing a reduction in diffusing capacity that may be asymptomatic in patients with otherwise healthy lungs.[227,240] Among those manifesting subacute symptoms, patterns of abnormalities identified on lung biopsy include eosinophilic pneumonia, nonspecific interstitial pneumonitis with or without fibrosis, chronic organizing pneumonia (BOOP), and rarely nodular lung disease.[230,231,241,242]

Discontinuation of the drug results in gradual symptomatic improvement in most patients and resolution of physiologic and radiographic abnormalities over several months. Clinical evidence supports corticosteroid treatment, particularly for more advanced disease. Recurrence of symptoms was observed in some patients as steroid doses were tapered, potentially related to extended storage of drug in the lung. Alternative approaches for patients who must remain on amiodarone because of life-threatening refractory dysrhythmias are limited. Reinstitution of amiodarone therapy at lower doses after resolution of pulmonary disease, alone or in combination with low-dose corticosteroid therapy, has been successful in a few patients.[243]

Mechanisms that may contribute to lung injury include direct cytotoxic effects on type II pneumocytes and other lung parenchymal cells, immune mediated injury, and injury related to activation of the angiotensin enzyme system leading to apoptosis of alveolar epithelial cells.[227,244–253]

## Hydroxymethylglutaryl Coenzyme A Reductase Inhibitors

Hydroxymethylglutaryl coenzyme A (HMG-CoA) reductase inhibitors or statins, widely used in the treatment of hypercholesterolemia, have been rarely associated with lung disease heralded by onset of dry cough, dyspnea and bilateral infiltrates, often with ground glass changes on chest CT, after months to years of treatment.[254–258] When measured, lung function has shown a restrictive pattern with reduction in $DL_{CO}$. In a few cases, BAL fluid or tissue from lung biopsy has been demonstrated to contain "foamy" alveolar macrophages reminiscent of those in the BAL fluid of patients on amiodarone, which is considered indicative of so-called phospholipidosis.[256,258] Discontinuation of the drug and, in some cases, use of corticosteroids have been associated with resolution of symptoms, although mortality of about 25% is described.

# Other Agents

A number of other drugs have been implicated sporadically in the development of hypersensitivity/eosinophilic lung disease. Table 59.3 shows a representative list with a focus on medications that may be given to children or adolescents,[259–284] and an extensive compilation has been published by Allen.[259] Eosinophilic granulomatosis with polyangiitis (asthma, eosinophilia, neuropathy, pulmonary infiltrates, and sinus disease) has been linked with *leukotriene antagonists* in a small number of asthma case reports, including some in children.[272–274] *Aspirin* and other nonsteroidal anti-inflammatory drugs (NSAIDs) induce bronchoconstriction via altered leukotriene metabolism in patients with aspirin-exacerbated respiratory disease, a syndrome of chronic sinusitis, nasal polyposis, and often severe asthma.[285–287]

[b] Nonsteroidal anti-inflammatory drugs including naproxen, sulindac, piroxicam, fenbufen, diclofenac, ibuprofen.

[c] With overdose.

Drugs producing a clinical syndrome consistent with noncardiogenic pulmonary edema are listed in Table 59.4, as reviewed by Lee-Chiong and Matthay and others.[288–304] Some are associated with this clinical syndrome only after an overdose. Pulmonary edema is the pattern of injury most closely associated with heroin overdose.[305] Smoking of *crack cocaine* can be associated with acute respiratory illness including direct thermal injury to airways and air leak syndromes, and it is also associated with subacute syndromes including pulmonary edema, “crack lung” (pleuritic chest pain, dyspnea, hypoxia, diffuse alveolar damage, alveolar hemorrhage), interstitial pneumonitis, or BOOP.[305–308] *Cannabis* smoking can be associated with chronic bronchitis or emphysematous changes with secondary pneumothorax.[309] For both crack cocaine and cannabis, the tendency for air leak is likely related to deep inhalation with Valsalva maneuver to increase drug absorption. Intravenous injection of crushed tablets of methadone, analgesics like acetaminophen/hydrocodone, and other medications has been associated with dyspnea, pulmonary hypertension, and even sudden death related to microembolization of particles of excipients (filler materials used during production of tablets like talc, microcrystalline cellulose, crospovidone, and starch).[310,311] Diffuse nodular changes on chest imaging and angiogranulomatous changes often with demonstration of excipients on lung histology are characteristic. Intravenous injection of crushed methylphenidate has been associated with a distinctive radiographic pattern of predominantly basilar panlobular emphysema.[310,312–314] While the incidence of venous thrombosis and pulmonary embolism is relatively low in childhood, *oral contraceptives,* the antipsychotic drugs *clozapine* and *olanzapine,* and *intravenous immunoglobulins (IVIG)* are used in children and are associated with increased risk.[315–318]

# Conclusion

Lung injury caused by pharmacologic agents is recognized increasingly as a significant clinical problem. Lung disease caused by cytotoxic agents is particularly troublesome and survivors of childhood cancer should be followed carefully for chronic pulmonary toxicity. Precise information about risk factors, including genetic predisposition, is required to bolster predictive capabilities for patients using these drugs. Additional information is needed regarding mechanisms of injury to develop more specific interventions. Finally, more sensitive and widely available diagnostic and monitoring approaches are important if early intervention is to be of value.

# Pulmonary Embolism and Thromboembolic Disease

*Peter Michelson MD, MS, James Kemp MD*

## Epidemiology

It is widely appreciated that the timely recognition of pediatric pulmonary thromboembolism (PTE) continues to lag despite recent strong efforts to broaden our understanding of thrombotic complications in children.[1,2] Agreement on standardized treatment algorithms has been delayed by limited prospectively obtained clinical evidence, limited acceptance by some that the incidence is increasing and limited evidence for independent risk factors for PTE among hospitalized patients. These factors, combined with the presumably low incidence of PTE in children compared to adults and the lack of evidence that PTE are preventable,[3] have slowed the development of guidelines on PTE diagnosis and prevention.[4]

A related explanation may be that PTE has been rarely recognized as the primary explanation for death in pediatric patients. An old review of over 46,000 “routine” pediatric autopsies found “fatal” pulmonary emboli in 2.7%, and many of these cases dated from the preantibiotic era when deep and untreated infections were common, resulting in thrombophlebitis and septic emboli.[5]

Occasionally, children dying from other fatal diseases are found to have clots in their lung tissue, but these are rarely assigned a primary role in the child's demise. However, as more children survive with support from an indwelling central venous line (CVL), an understanding of the potential significance of multiple, though smaller, PTEs must be developed. The importance of fatal PTE is beginning to be recognized by forensic pathologists confronted with a child dying suddenly and unexpectedly.[6] In addition, it is now accepted that previously, presumably, healthy children with unrecognized inherited thrombophilia, as well as children and adolescents with systemic lupus erythematosus (SLE) or malignancies are at small but unequivocal risk for PTE.[7,8]

The age distribution of pediatric PTE shows bimodal peaks, in infancy and adolescence.[8,9] The presence of a CVL is consistently recognized to play a critical role in PTE development, most commonly in the upper circulation (superior vena cava [SVC] and right atrium). Among both outpatients and in-patients, PTE is also often associated with clotting dysfunction defined as inherited thrombophilia; among inpatients, acquired and inherited thrombophilia contribute to venous thromboembolism (VTE) in general, especially among children with sepsis and myeloproliferative neoplasms.

In adults, the age-adjusted annual incidence of PTE is 10–20 per 10,000[8]; in pediatrics, the annual incidence is estimated to be 0.14–0.49 per 10,000.[7] Among sick newborns with CVL, the prevalence of deep vein thrombosis may be 80% or higher, but the incidence of clinically significant PTE is unknown.[10–12] The overall incidence cited for PTE among hospitalized pediatric patients is 0.86–5.7 per 10,000 patient years.[10,12] It should be emphasized that these incidence rate estimates are from retrospective reviews of data collected from many centers with variable propensities to consider the diagnosis of PTE. Data on the incidence of PTE in *prospective* studies are scarce, even among high-risk populations.

Adults with chronic thromboembolic disease of the lungs are at risk for pulmonary hypertension from nonlethal emboli showering the pulmonary arterial circulation. Pulmonary hypertension as a manifestation of chronic PTE is not often recognized in pediatric patients, either in published reports or from our personal experience. Perhaps this is because chronic PTE are rare, or, more likely, because more attention is paid to the higher pulmonary vascular resistance that occurs in the context of congenital cardiovascular malformations causing pulmonary overperfusion or to the effects of alveolar hypoxia in children with advanced lung disease who are often also supported with a CVL.

# Etiology

One of the dicta regarding PTE in pediatric patients is that there is nearly always an explanation in up to 90% of cases,[10] in contrast with adults where up to 30% of PTE are labeled idiopathic. In children, immobility leading to peripheral DVT is less often invoked than in adults, perhaps because they are less often immobile. After serious trauma involving the spine or lower extremities,[3] and after orthopedic surgery, pediatric patients, particularly adolescents, develop PTE, and advice regarding routine care for these patients often includes, for example, pressure dressings for at-risk lower extremities.[13]

As in adults, DVT and PTE have been linked to estrogen and progesterone use in patients 18 and younger. Injectable medroxyprogesterone and contraceptive patches are associated with an increased risk for eventual DVT.[14]

Adults who are obese (body mass index [BMI] > 30 kg/m$^2$) have a twofold increased risk for having PTE. Since 17% of children in the United States have a BMI greater than 95%,[15] one would expect increased occurrence of PTE in these patients, but limited data exist, linking the obesity epidemic to more PTE in patients less than 18 years old, and the strength of the expected association is not yet clear.[16] Prospective studies are needed in obese pediatric patients evaluating additional antecedent risk factors, such as established deep vein thrombosis or inherited thrombophilia, and these studies would serve to clarify an appropriate index of suspicion, particularly in obese adolescents.

## Age-Specific Etiologies

Although there are overlaps, the recognized etiologies are somewhat different along the bimodal age distribution of pediatric PTE.

Among *infants,* two etiologic factors in the pathogenesis of PTE are particularly noteworthy, congenital heart disease and the CVL (Table 60.1). With increasing long-term survival of infant born before 28 weeks gestation and of infants with abdominal surgical problems, CVLs reaching into the SVC or right atrium are a mainstay of supportive care. The rate of clinically apparent thrombotic complications from CVL in preterm infants is not clear, however, as it is difficult to make an accurate estimate because of the complexity and acuity of these extremely low gestational age newborns. One review contends that frequent PTE among preterm infants makes them the most commonly affected pediatric age group.[8] It is our impression that there is a wide difference among newborn intensive care units in the practitioners' index of suspicion for PTE.

**Table 60.1**

**Risk and Etiologic Factors in the Pathogenesis of Pulmonary Thromboemboli in Childhood and Adolescence**

| | |
|---|---|
| Congenital heart disease | Central intravenous line (CVL) |
| Contraceptive treatment with estrogen and medroxyprogesterone | Cancer (acute lymphoblastic leukemia, in particular, and treatment with L-asparaginase) |
| Inherited thrombophilia | Deep soft tissue or bone infection with septic thrombophlebitis |
| Obesity | Longer hospital stay |
| Systemic lupus erythematosus | Orthopedic and spinal surgery |
| Vascular malformations | Trauma with immobilization |

*Adolescents,* because they are at risk for serious physical trauma and resultant immobility, are at particular risk among pediatric patients for the same types of DVT leading to PTE as adults. Children older than 2 years, and adolescents in particular, are much more likely to have surgery for scoliosis and other skeletal deformities,[13] with the types of skeletal manipulation and immobility that lead to DVT and PTE in adult patients.

## Inherited and Acquired Thrombophilia

A variety of clotting abnormalities broadly designated as thrombophilias are particularly important to consider when confronted with a child or adolescent with PTE. While PTE does occur without clotting abnormalities, inherited thrombophilia should be considered as an additional "prothrombotic risk factor," especially when patients have a CVL for treatment of a malignancy.[17] Furthermore, inherited thrombophilias are more commonly found when thrombosis and PTE occur in otherwise healthy children. When studied, genetic thrombophilia traits have usually been shown to be associated with increased risk for VTE, with an adjusted odds ratio of 2.63 for clotting Factor II deficiency and up to 9.44 for antithrombin deficiency among previously healthy children with obvious and severe PTE.[18]

Inherited thrombophilias include genetic mutations altering the amount or function of a protein controlling the coagulation system. Gain-of-function mutations include genes controlling Factor V (Leiden) and prothrombin gene 20210. Relatively frequent loss-of-function mutations causing thrombophilia affect antithrombin, protein C, and protein S. Pulmonologists should be aware that these mutations are not at all rare in the general population. For example, the prevalence of Factor V Leiden gain-of-function mutations is 2%–7% in the general population.[18]

Evaluation for inherited thrombophilias should be undertaken in consort with a specialist in coagulation who is aware of when the testing will or will not be useful and has ready access to a laboratory skilled in this type of testing. In both children and adults with palliative shunts involving the pulmonary circulation, a patient may have a lifetime need for anticoagulation, and the factors contributing to the PTE are less important. However, among otherwise healthy children who present with PTE, without CVL or known malignancy, testing for hereditary thrombophilia is recommended.[7]

Acquired thrombophilia is a part of the antiphospholipid syndrome complicating SLE, but it also occurs during frank sepsis, during treatment with corticosteroids, and as a complication of nephrotic syndrome and myeloproliferative neoplasms.

## Disease-Specific Etiologies

Other diseases with an etiologic link to embolic phenomena and PTE (see Table 60.1) include nephrotic syndrome,[19] inherited thrombophilia,[17] inflammatory bowel disease,[20] sickle cell-related hemoglobinopathies, both solid and lympho-hematogenous malignancies,[21] vascular malformations including the Klippel-Trénaunay-Weber syndrome,[22] and sepsis with vascular endothelial injury due to thrombophlebitis.[23] These diseases, while more common beyond infancy, have a lesser age-dependent association with PTE.

## Treatment-Specific Etiologies

*Females receiving estrogens* to prevent pregnancy or to address menstrual problems, or ovarian dysfunction also share risks not found in infants. Concern might be directed toward those who are obese and receiving estrogen for the polycystic ovary syndrome, but published reports have not yet quantified risk in these patients.

# Pathology/Pathogenesis

When death is attributed to PTE, the gross pathology is that of a clot, often twisted and branched, which **occludes** a large pulmonary artery. Very large clots can cause acute right heart failure. In adults, however, fatal PTE are macroscopic, yet not necessarily critically occlusive, and are believed to cause circulatory collapse, most likely because they elicit release of thromboxane, serotonin, histamine, thrombin, and related vasoactive substances from the vascular endothelium.[24,25]

Very large clots in the pulmonary arterial circulation appear to cause sudden death with inadequate time for lung infarction to develop. The contribution of smaller PTE to nonlethal pulmonary infarction is likely but can only be speculated upon. In children, because deaths are rarely attributed to PTE as a primary cause, it is likely that understanding of the gross "pathology" of PTE in children will depend on imaging studies.[26]

The microscopic picture of a PTE is that of a true thrombus arising in veins elsewhere.[24] The clots are longer and more castlike than the typical arterial thrombus. Thrombi lodging in the pulmonary circulation are composed of platelets in various stages of senescence, red blood cells and white blood cells, in irregular shapes within a fibrin sheath.

In adults, PTE have arisen, most commonly, from thrombi in the venous circulation of the legs and from the pelvic veins during and after pregnancy. In children, trauma and surgery can also give rise to venous thrombi in the lower extremities. More commonly, however, the “upper” circulation is the site of thrombus origin as a complication of a CVL.[1]

Imaging with computed tomography (CT) angiography suggests that segmental pulmonary arteries are the most common final site of PTE in children. In one report, over a third of images diagnostic for a PTE showed it in segmental arteries, followed by lobar and subsegmental arteries. Main pulmonary arteries, the most frequent site of fatal PTE, were the site for nonfatal PTE in only 9% of images.[26]

The classic paradigm for the *pathogenesis of thrombosis* was suggested by Virchow in the 1840s. The causation of thrombi involves (1) *Slowing of blood flow,* (2) *Changes in the vessel wall,* and (3) *“Susceptibilities” arising from the blood itself.*[24] Virchow's triad still seems to be useful, and the venous circulation is a low-velocity system whose blood velocity is very sensitive to diminished cardiac output and the depth of breathing. Veins are relatively easily compressed during times of muscular inactivity. Unlike arterial atheromas, venous thrombi are often associated with demonstrable injury to the vascular intima. Changes in the venous wall can be induced, of course, by in-dwelling CVL, accidental or surgical trauma, and, primarily in the preantibiotic era, deep soft tissue or bone infections leading to septic thromboemboli. In children, developmental changes in the propagation of thrombi[27,28] and inherited or acquired thrombophilias, described above and discovered over the last 30 years, would seem to qualify as “susceptibilities” in the blood itself predicted by Virchow over 150 years ago.

## Clinical Features

It is likely that PTE is much more common than currently recognized. In our experience, PTE is rarely considered in pediatrics unless an at-risk patient has a sudden and severe worsening of his/her respiratory status, for example, a patient with lupus erythematosus. Clinicians rarely consider PTE as an explanation for gradual clinical decline. In an era when most patients with severe diseases are surviving, autopsies are less common than in times past. Except in those fatal instances of large, central clots, the absence of standard interpretive criteria undermines our ability to define whether smaller PTE seen at postmortem is incidental or instrumental in contributing to the child's death.

Among adults and older pediatric patients able to articulate their symptoms, clinicians often recognize PTE symptoms retrospectively after diagnostic CT imaging. The symptoms are nonspecific, a “sense of unease,” and dyspnea. Pain is relatively late and occurs when the PTE causes significant ischemia or infarction to lung tissue close to the pleura. Though the pain is most often pleuritic, in adults, it is frequently first attributed to myocardial ischemia. In one series incorporating CT pulmonary angiography for patients aged 4 months to 18 years suspected of having a PTE, 52% described pleuritic pain, but pleuritic pain was equally common among patients suspected of having a PTE but with nondiagnostic CT angiography.[26]

Symptoms eventually linked to PTE in infants and young children are nonspecific, e.g., irritability, poor feeding, and inactivity, and recognized in retrospect in patients with long-standing CVL or solid tumors of the mediastinum.

At all ages, shock, cyanosis, with low $SpO_2\%$, and cardiovascular collapse are physical findings consistent with a very large PTE. Other common though nonspecific signs include tachypnea, rapid shallow breathing, and, in small children, chest wall retractions. When pleuritic pain can be described in older patients, physical signs arising from the PTE might include dullness to chest percussion, diminished breath sounds by auscultation, and a pleural friction rub. When diagnosing PTE, two considerations that are of paramount importance in patients of all ages are awareness of the underlying diagnosis and inspection of the patient's extremities for a source of PTE. Finally, although PTE, in general, is rare in children, the prevalence may be as high as 15% among pediatric patients at high risk (see Table 60.1) who also have dyspnea, pleuritic pain, and the other findings of PTE.[26]

## Diagnosis and Differential Diagnosis

The differential diagnosis of PTE includes a long list of pulmonary conditions including pneumonia, atelectasis, chest trauma, alveolar hemorrhage, and malignancy. Since all these processes can result in chest pain, dyspnea, hemoptysis, and/or hypoxemia, they all need to be considered as diagnoses.[11] In fact, only relatively large PTEs result in such symptoms, whereas smaller emboli present with more subtle symptoms and less specific clinical features.[7] As a result of the subtlety of the presenting symptoms, a high index of suspicion is critical. In considering PTE, one must also be cognizant of the patient's age, since the recognized occurrence of PTE in childhood is bimodal, as discussed previously.[8]

Infants who present with PTEs have nonspecific symptoms, and the diagnosis is frequently overlooked. As tachypnea and hypoxemia are the primary features of neonatal PTE, the overlap with respiratory distress syndrome, sepsis, birth asphyxia, and congenital heart disease makes confirmation of this diagnosis difficult and affects estimates of incidence rates of PTE in neonates.[29] With younger and more complicated neonates having improved survival, there is an increased use of indwelling catheters that increases the risk of PTE. In addition, increased use of CVL, combined with more awareness, has led to greater recognition of PTE. Central venous catheters and inherited prothrombotic risk factors are the greatest predisposing risk factors for PTE in infants.[30]

In the adolescent age range, the depiction of the presentation and diagnostic criteria of PTE needs revision. Traditionally, presentation with chest pain, dyspnea, and hemoptysis has been described; however, a recent multicenter retrospective review suggests that tachycardia and tachypnea, combined with pleuritic chest pain and dyspnea, are the most common presenting symptoms.[31,32] Additional risk factors identified include obesity, oral contraceptive use, and a history of coagulopathy. Hypercoagulability risk includes rheumatoid disease (e.g., SLE), malignancy and postoperative immobility; nephrotic syndrome and sickle cell anemia were also identified as comorbidities.

In adults presenting with concern for a PTE, clinical prediction rules based on signs, symptoms, and risk factors are frequently used. While these tools are intended to lessen unnecessary testing, no similar tools have been validated for children less than 18 years of age. The Wells criteria[33] were designed to help diagnose PTE in patients with VTE or at risk for VTE; and the revised Geneva score[34] followed to assist in the accuracy of this effort. However, both still have limited sensitivity, especially in children.[35] Neither addresses pediatric-specific concerns, so adult diagnostic criteria are still frequently used, especially in the adolescent age group. Chest radiography, arterial blood gas analysis, and electrocardiography are still encouraged, both to rule out other disorders and to confirm/exclude a PTE.[7] Ultrasonography to assess for deep vein thrombosis is appropriate if suggested by the history or physical examination. Multidetector CT angiography is now the main imaging modality if PTE is suspected.[36]

# Imaging

Radiologic imaging is essential in evaluating for PTE in children. Chest radiography alone is of little benefit except to exclude obvious pathology such as pneumonia or a pneumothorax.[8] Nonspecific signs are frequently seen with PTE including parenchymal infiltrates or atelectasis. Multidetector computed tomography pulmonary angiography (CTPA) has become the diagnostic imaging modality of choice with its high sensitivity and specificity, and the apparent sensitivity of this technique yields a truer estimate of childhood PTE incidence rates.[9]

Dual-energy CT scanning shows both anatomical and functional data in a single study. Chest scan times are rapid, sedation is not required except in the youngest patients, and specific techniques can be employed based on age and size to decrease the radiation dosage without compromising the image quality.[26,37] Multiplanar reformatted CT imaging in the sagittal and coronal planes can improve the diagnostic confidence as well as the sensitivity of this technique (Figs. 60.1 and 60.2).[38]

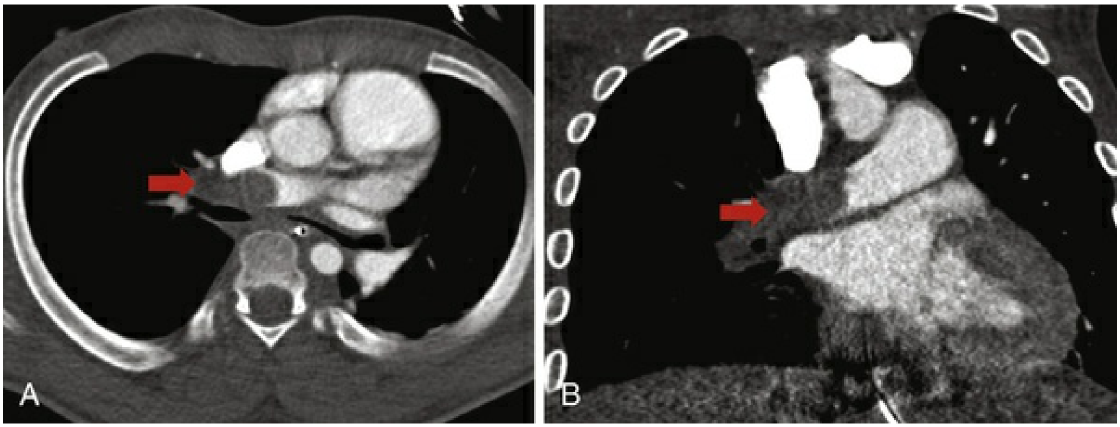

**FIG. 60.1** (A) Transaxial computed tomographic pulmonary angiogram image of the chest obtained after administration of intravenous contrast material following a pulmonary embolism protocol. There is a large pulmonary embolism seen within the right main pulmonary artery *(arrow).* No flow is seen distal to this pulmonary embolism. (B) Coronal computed tomography pulmonary angiogram image of the same area demonstrating a large right main pulmonary artery pulmonary embolism completely occluding the vessel with no contrast distal to the obstruction *(arrow).*

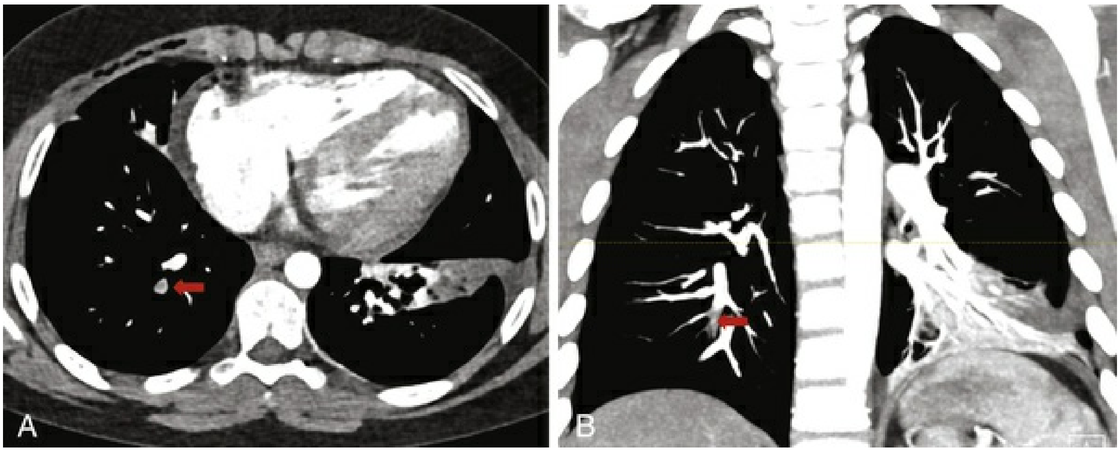

**FIG. 60.2** (A) Transaxial computed tomography (CT) image of the chest obtained after administration of intravenous contrast material demonstrating a segmental right lower lobe pulmonary artery embolus *(arrow).* Additionally, right middle and left lower lobe atelectasis are visualized. (B) Coronal CT image again demonstrating the segmental right lower lobe pulmonary artery embolism *(arrow)* with left lower lobe

atelectasis present.

Additional imaging techniques include ventilation-perfusion (V-Q) scanning and magnetic resonance imaging (MRI). While lung ventilation/perfusion scintigraphy was previously the gold standard of imaging,[39] difficulties with image interpretation, often confounded by underlying disease plus reduced specificity, has lowered its usefulness.[40] Although V-Q scanning is easily performed and well tolerated, the limitation of this technique is that most patients will have results that are nondiagnostic.[41] Newer algorithms combining risk factors and V-Q scanning improve the sensitivity; nonetheless, CTPA is still preferred.[42] Limited data, cost, and scanner availability has prevented widespread utilization of MRI in diagnosing PTE. Until more data become available to justify the benefit of MRI, CTPA remain the preferred technique.[43]

# Additional Diagnostic Testing

Risk factors for PTE and VTE in children are similar and include venous stasis, endothelial injury, and hypercoagulability. These previously described risk factors are attributed to Virchow (Virchow triad).[44] In children with VTE or PTE, the existence of hypercoagulable states are often not previously established.[17] Although reported rates of inherited prothrombotic disorders vary between neonates and adolescents, a positive family history is associated with an increased odds ratio of a prothrombotic condition.[45] In other studies of VTEs, the prevalence of inheritable prothrombotic conditions were sixfold higher among patients with a spontaneous event compared to children with a known medical condition.[46] Factor V Leiden and prothrombin gene mutations were the most likely causes in those studied.

## Ultrasonography

At-risk patients who present with a PTE should have ultrasonographic examination of any affected extremity, as a diagnosis of a deep venous thrombosis (DVT) may indirectly suggest the diagnosis of PTE. While there are many approaches to diagnostic testing, the presence or absence of a DVT via venous ultrasonography does not preclude further examination if clinical evidence is compelling.[47] With limited pediatric data, the prudent clinician should incorporate ultrasonographic examination for DVT if there is a history of central venous access or appropriate clinical context (see Table 60.1).

## Echocardiography

There are two clear rationales for echocardiographic evaluation. Echocardiography, either transthoracic or transesophageal, can visualize indirectly associated findings of PTE such as right ventricular dilation, tricuspid regurgitation, or other features of right ventricular dysfunction.[8] Furthermore, imaging of the heart or central pulmonary arteries may directly visualize clots.[7,48] Risk factors associated with poor outcomes in adults that might be identified on echocardiography include free floating right heart thrombi and findings of persistent pulmonary hypertension, right ventricular dilation, and hypokinesis of the septum; and the presence of these findings warrants consideration for embolectomy and/or thrombolysis.[49] Although echocardiography is not sensitive as an imaging modality, it is noninvasive and safe and provides complementary information to assist in the care of the critically ill patient.

## Pulmonary Angiography

Selective percutaneous pulmonary arteriography remains the gold standard for diagnosing PTE. Although not universally available, pulmonary angiography is the most sensitive method for discerning the presence of a PTE. In a large prospective trial of adults with acute PTE, the definitive diagnosis was established with a sensitivity of 96%.[50] Direct signs for PTE include contrast filling defects or nonfilling of pulmonary arteries with abrupt termination of the contrast agent.[11] Even in centers with expertise, bleeding risk and renal insufficiency are relative contraindications. In a large trial, the Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED), the overall complication rate was 1%, so careful consideration should be associated with a request for pulmonary angiography.[42]

## Management

Treatment of PTE in children has followed adult recommendations and has been guided by the child's clinical stability and the relative risks associated with each intervention. Although no severity scoring has been validated in children, therapy is stratified with higher risk patients or symptomatic patients receiving more aggressive care, which is similar to adults. This may include anticoagulation therapy, thrombolysis, inferior vena cava (IVC) filters and/or surgical, or catheter-directed thrombectomy.[40,51] Lower risk patients who demonstrate clinical stability will likely require thrombolytic therapy alone.

Hemodynamically stable patients should receive anticoagulation therapy to prevent extension of the thrombus and the development of recurrence or postthrombotic complications.[11] Before therapy initiation, careful testing for genetic or acquired causes of thrombophilia should be performed. Options for anticoagulation include unfractionated heparin, which is the most frequently used anticoagulant in pediatrics, low-molecular-weight heparin (LMWH), and vitamin K antagonists (warfarin).[8,9] Complications associated with both heparin and LMWH support consideration of early transition to oral therapy with warfarin. Newer anticoagulant drugs, including rivaroxaban, are now available for adult patients with thromboembolic disease, but no pediatric data are available.[52] Although drug level monitoring in children may be difficult, anticoagulant therapy is traditionally recommended for 3 months or longer based on the severity and extent of the lesion.[53] Unfortunately, adherence rates in children are variable with up to one-third of patients being inconsistent with their medication regimen.[54]

In patients with unstable hemodynamics caused by PTE, thrombolytic agents, specifically tissue plasminogen activator (tPA), may be indicated.[8] This may be particularly important in infants in whom plasminogen levels may be reduced. If there are no contraindications (e.g., recent surgery), tPA may be appropriate, especially for catheter-related or localized therapy.[55] Surgical embolectomy or transvenous catheter embolectomy are useful for the unstable individual for whom thrombolysis is unsuccessful or inappropriate. Several techniques are reported including surgical embolectomy on extracorporeal life support (ECLS).[56] Finally, IVC filters may be placed for PTE prevention, but evidence to support their use is limited, and complications and size restrictions have reduced their utilization in children.[57]

Childhood PTE is associated with a mortality of approximately 10% in limited studies,[12,58] but underestimation of incidence rates is likely. Deaths associated with PTE may exceed 10%, but they are most commonly attributed to the underlying diagnosis, where congenital heart disease and malignancy are associated with a worse prognosis. With increasing use of indwelling central venous catheters, the incidence of childhood PTE is likely to increase, as well as consideration of alternative or prophylactic anticoagulant regimens.[8,59]

## Prevention

Although VTE prevention and prophylaxis is common in adults, only recently has pediatric VTE prophylaxis become generally recommended.[3] Improved clinical effectiveness has been demonstrated with computerized decision support tools, and these alerts have been shown to sustain their effectiveness over time.[4,60] Utilization of computer-based clinical decision-making systems has been useful both in alerting health care providers of treatment options for acutely symptomatic hospitalized patients and in initiating appropriate preventative care. With a combination of education and electronic medical record (EMR) alerts, a reduction and ultimately prevention of VTE and childhood PTE should be achieved.

# Diffuse Alveolar Hemorrhage in Children

*Timothy J. Vece MD, Marietta Morales De Guzman MD, Claire Langston MD, Leland L. Fan MD*

The lungs receive blood from two separate systems: the bronchial circulation and the pulmonary circulation. The bronchial circulation is a high-pressure, low-volume circuit supplied by the bronchial arteries, which vary in number and origin, but most often arise directly from the aorta or one of its branches. These vessels provide blood to the conducting airways from the mainstem bronchi to the terminal bronchioles. Because the bronchial circulation is subject to high pressures, bleeding from this system has the potential to be profuse, sometimes resulting in massive hemoptysis and death.[1–4] In contrast, the pulmonary circulation is a low-pressure, high-capacitance circuit that arises from the right ventricle and provides blood flow to the acinar units involved with gas exchange. Disruption of this system results in alveolar hemorrhage, which is often low-grade, chronic, and diffuse. Although massive hemoptysis is rare, uncontrolled alveolar hemorrhage can be fatal.[3]

Pulmonary hemorrhage arising from either the systemic or pulmonary circulation has multiple etiologies and can be localized or diffuse (Box 61.1). Bleeding from the nasopharynx, oropharynx, or upper digestive tract is common and must be ruled out as a source of “simulated” hemoptysis, or true hemoptysis when the blood is aspirated.[3] Bleeding from the upper airway can occur from intrinsic lesions, such as a subglottic hemangioma or tumor, or from extrinsic causes, such as an inhaled foreign body or intubation.[5–10] Intubation may induce ulceration and granulation tissue formation in the airway wall, which may eventually lead to hemorrhage. More serious iatrogenic causes capable of inducing massive and fatal hemoptysis include erosion of a tracheostomy tube into the aorta or innominate artery, and perforation of the pulmonary artery by a Swan-Ganz catheter.[11–14]

**Box 61.1**

### Causes of Pulmonary Hemorrhage in Children

**Infection**
  Bronchitis
  Bronchiectasis/cystic fibrosis
  Primary ciliary dyskinesia
  Immunodeficiency
**Lung Abscess**
**Pneumonia**
**Trauma**
  Airway laceration
  Lung contusion
  Artificial airway
  Suction catheters
  Foreign body
  Inhalation injury
**Vascular Disorders**
  Pulmonary embolism/thrombosis
  Pulmonary arteriovenous malformation
  Pulmonary hemangioma
**Coagulopathy**
  Von Willebrand's disease

    - Thrombocytopenia
    - Anticoagulants
- **Congenital Lung Malformations**
    - Sequestration
    - Congenital pulmonary airway malformations
    - Bronchogenic cyst
- **Miscellaneous**
    - Catamenial
    - Factitious
    - Neoplasm
- **Diffuse Alveolar Hemorrhage Syndromes**

In children with advanced cystic fibrosis, hemoptysis is relatively common because severe, chronic airway inflammation leads to progressive bronchiectasis with increased dilatation and fragility of vessels in the airway walls.[2,9,15,16] Bleeding can also occur with other etiologies of bronchiectasis including primary ciliary dyskinesia and immunodeficiency.[17,18] Infection of the airways or lung parenchyma from viruses, fungi, and bacteria, particularly *Streptococcus pneumoniae* and *Staphylococcus aureus,* is a common cause of hemoptysis in children. In such cases, mechanical trauma from forceful coughing may contribute to bleeding. Finally, factitious hemoptysis should be considered in a child with unusual symptoms and a negative evaluation.

This chapter focuses on diffuse alveolar hemorrhage (DAH) arising from the small vessels of the pulmonary circulation. A cardinal feature of DAH is the presence of hemosiderin-laden macrophages in the acinar units, as macrophages are responsible for clearing free erythrocytes from airspaces. In a simulated alveolar hemorrhage model, hemosiderin-laden macrophages first appeared 3 days following a hemorrhage, peaked at days 7–10 with hemosiderin staining in 60% of macrophages, and continued to be present at 2 months in 10% (Fig. 61.1).[19] The etiology of DAH includes both immune-mediated and nonimmune-mediated disorders (Box 61.2).

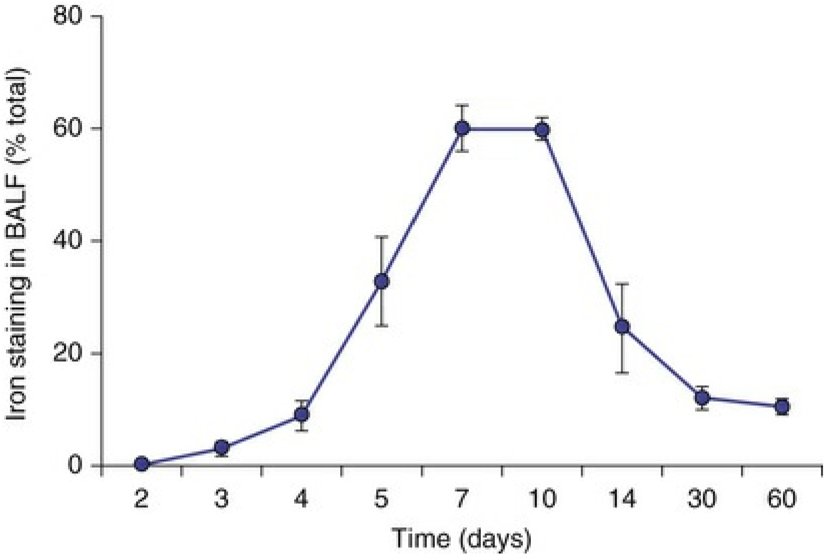

**FIG. 61.1** Time course of hemosiderin-laden macrophage production following a single episode of simulated alveolar hemorrhage in mice. *BALF,* Bronchoalveolar lavage fluid. (From Epstein CE, Elidemir O, Colasurdo GN, Fan LL, et al. Time course of hemosiderin production by alveolar macrophages in a murine model. *Chest*. 2001;120:2013-2020, with permission.)

## Causes of Diffuse Alveolar Hemorrhage

### Immune Mediated

Idiopathic pulmonary capillaritis
Granulomatosis with polyangiitis
Microscopic polyangiitis
Anti-GBM disease
Systemic lupus erythematosus
Henoch-Schönlein purpura
Behçet's disease
Cryoglobulinemic vasculitis
Juvenile idiopathic arthritis
COPA Syndrome

### Nonimmune Mediated

Idiopathic pulmonary hemosiderosis
Acute idiopathic pulmonary hemorrhage of infancy
Heiner's syndrome
Asphyxiation/abuse
Cardiovascular causes
Pulmonary vein atresia/stenosis
Total anomalous pulmonary venous return
Pulmonary veno-occlusive disease
Mitral stenosis
Left-sided heart failure
Pulmonary capillary hemangiomatosis
Pulmonary telangiectasia

# Etiology of Diffuse Alveolar Hemorrhage

## Immune-Mediated Alveolar Hemorrhage

A subgroup of children and adolescents with DAH has the pathologic findings of pulmonary capillaritis (PC). Though a histologic diagnosis, PC usually defines an underlying systemic vasculitis or an immune-mediated disease process. PC can occur as an isolated disorder; as part of an antineutrophil cytoplasmic antibody (ANCA)–associated vasculitis; or a systemic disorder, such as systemic lupus erythematosus (SLE). Of the ANCA-associated vasculitides, DAH from PC has been reported in 12%–55% of patients with microscopic polyangiitis[20,21] and in 7%–45% of patients with granulomatosis with polyangiitis (formerly known as Wegener's granulomatosis).[22] In contrast, SLE, a more common disease, has a lower incidence of pulmonary hemorrhage, but the hemorrhage can be life threatening and should be treated aggressively. (See Chapter 58 reviews SLE in detail.) PC also has been reported in Henoch-Schönlein purpura, Behçet's disease, cryoglobulinemic vasculitis, and juvenile idiopathic arthritis.[23,24]

### Pathophysiology

ANCA is frequently associated with diseases characterized by the presence of vasculitis, affecting small- and medium-sized vessels. These diseases are associated with circulating autoantibodies directed against the neutrophil granule components, myeloperoxidase (MPO) and proteinase 3 (PR3). In the correct clinical context, the specificity of these autoantibodies for ANCA-associated vasculitides is as high as 98%. This group of disorders includes granulomatosis with polyangiitis, microscopic polyangiitis, and eosinophilic granulomatosis with polyangiitis (formerly Churg-Strauss syndrome). Despite some overlap, PR3-ANCA is particularly associated with granulomatosis with polyangiitis, and MPO-ANCA, with microscopic polyangiitis.[25,26] The primary events in the pathogenesis of these necrotizing vasculitides are not known. Several hypotheses propose that infectious agents trigger and perpetuate such events.[27–30] The presence of these autoantibodies most likely reflects a pathobiological series of events in which neutrophils and monocytes attack the endothelium of small vessels, causing the release of autoantigens with their eventual presentation to the immune system and consequent autoantibody formation. In ANCA-associated vasculitis, it has been shown that autoantibodies to endothelial cell constituents (antiendothelial cell antibodies [AECA]) are commonly produced following the activation and injury of endothelial cells. During this inflammatory attack on the vessel walls, the basal membrane of some vessels also can be damaged and autoantibodies produced to the basement membrane $\alpha 3$ domain of type IV collagen of the pulmonary vessels and glomeruli.[26]

Other autoantibodies have been described in ANCA-associated vasculitis. These autoantibodies are likely related to other factors in the inflammatory cascade and may even be part of an orchestrated attack on the endothelium and basement membrane. They include AECA, antiglomerular basement (GBM) antibodies, antibasal membrane laminin antibodies, and antiphospholipid antibodies (APLA). With the exception of the antibasal membrane laminin antibodies, these autoantibodies are considered to be clinically significant.

Antibodies to constituents of the endothelium are directed to small-vessel endothelial cells, reflecting the typical distribution of such cells in the lungs, nose, and kidneys.[31] An increase in AECA levels has been described in patients with increasing vasculitic activity in idiopathic ANCA-associated and drug-induced vasculitis. An increase of these autoantibodies has been observed in both ANCA-negative and ANCA-positive patients during disease relapse. Levels of ANCA and AECA fluctuate independently as these autoantibodies do not cross-react with the target antigens.[32]

Among patients with anti-GBM disease (also known as Goodpasture syndrome), antibodies to the alpha domain of type IV collagen have been well described. Several groups have found anti-GBM antibodies cooccurring with ANCAs in patients with idiopathic ANCA-associated vasculitis.[33] Anti-MPO antibodies are the most specific in these patients. Some have proposed that it is essential to test for both types of autoantibodies because the cooccurrence of anti-GBM antibodies and ANCAs may be associated with more severe renal involvement leading to end-stage renal disease and poorer survival.[34]

The presence of APLA, which include anti-beta2 glycoprotein1 antibodies, anticardiolipin antibodies, and the lupus anticoagulant, can be a feature of idiopathic ANCA-associated vasculitis.[35] Several reports have indicated that patients with both ANCA and APLA experience more extensive and more severe disease. In drug-induced vasculitis, APLA of the immunoglobulin M class are more frequently seen. If antihistone antibodies and ANCAs directed to more than one ANCA antigen are found together, a drug-induced condition should be suspected.[36]

## Antineutrophil Cytoplasmic Antibody Associated Vasculitis

### Granulomatosis With Polyangiitis.

Granulomatosis with polyangiitis is a necrotizing vasculitis of the small- and medium-sized blood vessels associated with granulomatous inflammation, which usually affects the respiratory system first and then the kidneys. Upper and lower respiratory manifestations include chronic rhinitis; sinusitis; serous otitis media; nasal cartilage destruction leading to saddle nose deformity; salivary gland swelling, subglottic stenosis, and tracheobronchial ulceration; parenchymal lung nodules or masses that tend to cavitate; and DAH from PC.[22] Clinically, patients have dyspnea, cough with or without hemoptysis, and hypoxemia. Patients with renal involvement have hematuria and red cell casts. Other affected organs include the eye, heart, gastrointestinal tract, spleen, joints, skin, central nervous system, and pituitary gland.[37–56]

Laboratory evaluation should include a complete blood count (CBC) to identify anemia, erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) as nonspecific markers of inflammation, and blood chemistries with urinalysis to look for renal disease. Finally, testing for ANCA is essential because the majority of patients will have serum anti-PR3 antibodies (c-ANCA pattern).

Chest radiographs may show impressive nodules or masses with or without cavitation that are disproportionate to respiratory symptoms or pulmonary function studies. Computed tomography (CT) scans of the chest not only better characterize these nodules or cavitary lesions, but also may show diffuse ground glass densities, consolidation related to DAH, or airway abnormalities (Fig. 61.2). Sinus CT is useful in identifying sinus opacification and bony destruction.

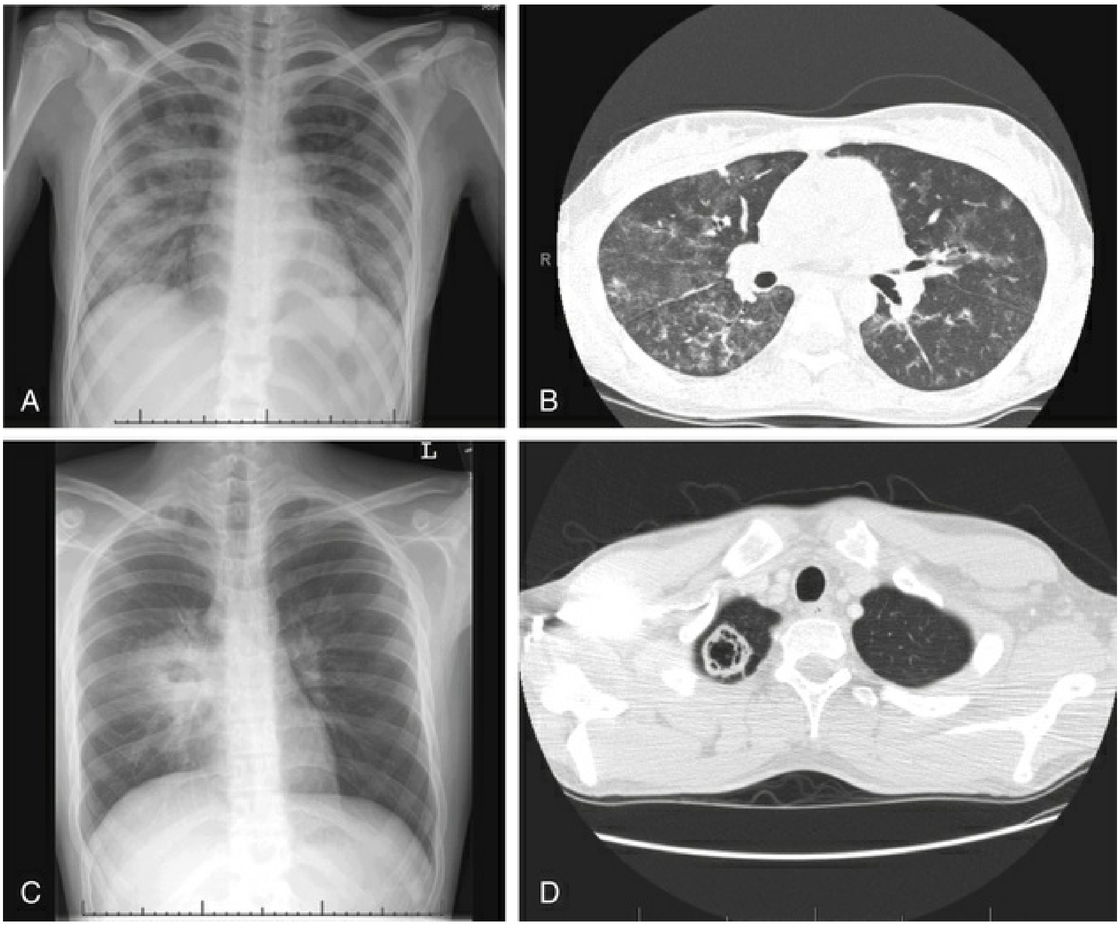

**FIG. 61.2** Radiographic findings in granulomatosis with polyangiitis. Radiographic findings in granulomatosis with polyangiitis are variable. Chest x-rays can show diffuse alveolar infiltrates consistent with alveolar hemorrhage (A) with a corresponding chest computed tomography (CT) with diffuse ground glass opacities and septal thickening (B). Alternatively, the chest x-ray can show no evidence of alveolar hemorrhage with cavitary lesions (C). A CT scan in this case will have an absence of ground glass opacities with large cavitary lesions (D).

Bronchoscopy may identify upper and lower airway lesions including ulceration, granulomata, stenosis, and malacia. In patients with diffuse infiltrates, bronchoalveolar lavage may be overtly bloody and contain red blood cells and hemosiderin-laden macrophages consistent with DAH.

Histopathologic confirmation is still considered the gold standard for the diagnosis of granulomatosis with polyangiitis in children. Characteristic features include vasculitis of the medium and small vessels and capillaritis associated with necrotizing granulomata (Fig. 61.3). Biopsies from the lung or upper respiratory tract are preferred because of their high sensitivity and specificity. Kidney biopsies typically show segmental necrotizing glomerulonephritis with or without crescent formation, which is nonspecific and can be seen in other immune-mediated renal disorders. However, the paucity of immune complexes is an important characteristic feature of this subset of renal disease.

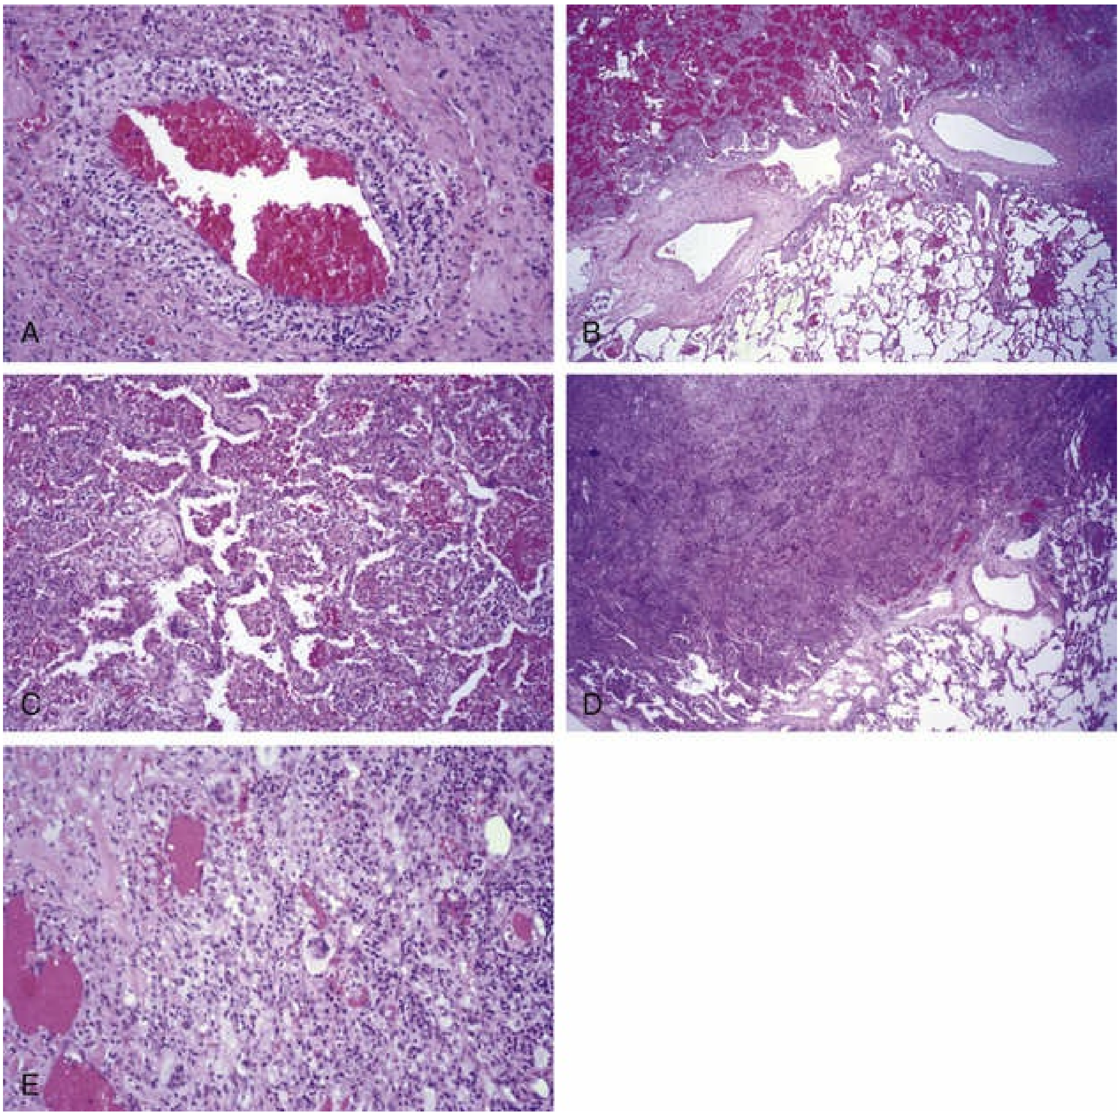

**FIG. 61.3** In granulomatosis with polyangiitis, there is vasculitis with parenchymal inflammation and hemorrhage. The vasculitis (A) involves medium-sized and smaller vessels and may be transmural and involve the complete circumference of the vessel as here, or it may involve only a portion of the vessel wall.

There may be capillaritis (B) with hemorrhage (C). Necrosis is basophilic due to its neutrophil content, and is geographic (D). There is abundant inflammation with lymphocytes, plasma cells, macrophages, neutrophils, and occasional multinucleate giant cells (E).

In 1994, the Chapel Hill Consensus Conference declared that histopathologic documentation of granulomatous involvement of the respiratory tract was not explicitly required to diagnose granulomatosis with polyangiitis.[25] Thus, the diagnosis of granulomatosis with polyangiitis now rests on clinical, serologic, radiographic, and pathologic correlations.

### Microscopic Polyangiitis.

Microscopic polyangiitis is a small-vessel vasculitis that, in children, appears to be more common than granulomatosis with polyangiitis. The presentation is similar to the other pulmonary-renal syndromes with hemoptysis, anemia, and new chest x-ray infiltrates in adults. However, hemoptysis is not always present in young children.[4,57] Patients can present with an acute, life-threatening event or with a more indolent course. Hypoxemia, often found at presentation, can be profound and can require intubation and mechanical ventilation. Although renal disease is found in some patients at presentation, its absence does not exclude the diagnosis. Physical exam often reveals diffuse crackles, and imaging studies show characteristic but nonspecific changes of diffuse alveolar infiltrates, sometimes with a tree-in-bud pattern and septal thickening on chest CT (Fig. 61.4). Bronchoscopy and bronchoalveolar lavage reveal evidence of alveolar hemorrhage with blood-tinged lavage and hemosiderin-laden macrophages on cytologic examination. In the absence of renal disease, all of the findings described above are nonspecific and cannot distinguish microscopic polyangiitis from idiopathic pulmonary hemosiderosis (IPH) or any other alveolar hemorrhage syndrome.

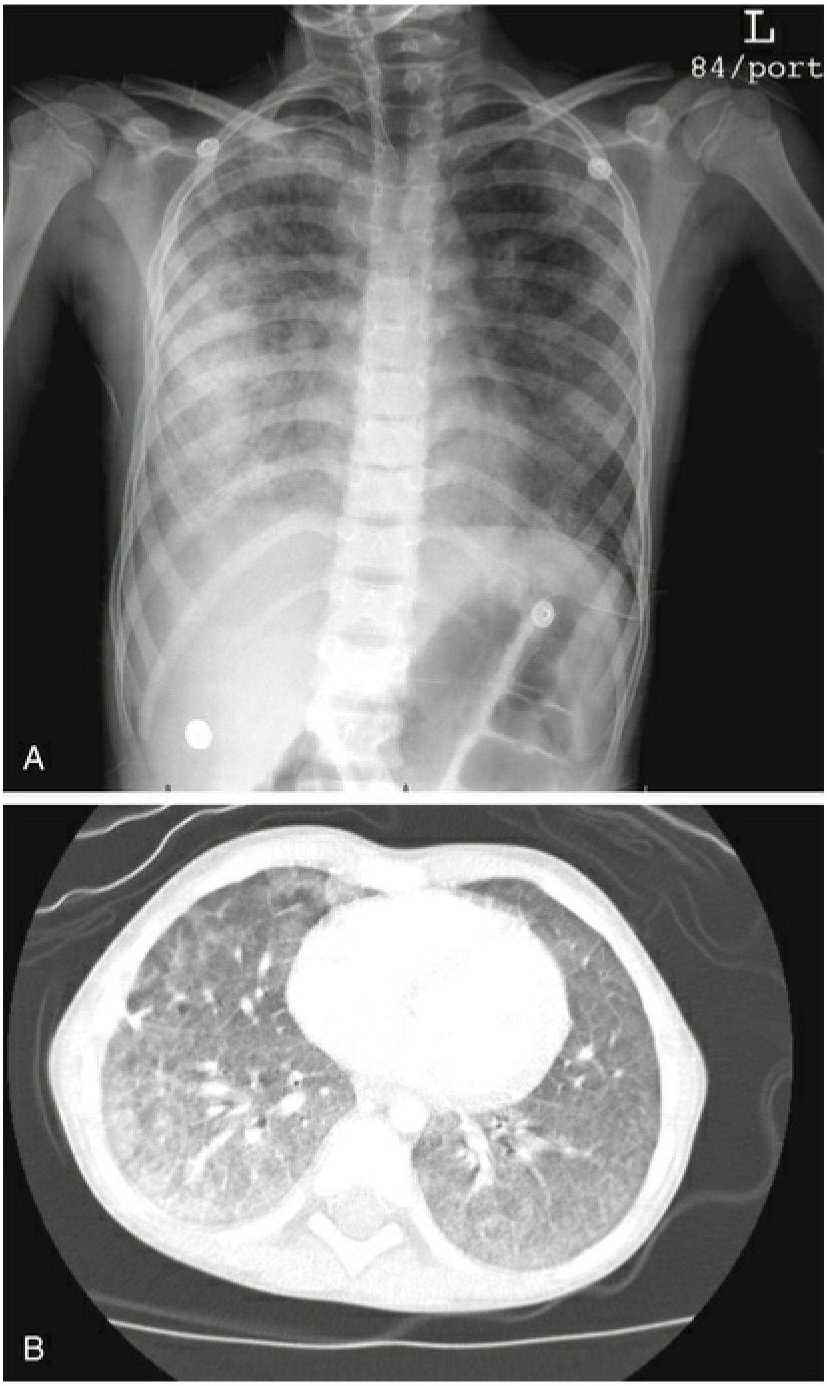

**FIG. 61.4** Radiographic findings in microscopic polyangiitis. Chest x-rays in microscopic polyangiitis show diffuse alveolar infiltrates consistent with alveolar hemorrhage (A). Chest computed tomography demonstrates diffuse ground glass opacities with septal thickening that can be subtle (B). These findings are nonspecific and are seen in many causes of alveolar hemorrhage.

A diagnosis of microscopic polyangiitis is suggested by the presence of serum anti-MPO antibodies (p-ANCA pattern). Lung histopathology in microscopic polyangiitis shows PC with neutrophilic infiltration of small arterioles, venules, and capillaries associated with fibrinoid necrosis (Fig. 61.5). Granulomatous vasculitis, characteristic of granulomatosis with polyangiitis, is not seen. Renal involvement, when present, is typically manifest on biopsy as segmental necrotizing glomerulonephritis.

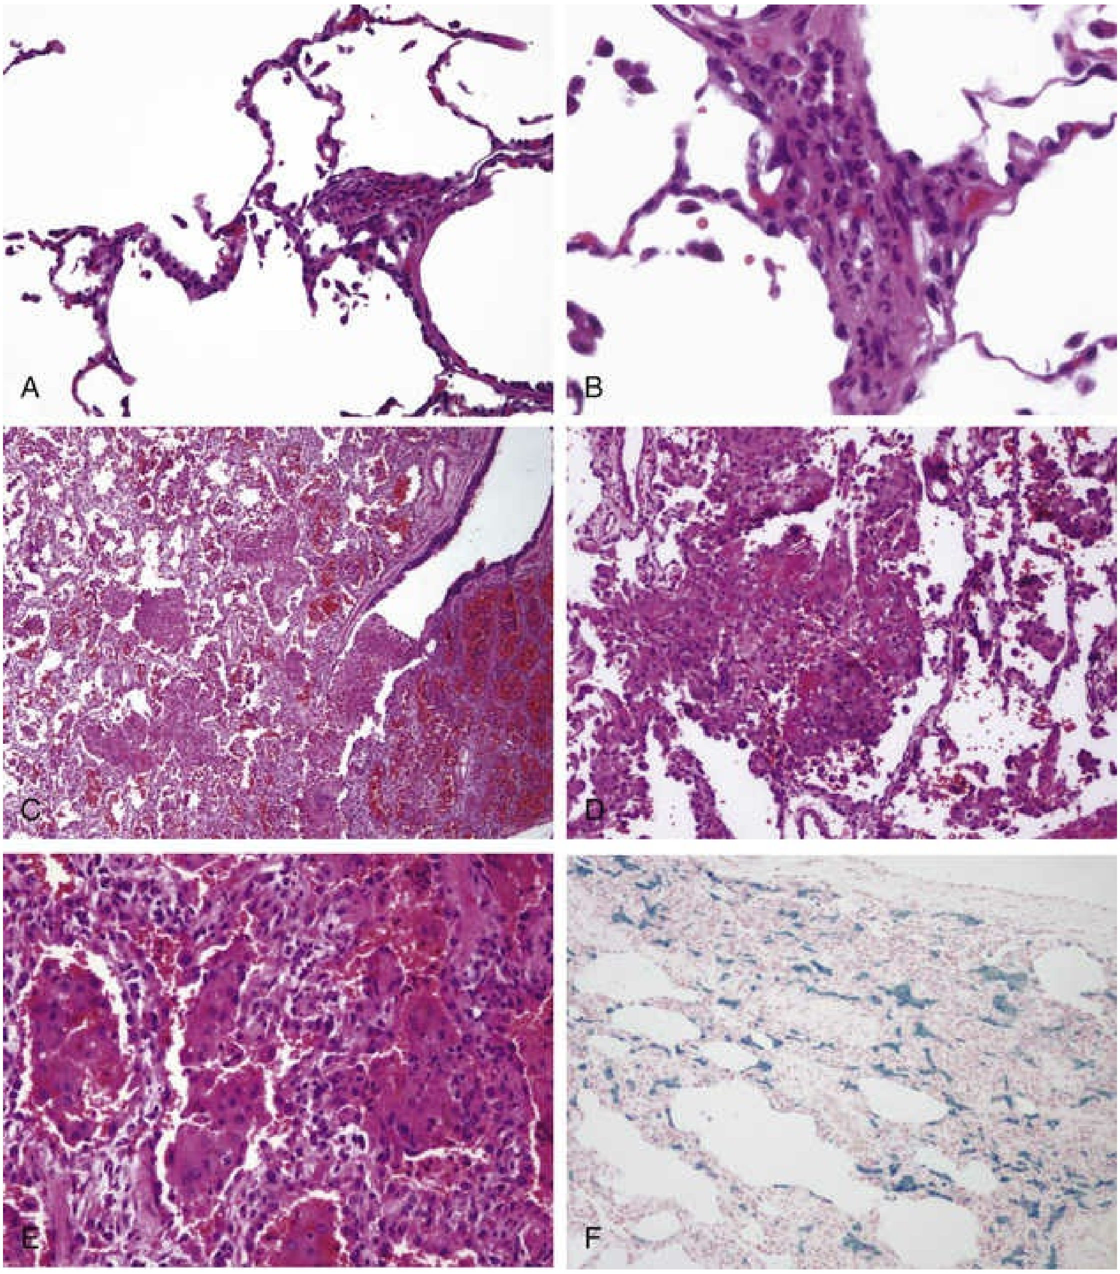

**FIG. 61.5** Small-vessel vasculitis is a feature of a number of immune-mediated vasculitic disorders that involve the lung, although in childhood, it is most often

related to microscopic polyangiitis, and is often associated with glomerulonephritis (pulmonary-renal syndrome). It is characterized by multiple foci of acute inflammation with clusters of neutrophils widening alveolar walls (A) and infiltrating the walls of small blood vessels within alveolar walls (B). There is often extravasation of erythrocytes with a background of diffuse hemorrhage filling airspaces (C), and there may be evidence of alveolar wall necrosis with fibrinous exudates and neutrophils spilling into airspaces (D), alveolar epithelial hyperplasia, focal organization and more diffuse alveolar wall widening (E), and hemosiderin deposition (F, iron stain).

## Treatment of ANCA-Associated Vasculitis

Treatment for ANCA-associated vasculitis in children is broadly similar to the approach used for adult patients based on evidence from a number of clinical trials conducted by the European Vasculitis Study Group.[58] With major concern for the high morbidity and mortality, therapy in ANCA-associated vasculitis is aimed at the preservation of organ function, mainly renal and pulmonary, and maintaining clinical remission.

Induction therapy has traditionally included glucocorticoids and cyclophosphamide. In children, we use both pulse IV methylprednisolone (30 mg/kg, maximum 1 g, for 2–3 days, and then once weekly) and oral prednisone (1–2 mg/kg, daily). Regimens involving oral or IV cyclophosphamide therapy, given over a period of 3–6 months, have demonstrated efficacy in inducing remission, lengthening time to relapse, and reducing adverse events.[59,60] IV pulse cyclophosphamide was shown to be as effective as daily oral cyclophosphamide with a 50% decrease in cumulative cyclophosphamide dose, and therefore fewer adverse effects.[61,62] Despite the efficacy of glucocorticoids and cyclophosphamide in inducing remission, disease relapses occur in as many as 50% of patients, and 20%–53% may develop a relapse within the first 1–2 years following treatment. Disease relapses occur when the drugs are reduced or withdrawn. Given the adverse effects of cyclophosphamide, newer treatment strategies directed at

B cell depletion have been developed. In a recent trial, rituximab was as effective as cyclophosphamide in inducing remission with a similar side-effect profile.[63]

Other important components of induction therapy in children include intravenous immunoglobulin (IVIG) and plasmapheresis. In addition to three open studies demonstrating beneficial effect on ANCA-associated vasculitis, a small randomized, placebo-controlled trial of 34 patients showed a significantly higher rate of remission in the IVIG-treated group compared with placebo (15 vs. 6 remissions, $P = .015$).[64] Plasmapheresis has been shown to decrease morbidity in patients with worse renal disease, as part of the induction therapy.[65,66] No controlled trials are available with respect to alveolar hemorrhage and plasmapheresis; however, a retrospective analysis of 20 patients with alveolar hemorrhage who received plasmapheresis reported resolution of hemorrhage in all patients.[65] We believe that plasmapheresis should be considered in the early management of DAH, particularly in an intensive care unit setting due to granulomatosis with polyangiitis, microscopic polyangiitis, macrophage activation syndrome, antiglomerular basement membrane antibody disease, antiphospholipid antibody syndrome, and SLE.

After patients are disease-free for 6 months, maintenance therapy should be initiated with low-dose prednisone and either methotrexate or azathioprine for at least 1–2 years.[67] To date, the optimal duration of maintenance therapy is unknown. A well-defined and structured clinical assessment with urinalysis and basic laboratory testing should be performed regularly to assess for disease activity and relapse, treatment response, and drug adverse effects.

## Anti-GBM Disease

Similar to granulomatosis with polyangiitis and microscopic polyangiitis, anti-GBM disease presents with alveolar hemorrhage and renal disease. However, in contrast to the other pulmonary-renal syndromes that may have more systemic involvement, anti-GBM disease is almost exclusively limited to the lung and kidneys. Diagnostic imaging and bronchoalveolar lavage will yield findings consistent with nonspecific DAH. However, the classic distinguishing feature includes the detection of anti-GBM antibodies in serum and by immunofluorescence along the basement membrane in lung and renal tissue (Fig. 61.6). Treatment of anti-GBM disease is similar to that of ANCA-associated vasculitis, with corticosteroids used as primary treatment, and cyclophosphamide added in severe cases. One important difference is that plasmapheresis is used in all cases of anti-GBM disease to remove the circulating anti-GBM antibodies, limiting the amount of damage in the lungs and kidneys.[68–70]

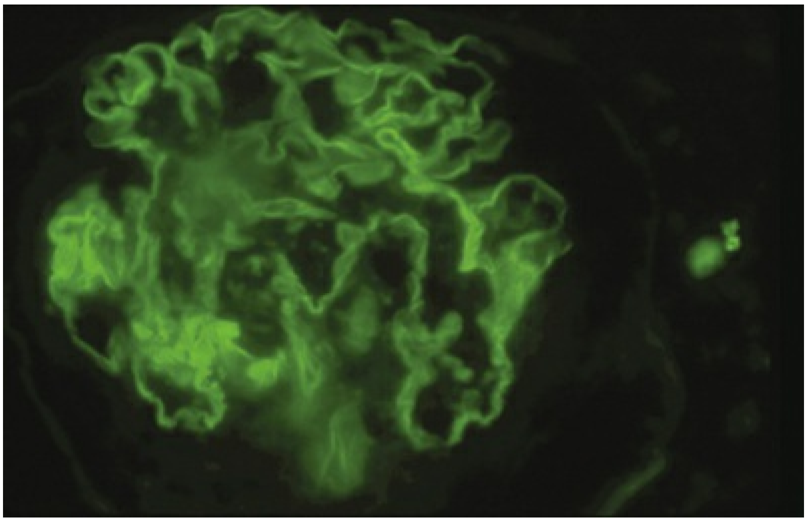

**FIG. 61.6** In antiglomerular basement membrane (anti-GBM) disease, diagnosis depends on the detection of antibodies with specificity for the anti-GBM antibodies, either in lung or kidney biopsy tissue. In this case, the kidney shows immunofluorescent staining of the GBM with anti-GBM antibody.

## Isolated Pulmonary Capillaritis

In children, isolated PC presents with signs and symptoms of alveolar hemorrhage without renal or other systemic manifestations.[57] Patients have diffuse alveolar opacities on diagnostic imaging studies; low hemoglobin; hemosiderin-laden macrophages on bronchoalveolar lavage cytology; and a normal blood urea nitrogen (BUN), creatinine, and urinalysis. ESR and CRP are often quite elevated. Compared with IPH, PC is associated with a lower hemoglobin and higher ESR.[57] The presence of ANCA, usually MPO but occasionally PR3, is often, but not always, found. In the absence of positive ANCA, lung biopsy is required for diagnosis. Because the neutrophilic capillaritis can be patchy and subtle, an experienced pediatric lung pathologist should review the histopathology.

As with other immune-mediated alveolar hemorrhage, isolated PC can have a fulminate presentation, and aggressive therapy with the same protocol as ANCA-associated vasculitis should be instituted early.

## COPA Syndrome

The recent discovery of a genetic cause of familial pulmonary hemorrhage may shed light on the pathophysiology of alveolar hemorrhage. Watkin et al. described five families with autosomal dominant pulmonary hemorrhage syndrome and variable renal disease.[71] Whole exome sequencing revealed mutations in the cotamer-assocated protein alpha (COPA) gene in all affected subjects, leading to the description of this new disease entity now known as COPA syndrome.[72] COPA is part of the coat protein complex I, responsible for retrograde Golgi to endoplasmic reticulum (ER) transport. This process is integral for proper recycling of proteins and lipids necessary for the transport of nascent protein from the ER to the Golgi for further posttranslational processing and trafficking.[73–74] COPA gene mutations lead to increased ER stress and dysfunctional autophagy through unknown mechanisms. The end result is $T_H17$ skewing in $CD4^+$ cells and immune dysregulation, manifest mainly as pulmonary hemorrhage. Patients often present at a young age with alveolar hemorrhage and have a chronic, relapsing, and remitting course. Chest CT may be important in identifying COPA syndrome as many patients have cystic disease on CT scan.[72] Currently, treatment is similar to other PC disease processes; however, given our understanding of the molecular mechanisms underlying this specific disease, there is hope for more targeted therapies in the near future.

## Nonimmune-Mediated Alveolar Hemorrhage

Examples of nonimmune-mediated alveolar hemorrhage include IPH, acute idiopathic pulmonary hemorrhage of infancy (AIPH), Heiner's syndrome, child abuse, and primary cardiovascular disease. Much controversy remains as to whether Heiner's syndrome, alveolar hemorrhage caused by milk allergy, actually exists.[75–77] A diverse group of cardiovascular disorders, including mitral stenosis, veno-occlusive disease, pulmonary capillary hemangiomatosis, and pulmonary telangiectasia, can result in a congestive vasculopathy with resultant hemosiderin-laden macrophages in airspaces (Fig. 61.7). In a recent report of 30 cases of veno-occlusive disease and five cases of pulmonary hemangiomatosis, Lantuejoul and colleagues[78] found histologic evidence of pulmonary hemosiderosis in 80%. Pulmonary hypertension and pulmonary embolism can both cause hemorrhage with resultant hemosiderin-laden macrophages and should be in the differential diagnosis of pulmonary hemosiderosis.

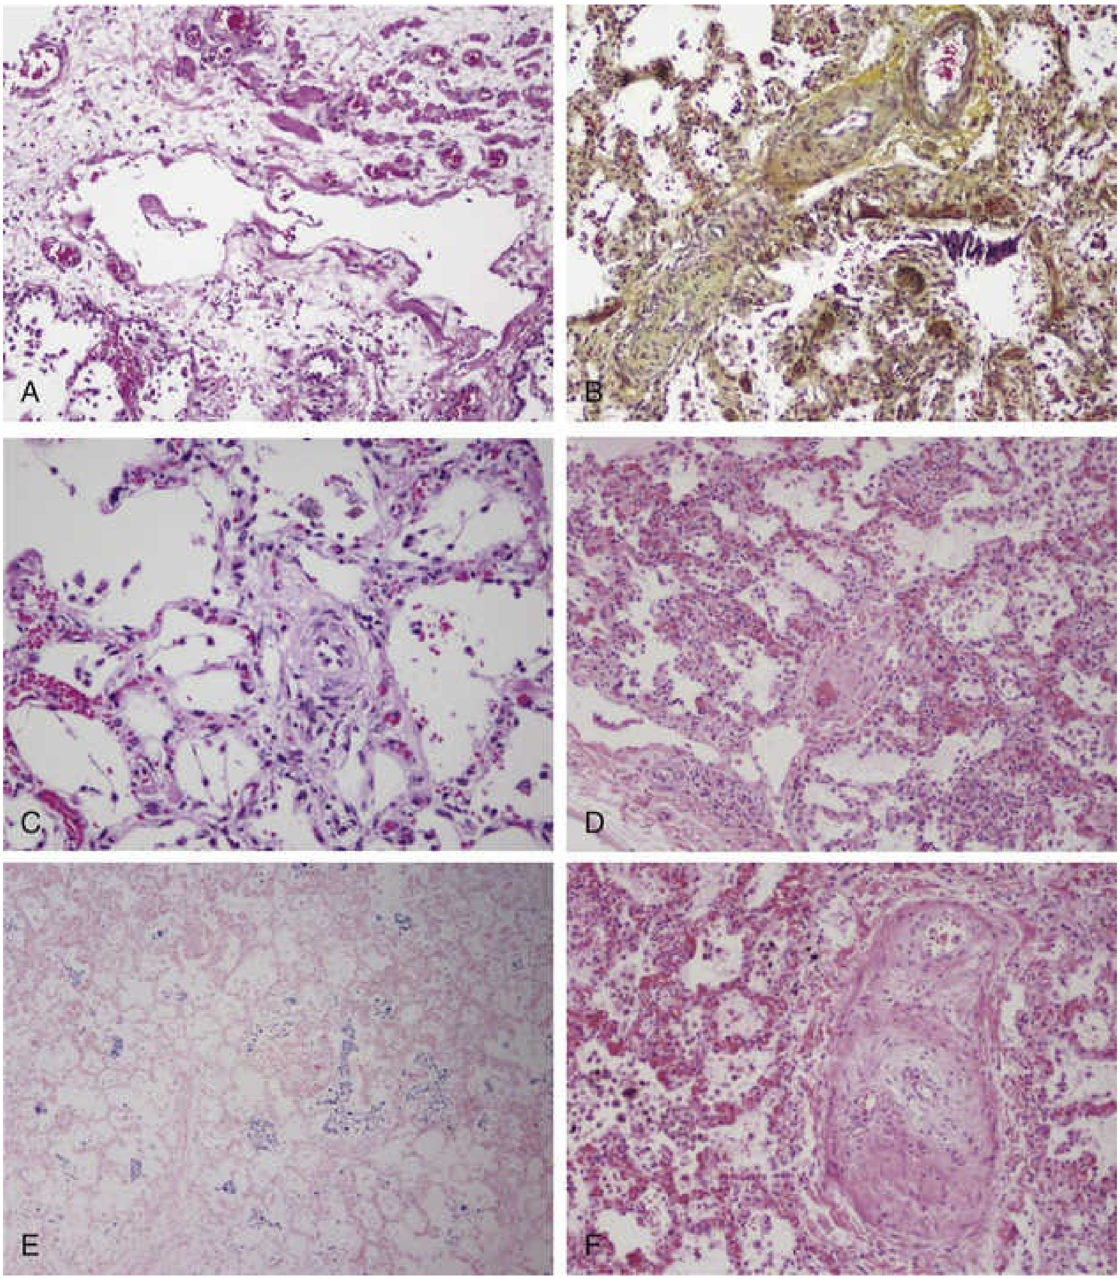

**FIG. 61.7** Congestive vasculopathy is a feature of a number of conditions in which there is long-standing elevation of pulmonary venous pressure from a variety of etiologies, including elevated left atrial pressure and pulmonary venous obstruction, which includes pulmonary veno-occlusive disease. Pathologically congestive vasculopathy shows vascular remodeling affecting pulmonary veins with medial hypertrophy, arterialization, and perivenous fibrosis; lymphatics with dilatation and often lymphatic smooth muscle hyperplasia (A); arteries with mild medial hypertrophy and often eccentric intimal fibrosis (B, Movat pentachrome stain); and arterioles with more

prominent muscularization (C). There are also parenchymal changes with edema, alveolar wall widening (D), and hemosiderin deposition (E, iron stain). In pulmonary veno-occlusive disease there is also venous intimal fibrosis that may be occlusive (F), and there may be arterial thrombosis and focally prominent alveolar capillary dilatation and congestion resembling foci of pulmonary capillary hemangiomatosis.

## Idiopathic Pulmonary Hemosiderosis

Previously considered the most common form of DAH, IPH is now a diagnosis of exclusion. Although IPH was reported to have a high mortality in the older literature, more recent studies have suggested a better prognosis.[79–81]

As in any alveolar hemorrhage syndrome, the clinical presentation of IPH is nonspecific with symptoms of malaise, cough, dyspnea, and tachypnea. Hemoptysis may not be present, especially in young children, who swallow their sputum. On physical examination, pallor, crackles, and clubbing, especially in long-standing disease, are present. Previously, the findings of iron-deficiency anemia; diffuse alveolar infiltrates on imaging studies; and hemosiderin-laden macrophages in sputum, gastric aspirate, or bronchoalveolar lavage were considered sufficient for diagnosis, especially when there was no evidence of systemic disease and negative autoimmune serology. Lung biopsy was not deemed necessary in such cases.[3,82]

Recent articles have shown a much higher rate of capillaritis than IPH in children, and many of the patients with capillaritis have negative serology for autoantibodies.[57] Therefore, we recommend that patients with DAH without a cardiovascular cause and negative serology undergo a lung biopsy. In IPH, the biopsy characteristically shows evidence of bland alveolar hemorrhage with multiple hemosiderin-laden macrophages in the airspaces, in the absence of significant inflammation or any evidence of capillaritis or vasculitis (Fig. 61.8). However, we emphasize that the pathologic features of capillaritis can be quite subtle and, on further review, cases with an initial diagnosis of IPH have shown features of PC.

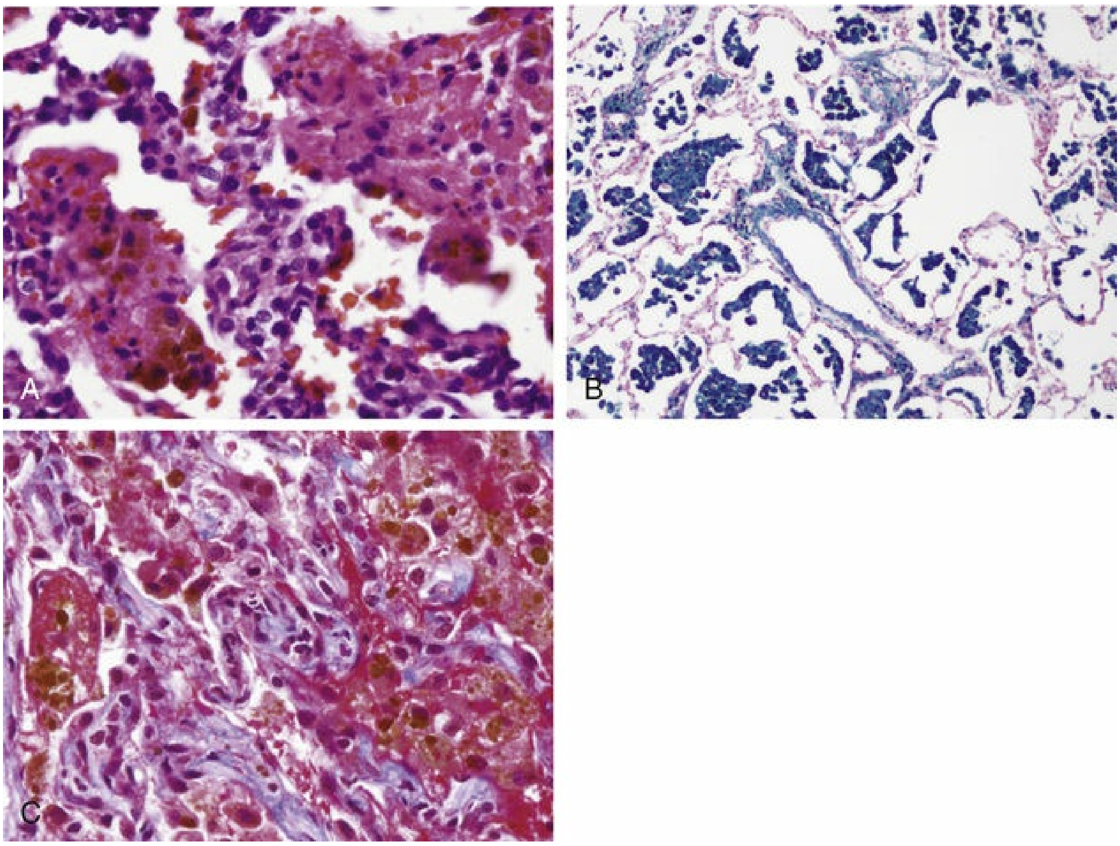

**FIG. 61.8** In idiopathic pulmonary hemosiderosis, diffuse alveolar hemorrhage (A) and hemosiderin-laden macrophages (B, iron stain) are present. Although there is mild alveolar wall fibrosis (C, Movat pentachrome stain) and mild alveolar epithelial hyperplasia, there is no alveolar wall or vascular inflammation.

It is important to distinguish between IPH and PC because the treatments are different. In general, PC is much more difficult to treat and requires cytotoxic therapy to induce remission and prevent recurrence. In contrast, many cases of IPH can be successfully treated with corticosteroids alone, with hydroxychloroquine or azathioprine used as steroid-sparing agents when additional therapy is required. However, severe cases may warrant therapy similar to that used for life-threatening immune-mediated DAH and even extracorporeal membrane oxygenation support.[83] In a recent series, 6-mercaptopurine was used successfully as long-term maintenance therapy.[84]

# Approach to the Child With Pulmonary Hemorrhage

## Diagnosis

A systematic approach to the child with suspected pulmonary hemorrhage is required to determine the specific etiology and institute timely and appropriate therapy. In patients with unexplained hemoptysis, the diagnostic studies to consider include chest CT with contrast to investigate for pulmonary embolism and arteriovenous malformations; tests for coagulation defects; and bronchoscopy to detect foreign bodies, airway hemangiomata, or tumors. Children with hemoptysis and bronchiectasis related to cystic fibrosis or other disorders rarely need additional diagnostic evaluation, but they may require intervention with bronchial artery embolization if hemoptysis is severe. In those with possible infectious pneumonia, blood and sputum cultures and a tuberculosis purified protein derivative should be considered, with bronchoscopy and bronchoalveolar lavage reserved for patients who do not respond to conventional therapy.

In any child with diffuse alveolar opacities, cardiovascular causes should be excluded by echocardiogram, CT with contrast, magnetic resonance imaging, or cardiac catheterization as appropriate. In patients with suspected or documented DAH and renal involvement, rash, joint disease, and other systemic manifestations, an immune-mediated vasculitis should be considered, and a pediatric rheumatologist should be consulted. Appropriate diagnostic studies include an antinuclear antibody (ANA) profile, ANCA, CBC, ESR, CRP, urinalysis, metabolic panel, d-dimers, von Willebrand's factor, antiphospholipid antibody, lupus anticoagulant, and other tests as indicated. The cytologic identification of hemosiderin-laden macrophages in sputum, gastric aspirate, or bronchoalveolar lavage may confirm alveolar hemorrhage, but it is not specific as to the cause. Table 61.1 summarizes the distinguishing features of the alveolar hemorrhage syndromes.

## Table 61.1

### Clinical Manifestations of Diffuse Alveolar Hemorrhage Syndromes

| | GPA | MPA | Anti-GBM | PC | SLE | IPH | COPA Syndrome |
|---|---|---|---|---|---|---|---|
| Alveolar hemorrhage | ++ | ++++ | ++++ | ++++ | + | ++++ | ++ |
| Glomerulonephritis | ++++ | ++++ | ++++ | − | ++++ | − | − |
| Elevated ESR/CRP | ++++ | ++++ | + | ++++ | ++++ | + | + |
| Serologies | PR3 | MPO | GBM | PR3, MPO | ANA | − | ANCA, ANA, RF |
| Extrarenal findings | +++ | +++ | − | − | ++++ | − | ++++ |

*ANA,* Antinuclear antibody; *ANCA,* antineutrophil cytoplasmic antibody; *anti-GBM,* anti-GBM disease; *COPA,* cotamer-assocated protein alpha; *CRP,* C-reactive protein; *ESR,* erythrocyte sedimentation rate; *GBM,* glomerular basement; *GPA,* granulomatosis with polyangiitis; *IPH,* idiopathic pulmonary hemorrhage; *MPA,* microscopic polyangiitis; *MPO,* myeloperoxidase; *PC,* isolated pulmonary capillaritis; *PR3,* proteinase 3; *RF,* rheumatoid factor; *SLE,* systemic lupus erythematosus.

In patients with DAH who have no cardiac, renal, or other systemic disease and negative ANA, ANCA, and anti-GBM antibodies, we strongly recommend that a transthoracic biopsy be done either through a mini-thoracostomy (“open”) or with video-assisted thoracoscopic surgery (VATS). Lung tissue should be processed according to the guidelines set forth by the Children's Interstitial Lung Pathology Cooperative Group.[85] As discussed, histopathology of PC shows intraalveolar and interstitial red blood cells; pauci-immune hemorrhagic, necrotizing alveolar capillaritis with neutrophilic infiltration resulting in fibrinoid necrosis and dissolution of the arteriolar and venular walls; and intraalveolar hemosiderosis. The presence of granulomatous inflammation is consistent with a diagnosis of granulomatosis with polyangiitis. Anti-GBM antibodies along the capillary basement membranes in the lung demonstrated by immunofluorescence are diagnostic of anti-GBM disease. If bland alveolar hemorrhage with hemosiderin-laden macrophages is found, and capillaritis is excluded, a diagnosis of IPH can be made. It is highly recommended that the biopsy be performed before treatment is initiated as treatment may obscure the histologic picture.

## Treatment

Treatment of pulmonary hemorrhage is based on the presentation and cause. In cases of massive hemoptysis, intubation and mechanical ventilation with high positive end-expiratory pressures may be necessary. If massive hemorrhage is unilateral, the use of a double-lumen endotracheal tube allowing for airway occlusion of the affected side and ventilation of the unaffected side should be considered. Bronchial artery embolization is the treatment of choice to control bleeding. Underlying etiologies, such as coagulopathy, cystic fibrosis exacerbations, pneumonia, arteriovenous malformations, or foreign bodies, should be treated appropriately.

For patients with immune-mediated alveolar hemorrhage and life-threatening presentation, in addition to airway and ventilatory support, aggressive pharmacologic treatment with pulse and oral corticosteroids, cyclophosphamide, plasmapheresis, and IVIG should be given, as discussed previously. Those with less severe presentations may require corticosteroids and cyclophosphamide or another steroid-sparing agent. Following successful induction, treatment with low-dose prednisone and either methotrexate or azathioprine is appropriate. For most patients with IPH, corticosteroids and hydroxychloroquine or another steroid-sparing agent will control DAH.

## Summary

Because of the unique blood supply to the lungs, pulmonary hemorrhage can arise from either the bronchial or pulmonary circulation. Diagnostic considerations and management are different for each system. In patients with DAH, disorders associated with PC must be ruled out before a diagnosis of IPH can be entertained. This requires lung biopsy when serologic markers of immune-mediated disease are negative. Aggressive intervention is required for life-threatening DAH because morbidity and mortality are high.

# The Lung in Sickle Cell Disease

*Anne Greenough MD (Cantab), MB BS, DCH, FRCP, FRCPCH, Jennifer Knight-Madden MBBS, PhD*

## Epidemiology

Sickle cell disease (SCD) is the most common inherited disorder affecting African and Caribbean populations. There are more than 200 million carriers of the sickle cell trait, and approximately 250,000 children are born each year with SCD. The sickle cell mutation arose on at least four separate occasions in Africa and as a fifth independent mutation in Saudi Arabia or central India. SCD occurs most commonly in tropical Africa where it affects approximately 1% of all infants, and the sickle cell trait is found in approximately 8% of African Americans and also occurs in the Middle East, Greece, and India. There is a high prevalence of the HbS gene in areas where malaria is common, suggesting that sickle cell trait gives an advantage against severe malaria syndromes. Indeed, although children with sickle cell trait are infected by *Plasmodium falciparum,* the parasite count is low.[1] Individuals with SCD suffer increased respiratory related mortality and morbidity, as discussed in this chapter.

## Etiology

Homozygous inheritance of the gene for HbS results in sickle cell anemia (HbSS), the most severe form of SCD. Other clinically important forms of SCD include sickle hemoglobin C disease (HbSC), sickle $\beta^0$, and $\beta^+$-thalassemia (HbSβthal). The sickle gene results in the substitution of valine for glutamic acid at the sixth position of the amino acid sequence in the beta-globin chain, forming HbS. HbC is produced when the glutamic acid is substituted by lysine at the same position. The β thalassemias have normal structured, but inadequate quantities of hemoglobin A. Coinheritance of various polymorphisms associated with these pathways may explain some of the variation in clinical presentation that occurs in those with identical sickle cell genotypes.

When deoxygenated, partially or fully, HbS undergoes conformational changes, a hydrophobic region surrounding the valine site in the β subunit is left exposed. Polymerization with other hemoglobin tetramers then occurs resulting in the formation of aggregates (crystals) that distort the red blood cell membrane. Neither fully oxygenated HbS nor fetal hemoglobin (HbF) polymerizes. When a “sickle” cell is exposed to a relatively hypoxic/acidic environment, the $K^+Cl^-$ cotransport is activated with loss of potassium from the cell. Deoxygenation also increases intracellular free calcium, and calcium dependent dehydration occurs. HbS molecules form a viscous solution within the erythrocyte. The changes in the membrane stiffen the red blood cell and change it from a biconcave to a sickle shaped cell that is less deformable and subject to hemolysis. In addition, the rigid cells can obstruct small blood vessels, and over time, cells that have sickled repeatedly become irreversibly sickled. Deoxygenation is maximal in the venous circulation, and the sickled cells may cause extensive and progressive damage to the pulmonary vascular bed. The sickle cells occlude vessels especially to organs with sluggish circulation, such as atelectatic areas of the lung.

# Pathogenesis

The systemic effects of ongoing hemolysis, the altered adhesion of cellular elements in blood to each other and the endothelium and the elevated activity of inflammatory pathways all interact to cause the morbidity of SCD involving all organ systems, but particularly the lungs.

Intact sickle erythrocytes are deficient in antioxidants (superoxide dismutase, catalase, and glutathione peroxidase) and are excessive producers of oxidant species. This may reflect the greater autooxidation of HbS compared to HbA red blood cells, which means that superoxide and hydrogen peroxide are removed less efficiently. Intravascular hemolysis in SCD produces high levels of cell free Hb and extracellular heme, which is a potent proinflammatory agent and oxidant and now classified as a damage-associated molecular pattern molecule (DAMP).[2] Heme and other oxidant species promote the release from activated neutrophils of neutrophil extracellular traps (NET) that are decondensed chromatin decorated by granular enzymes.[3] NET plasma levels increase during painful crises and are particularly elevated during ACS episodes.[4] The scavenging capacity of plasma proteins, particularly haptoglobin and hemopexin, is overwhelmed, leaving them depleted. Hypoxia inhibits nitric oxide (NO) production by decreasing protein levels of constitutive NO synthase in the endothelium, and there is inactivation of NO by free radical species liberated from activated macrophages and leucocytes. Furthermore, extracellular heme scavenges NO resulting in increased cellular adhesion and diminished vasodilation, as NO inhibits endothelin vascular cell adhesion molecule (VCAM-1) upregulation and inhibits endothelin-1 production. The products of hemolysis have been linked to acute lung injury in a murine model of SCD.[5] Toll-like receptor 4 (TLR4) was critical to that model, as TLR4-null mice remained asymptomatic when challenged with hemin, and the TLR4 antagonist TAK-242 was protective in exposed mice.

Enhanced adhesion of sickle erythrocytes to each other and the endothelium is an important part of the pathophysiology of SCD. In addition, neutrophils may adhere both to the endothelium and to the sickled erythrocyte. In murine SCD models, circulating erythrocytes were shown to attach to adherent neutrophils in the postcapillary venules initiating a vaso-occlusive crisis (VOC). Other leukocytes, including monocytes and T-lymphocytes, are involved in this adhesion cascade[6]; and the monocytes are activated by the nuclear factor κB (NF-κB) pathway.[7] Platelet activation, as indicated by circulating platelet-monocyte and platelet-neutrophil aggregates, occurs in VOC, and human platelet alloantigens (HPA) 3 polymorphisms are related to VOC risk.[8]

Monocytes from patients with SCD have elevated tumor necrosis factor-alpha (TNF-$\alpha$) and interleukin (IL)-1β production.[7] Invariant natural killer T cells (iNKT) cells rapidly produce high levels of cytokines after stimulation by specific antigens,[9] and NF-κB activation in $CD4^+$ iNKT cells may be integral to reperfusion injury after VOC.[10] Platelet activation is elevated at steady state in SCD and further enhanced during VOC. In addition, at least in part through NETs, it may be implicated in the development of pulmonary hypertension (PH) in SCD.[11] Mast cell activation, resulting in the release of bioactive substances such as substance P, has been implicated in the pathophysiology of murine models of SCD[12] and has been found in a proportion of patients who had frequent VOC. Other inflammatory mediators are elevated at SCD steady state or during acute episodes including chemokines, moieties within the coagulation cascade,[13] and high-mobility group box 1 (HMGB1), a chromatin-binding protein that maintains DNA structure.[14] Leukotrienes produced by the 5-lipoxygenase pathway are arachidonic acid derived mediators of inflammation, and leukotriene $B_4$ (LTB4) promotes neutrophil activation and chemotaxis. $LTB_4$ has been shown to be elevated during steady state and VOC.[15]

## Clinical Features

SCD is a hemolytic anemia. Newborns, however, are asymptomatic, as they have a high level of HbF in their erythrocytes, but as the levels of HbF decline, the manifestations of SCD become apparent, this may be as early as 10–12 weeks of age. SCD patients have periods of relative stability punctuated with acute episodes such as painful crises or VOCs. They may suffer severe pain, have cerebrovascular accidents, acute splenic sequestration, and acute chest syndrome (ACS). The ongoing inflammatory process leads to chronic end-organ injury.

## Acute Chest Syndrome

The overall incidence of ACS is 10.5 per 100 patient years.[16] ACS episodes occur more commonly in children than adults, and 50% of SCD children will have an ACS episode prior to the age of 10 years.[17] The highest incidence of ACS occurs in children aged between 2 and 4 years of age, and recurrence is common. In addition, the majority of very young children who had an ACS episode were rehospitalized for ACS or severe pain within 1 year.[18] Furthermore, recurrent ACS is the most important risk factor for the development of sickle cell chronic lung disease (SCLD) and increases morbidity.[19]

### Risk Factors

There are a number of genetic risk factors for ACS,[17] and the incidence of ACS is most common in those with HbSS and less in those with HbSC. Similarly, the hemoglobin genotype influences the severity of ACS, being more severe in those with HbSS that in those with HbSC.[20] The ACS incidence also varies according to the beta–globin gene cluster haplotype, as indicated by the prevalence and recurrence of ACS episodes being lower in Saudi Arabia than in Africa. This may reflect an interaction between SCD and the "Asian" haplotype,[21] which is associated with a higher HbF level. The risk for ACS is also increased by certain endothelin NO synthase gene polymorphisms.[22] Genetic polymorphisms of heme oxygenase-1(HO-1), an essential enzyme in heme catabolism, have been associated with ACS risk, and a polymorphism enhancing its expression was associated with lower ACS rates.[23] ACS has been associated with rs6141803, a single nucleotide polymorphism (SNP) located 8.2 kilobases upstream of COMMD7, a gene highly expressed in the lung that interacts with NF-κB signaling.[24]

Steady-state hematological profiles impact ACS risk, and the incidence of ACS is inversely proportional to the HbF level[25] and directly proportional to the steady state white blood count. High HbF levels inhibit HbS polymerization, which protects against ACS. An elevated leucocyte count increases the risk as leukocytes release free radicals, elastase, proinflammatory mediators, and cytokines. Children presenting with fever have an increased risk of developing an ACS episode if they have an absolute neutrophil count greater than 9 × $10^9$/L, a hemoglobin level less than 8.6 g/dL, had a previous ACS episode, upper respiratory tract infection symptoms, or noncompliance to penicillin.[26]

Infection is implicated in at least 30% of ACS episodes. In a multicenter study, although 27 different pathogens were identified, *Chlamydia pneumoniae* was the most frequent pathogen, followed by *Mycoplasma pneumoniae* and respiratory syncytial virus. Parvovirus B10 has been associated with marrow necrosis and a particularly severe form of ACS. The causative pathogen in any one area, however, reflects which pathogen is most common locally; and the seasonal variation in ACS episodes in young children reflects the increase in viral infections during the winter months.

In approximately 10% of patients, an ACS is precipitated by a pulmonary fat embolism. Infarction of the bone marrow with embolization of the fatty bone marrow to the lungs results in activation of pulmonary secretory phospholipase A2 (SPLA2). SPLA2 cleaves phospholipids and liberates free fatty acids, which cause acute pulmonary toxicity. Arachidonic acid results in vasoconstriction and oleic acid increases the upregulation of VCAM-1. Infarction of the bony thorax or pain following abdominal surgery may cause splinting, hypoventilation, and atelectasis, leading to hypoxia and intrapulmonary sickling. In addition, opioids prescribed for the pain may suppress respiratory drive compounding the hypoventilation.

Asthma has been reported to be more common in those with ACS and specifically in those who have had recurrent ACS episodes.[27] In the cooperative study for SCD in which children were recruited before 6 months of age and followed beyond 5 years of age, asthma was associated with more frequent ACS episodes.[28] Asthma may, however, have been overdiagnosed in previous studies that used a physician's diagnosis rather than more objective tests such as determination of bronchial responsiveness. It is now apparent that wheezing, without a diagnosis of asthma, is associated with an increase in SCD complications. In a retrospective study, asthma and wheezing were independent risk factors for increased painful episodes, but only wheezing was associated with more ACS episodes.[29] In an observational cohort study, adults who reported recurrent, severe episodes of wheezing, regardless of a diagnosis of asthma, had twice the rates of ACS, decreased lung function, and increased risk of death compared with adults without recurrent wheezing.[30] Furthermore, in a cohort of 159 children followed from birth to a median of 14.7 years, an ACS episode prior to 4 years, female gender, wheezing with shortness of breath, and two or more positive skin prick tests were associated with future ACS episodes, but airways obstruction and a bronchodilator response were not.[31]

## Clinical Features

ACS episodes are characterized by chest pain, productive cough, and dyspnea; affected individuals are febrile and tachypneic and on auscultation there are crackles and wheezes.[31a] Fever and cough are more common in very young children, whereas chest pain, shortness of breath, and hemoptysis are more prominent with advancing age. Essential to the diagnosis of an ACS is a new pulmonary infiltrate on the chest radiograph (Fig. 62.1), and the lower and middle lobes are more frequently affected than the upper lobes.[31a] Ten to 15% of patients develop severe respiratory failure, necessitating mechanical ventilation and may progress to multiorgan system failure.

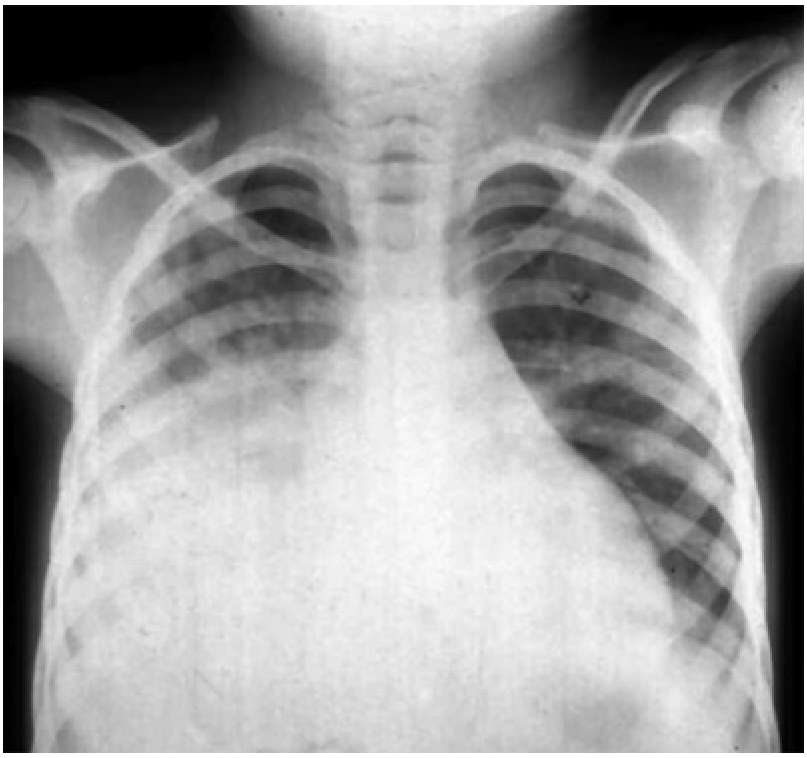

**FIG. 62.1** Chest radiograph demonstrating an acute chest syndrome episode, as there is a new pulmonary infiltrate consistent with alveolar consolidation including at least one complete lung segment.

If the ACS is precipitated by a fat embolism, the pulmonary signs and symptoms are preceded by bone pain. Affected patients have lower mean oxygen saturation at presentation and have a more severe clinical course.[25] There may be systemic signs of a fat embolism, including changes in their mental state, thrombocytopenia, and petechiae. In addition, they have significant decreases in the hemoglobin and platelet counts and lipid-laden macrophages are found in fluid obtained by bronchoalveolar lavage.

## Sickle Chronic Lung Disease

SCLD is a progressive disease with hypoxemia, restrictive lung disease, cor pulmonale, and evidence of diffuse interstitial fibrosis on chest radiography. Recurrent ACS episodes result in damage to the lung parenchyma resulting in restrictive lung disease.

## Pulmonary Hypertension

PH in SCD is characterized by progressive obliteration of the pulmonary vasculature. Possible causes include chronic hypoxic stress causing irreversible remodeling of the pulmonary vasculature, recurrent pulmonary thromboembolism, sickle cell related vasculopathy, and pulmonary scarring from recurrent ACS episodes. Sudden death in SCLD patients with PH is common due to pulmonary thromboembolism and cardiac arrhythmia. Adult SCD patients therefore should be screened for PH with echocardiography as, although initially the patients may be asymptomatic, their condition progresses and they suffer worsening hypoxia and chest pain with impaired exercise tolerance.

## Sleep-Disordered Breathing

Children with SCD may be at an elevated risk of sleep-disordered breathing (SDB) including chronic (>6 months) insomnia, restless leg syndrome, habitual snoring, daytime sleepiness evidenced by needing naps, waking up not feeling refreshed, short-term insomnia, and sleep onset latency.[32] The prevalence of obstructive sleep apnea syndrome (OSAS) in children and adolescents with SCD varies from 10.6%[33] to 94% in SCD children who had not undergone adenotonsillectomy.[34] In children investigated for OSAS, although similar sleep architecture was noted, children with SCD had lower median and minimal oxygen saturations than those without SCD. Indeed, children with SCD and OSAS, compared to children with uncomplicated OSAS, had a fourfold risk of a nocturnal oxygen saturation level below 85%.[35]

Risk factors for sleep-related disorders include acute pain and chronic pain syndromes. Functional asplenia leading to compensatory adenotonsillar hypertrophy in younger children and extramedullary hematopoiesis causing alterations in facial bone structure in older children may result in OSAS. An association has been reported between enuresis and SDB in children with SCD.[36] SDB, particularly with nighttime desaturation, has been demonstrated to be associated with increased SCD complications including executive dysfunction,[37] priapism in adults,[38] and possibly painful crisis.[39,40]

## Lung Function Abnormalities

Obstructive lung abnormalities were reported, in a cross-sectional study, in young children with restrictive abnormalities becoming more prominent with advancing age.[41] Those results have also been demonstrated in two longitudinal studies[42,43] but not in a third.[44] In a cohort of 45 children aged between 5 and 18 measured at baseline and approximately 4 years later, a predominately obstructive pattern was reported with increased prevalence over time. The occurrence of restrictive abnormalities also increased, but to a lesser extent.[44] In contrast, retrospective analysis of data from 413 SCD children aged between 8 and 18 years demonstrated that the prevalence of restrictive abnormalities increased with increasing age.[42] In two cohorts of SCD children, one of which was followed for 2 years and the other for 10 years, lung function deteriorated in the SCD children compared to contemporaneously studied ethnic and age matched controls.[43] In the cohort followed for 10 years, restrictive abnormalities became more common. The rate of deterioration in lung function was greater in the younger children in whom ACS episodes were more common.[43]

At all ages, obstructive, restrictive, and mixed lung function abnormalities have been documented, as well as normal lung function.[44,44a] Airways hyperresponsiveness (AHR) to methacholine has been reported to be more common in SCD children, but AHR to methacholine has not been related to signs or symptoms of allergy.[45] Overall, the responses to bronchial challenges such as cold air, exercise, or methacholine have been variable, ranging from a positive response rate of 0%[45] to 78%.[46]

### Etiology of the Lung Function Abnormalities

The obstructive lung function abnormalities seen in SCD children could be due to asthma. Exhaled NO is elevated in asthma, as there is enhanced expression of inducible NO synthase in inflamed airways. Yet, in a prospective study, the exhaled NO levels were similar in 50 SCD children and 50 controls and airway obstruction in SCD children was not associated with increased methacholine sensitivity or eosinophilic inflammation.[47] An alternative explanation for the airways obstruction in SCD is the hyperdynamic pulmonary circulation due to a raised cardiac output secondary to chronic anemia.[48] SCD children have an increased pulmonary capillary blood volume resulting from their chronic anemia, which has been shown to correlate with the degree of airways obstruction.[49] In a study of 18 SCD children compared to 18 ethnic and age-matched controls, the SCD children had a significantly higher respiratory system resistance, alveolar NO production, and pulmonary blood flow, but not airway NO flux. In addition, there was a significant correlation between the alveolar NO production and pulmonary blood flow, but not between airway NO flux and respiratory system resistance.[50] Furthermore, transfusion in SCD children acutely increased airways obstruction and this was significantly related to an increase in pulmonary capillary blood volume.[51] Those results suggest that the airway obstruction seen, at least in some SCD children, relates to their increased pulmonary capillary blood volume. The clinical implication of those results is that whether a child with SCD and airways obstruction would benefit from bronchodilators should be assessed by comparing lung function assessment results pre and post bronchodilator.

### Exercise Capacity

There have been few studies investigating the cardio-respiratory responses to exercise in children with SCD. They have been reported to have more adipose tissue with reduced fitness and exercise performance. Exercise capacity has been reported to be related to the baseline degree of anemia and significantly lower in subjects with a history of recurrent ACS.[52] The metabolic changes imposed by exercise may initiate sickling and vaso-occlusive episodes. Therefore exercise should be started slowly and increased progressively, hydration should be maintained, and sudden changes in temperature should be avoided.[52]

## Diagnosis

The sickle test, used in some settings as a screen, includes the HbS solubility test and sodium metabisulfite test.[53] Chemically induced sickling identifies those who have sickle cell trait or SCD but does not distinguish between the two. This test is unreliable in the first 6 months of life due to the predominance of HbF in infants. Other tests separate hemoglobins based on their chemical attributes and include the isoelectric point (isoelectric focusing [IEF]), ionic interaction with absorbent material in a column (high-performance liquid chromatography [HPLC]), and differential movement during electrophoresis in an alkaline environment (cellulose acetate membrane and capillary zone electrophoresis) or acid environment (citrate agar). Molecular methods may also be employed to identify causative genetic mutations. In most settings, two methods are used to ensure accurate diagnosis.

Primary prevention of affected infants is possible by screening adults of childbearing age and providing appropriate genetic counseling, and affected infants can be identified by prenatal testing or neonatal screening. Individuals may also be identified later in life when screened because of suggestive illnesses or the diagnosis of family members.

# Management

## Acute Chest Syndrome

Broad-spectrum antibiotics should be given, including macrolides or quinolones to treat atypical organisms. The choice of antibiotics should be guided by the patient's clinical condition and the “local” pathogens. Oxygen therapy should be used to treat any hypoxemia, but there may be a poor correlation of pulse oximetry readings with arterial oxygen tensions; hence, in those with suspected hypoxia, blood gas analysis should be undertaken. Patients should be hydrated but limited to 1.5 times the maintenance fluid rate to avoid further impairment of lung function by aggravating vascular leak in the lungs (Table 62.1). Packed red blood cell or exchange transfusion decreases the fraction of sickle hemoglobin and improves the oxygen carrying capacity of the blood. In patients with severe anemia, a “simple” transfusion is used, but if the patient has a relatively high hematocrit, then exchange transfusion should be undertaken to avoid increasing blood viscosity. Predictors of severity include increasing hypoxia, increasing respiratory rate, reduced platelet count, and multilobar disease.[54] Indications for escalation of respiratory support include those with extensive pulmonary involvement, as indicated by increasing hypoxia, dyspnea, and a pH falling below 7.25. In such patients, noninvasive ventilation has been demonstrated to improve oxygenation, but this may be poorly tolerated.[55]

### Table 62.1

**Management of Acute Chest Syndrome**

| Treatment | Comment |
|---|---|
| Supplemental oxygen | Maintain oxygen saturation >95% |
| Antimicrobials | Broad spectrum including a macrolide to cover atypical bacteria<br>Antivirals should be considered where appropriate |
| Blood transfusion | Exchange transfusion when the pretransfusion hemoglobin (Hb) level is close to steady state Hb or where there is rapid progression of the illness<br>Simple transfusion when the Hb has fallen |
| Fluids | Should be titrated replacing insensible losses but to avoid overload |
| Bronchodilators | In those with evidence of bronchial hyperresponsiveness |
| Incentive spirometry | Instituted in those with chest pain to prevent atelectasis |
| Analgesia | Sufficient to prevent splinting |

Analgesia should be given to control pain, but the amount limited to avoid respiratory depression. Patient controlled analgesia devices may reduce the risk of narcotic induced hypoventilation. An intercostal nerve block with a long acting local anesthetic can alleviate chest wall pain from rib infarcts and reduce the amount of systemic analgesia, and approximately 25% of patients wheeze during an ACS episode and may benefit from bronchodilator administration. In a small randomized controlled trial (RCT), dexamethasone administered to children with mild to moderately severe ACS was associated with a 40% reduction in the length of hospitalization, a shorter duration of supplementary oxygen requirement, and less need for analgesia. Readmission after an ACS episode, however, was more common in those who reported use of an inhaler or nebulizer at home or had received corticosteroids for the ACS episode.

Inhaled NO (20–80 ppm) in patients with ACS and PH has been reported to result in rapid pulmonary vasodilation. A large prospective trial, however, failed to show any significant differences in the time to resolution of crisis, length of hospitalization, pain scores, cumulative opioid usage, or ACS rate between those who received NO and placebo.[56]

## Pulmonary Hypertension

Management of adults with PH consists of anticoagulation for those with thromboembolism, supplementary oxygen for those with low oxygen saturations, treatment of left heart failure, and hydroxyurea or transfusions.[57] The recent guidelines from the American Thoracic Society make only a weak recommendation for either a prostacyclin agonist or an endothelin receptor antagonist but a strong recommendation against phosphodiesterase-5 inhibitor therapy for those with right heart catheterisation-confirmed PH with elevated pulmonary vascular resistance and normal pulmonary capillary wedge pressure.[58]

## Monitoring

It is important that children with wheeze are not assumed to have asthma as wheeze in SCD may have other causes. It is therefore important that they undergo assessment for bronchial hyperreactivity according to their lung function, and those with airway function less than 70% of predicted should receive a bronchodilator and those with better airway function better than 70% of predicted should receive either a cold air or exercise challenge. To ensure all children are appropriately diagnosed as having AHR, undertaking both a cold air and exercise challenge should be considered, as some children respond only to one type of challenge.[59] A methacholine challenge should not be used, as this can precipitate an ACS. If there is concern that a bronchial provocation challenge will precipitate an ACS or VOC, then a trial of inhaled steroids could be undertaken, but a detailed diary card and lung function analysis are required to determine if the inhaled steroids have had a positive effect.

The most rapid deterioration in lung function occurs in very young children[43]; thus, annual respiratory monitoring should begin early. Young children, however, have limited ability to perform lung function tests, and detailed lung function testing is not available in all centers. As a consequence, in those less than 5 years of age, impulse oscillometry is recommended, as this does not require volitional input by the child; in older children, spirometry gives additional information.

Certain methods of assessing oxygen saturation in SCD patients may be inaccurate. Pulse oximetry can yield inaccurate results in SCD patients, as the fraction of carboxyhemoglobin (COHb) is increased in some patients because of increased heme catabolism; some modern oximeters, however, can differentiate between COHb and oxyHb. In addition, the patterns of light absorption differ between HbS and HbA and HbA is used to calibrate oximeters.

Given the many reasons for an increased risk of SDB in children with SCD, patients should be screened with questionnaires and, where available, with polysomnography. An ongoing randomized trial may shed light as to whether therapy with overnight supplementary oxygen may ameliorate the impact of SDB on children with SCD.[60]

PH is usually diagnosed by a tricuspid regurgitant jet velocity (TRV) on echocardiography of greater or equal to 2.5 m/s. Echocardiography, however, overestimates the prevalence of PH against the gold standard of cardiac catheterization. An elevated TRV has been reported in 11%–31% of children and adolescents with SCD and associated with a decline in exercise capacity.

## Prevention

Agents that increase the HbF level reduce the complications of SCD. Hydroxyurea, a ribonuclease reductase inhibitor, blocks the synthesis of DNA and, because of bone marrow suppression, raises the HbF level. Hydroxyurea is also an NO donor and has been shown to reduce the adhesion of sickle cells to the vascular endothelin in vitro by reducing VCAM-1 production. A systematic review concluded that hydroxyurea is effective and safe in adults severely affected by sickle cell anemia. An RCT in children aged 9–18 months failed to achieve its primary aim, which is whether daily hydroxyurea would reduce spleen and renal damage by at least 50%. There were, however, significantly fewer SCD related events in the hydroxyurea group, including ACS episodes.[61] Hydroxyurea, however, may cause cytopenias and patients must be carefully monitored, especially early in the administration of therapy, and some physicians are reluctant to prescribe it. An evidence-based report by expert panel members gave a recommendation of moderate strength regarding offering treatment with hydroxyurea without regard to the presence of symptoms for infants, children, and adolescents.[62] Chronic transfusion in patients with a history of recurrent or severe ACS episodes has been demonstrated by both a retrospective review[63] and a randomized trial[64] to reduce the frequency of ACS episodes. Routine use of incentive spirometry is recommended in SCD patients admitted to hospital with chest or bone pain, as in an RCT, this was associated with a lower rate of pulmonary complications (atelectasis or infiltrates) on a subsequent chest radiograph.[65] A retrospective review demonstrated that introduction of a guideline initiating mandatory incentive spirometry in children with SCD admitted for nonrespiratory complaints resulted in a reduced number of transfusions and ACS episodes.[66] Stem cell transplantation in adults and children has been associated with no recurrence of painful crisis in those with stable engraftment.[67] The best results are obtained in young children who have human leukocyte antigen (HLA)-identical sibling donors and who are transplanted early in the course of their disease.[68] In certain pediatric populations, the success rate is 85%–90%.[69]

## Prognosis

Despite significant improvements in life expectancy in individuals with SCD, the median age of death for women is 48 years and the median age for men is 42 years. Fatal pulmonary complications occur in 20% of adults. The overall mortality for ACS is 3%, but 9% in adults, and the primary cause of death is respiratory failure from pulmonary emboli or bronchopneumonia. Those with SCLD and PH have significantly increased mortality; the median survival for patients diagnosed with PH by catheterization has been reported to be only 25.6 months.

*Daniel R. Ambruso MD, Pia J. Hauk MD*

## Chronic Granulomatous Disease

Chronic granulomatous disease (CGD) of childhood was first described by Berendes and colleagues[1] and by Landing and Shirkey[2] as a distinct clinical entity of unknown cause.[3] This disease is characterized by recurrent infections, usually with low-grade pathogens, formation of abscesses and suppurative granulomas, and normal humoral and cellular immunity. The usual onset of symptoms is early in life (most in the first 2 years of life). The disease is generally chronic, and unless diagnosed and treated, the outcome is commonly death from overwhelming infection.

After the original patients, similar cases were reported using various names.[4–7] CGD is now the generally accepted term for this syndrome. In 1967 Quie and colleagues[8] defined the basic step in pathophysiology as an inability of phagocytic cells to kill ingested bacteria; and Baehner and Nathan[6] reported that CGD neutrophils did not undergo the phagocytosis-associated "respiratory burst" of oxygen consumption and hydrogen peroxide ($H_2O_2$) production that characterizes phagocytic cells.

Although all of the cases initially documented were in males, later reports described females, suggesting the possibility of autosomal-recessive variants.[9,10] In the 1970s, progress was made in elucidating the nature of the basic biochemical defect, decreased oxidase activity, a process by which oxygen ($O_2$) is reduced to superoxide anion ($O_2^-$) using nicotinamide adenine dinucleotide phosphate (NADPH) as the electron source.[11–13] In 1978 Segal and Jones reported the association of a b-type cytochrome and the NADPH oxidase, as well as its deficiency in CGD. Continued studies firmly defined the relationship between X-linked CGD and deficiency of cytochrome $b_{558}$.[14] In the late 1980s, the gene that is abnormal in X-linked CGD was cloned and subsequently shown to produce the heavy-chain component of the cytochrome $b_{558}$ heterodimer (gp91phox).[15–17] Subsequently, the light chain (p22phox) was described and found to be the basis for the autosomal-recessive form of cytochrome b–deficient CGD.[18]

In the late 1980s and early 1990s, the molecular basis for other forms of autosomal-recessive CGD was defined. Cytosolic components, p47phox and p67phox, were identified, linked to distinct variants of CGD, and sequenced, and their genes were cloned.[19–22] Deficiency of p40phox has been more recently described.[23]

Thus, 84 years after Metchnikoff first posited that phagocytosis is essential in fighting infection (in 1883), studies in patients with CGD demonstrated for the first time clearly that a defect in phagocyte function is a major breach in host defense against severe infections. Since 1967, the biochemistry of the oxidase enzyme system has been elucidated, the major components defined, and the molecular basis for the most common variants of CGD described. Taking advantage of this syndrome as an "experiment of nature" has greatly expanded our knowledge of the role of the phagocyte in host defense.

## Clinical Features

The hallmark of this disease is the occurrence of purulent inflammation due to catalase-positive, low-grade pyogenic bacteria. This syndrome should be considered in any individual with recurrent catalase-positive bacterial or fungal infections. Table 63.1 summarizes the relative frequencies of the most common clinical findings in patients with CGD in the earliest reported cases, before the general use of prophylactic antimicrobial therapy.[24] A more recent analysis of infections in 368 patients enrolled in a registry for CGD[25,26] shows a general decline in most types of infection, with the notable exception of pneumonia (Table 63.2).

### Table 63.1

**Clinical Findings in the 168 Earliest Reported Patients With Chronic Granulomatous Disease**

| Finding | Percentage of Patients Involved |
|---|---|
| Marked lymphadenopathy | 82 |
| Pneumonitis | 80 |
| Dermatitis | 71 |
| Hepatosplenomegaly | 68 |
| Onset by age 1 year | 65 |
| Suppuration of nodes | 62 |
| Splenomegaly | 57 |
| Hepatic-perihepatic abscesses | 41 |
| Osteomyelitis | 32 |
| Onset with dermatitis | 25 |
| Onset with lymphadenitis | 23 |
| Facial periorificial dermatitis | 21 |
| Persistent diarrhea | 20 |
| Septicemia or meningitis | 17 |
| Perianal abscess | 17 |
| Conjunctivitis | 16 |
| Death from pneumonitis | 15 |
| Persistent rhinitis | 15 |
| Ulcerative stomatitis | 15 |

### Table 63.2

**Most Common Infections in 368 Patients Enrolled in a Registry for Chronic**

**Most Common Infections in 368 Patients Enrolled in a Registry for Chronic Granulomatous Disease**

| Infection | Percentage of Patients |
|---|---|
| Pneumonia | 79 |
| Abscess (any) | 68 |
| Subcutaneous | 42 |
| Liver | 27 |
| Lung | 16 |
| Perirectal | 15 |
| Brain | 3 |
| Suppurative adenitis | 53 |
| Osteomyelitis | 25 |
| Bacteremia/fungemia | 18 |
| Cellulitis or impetigo | 10 |

Data from Winkelstein JA, Marino MC, Johnston RB Jr, et al. Chronic granulomatous disease. Report on a national registry of 368 patients. *Medicine*. 2000;79:155.

Of the 368 registry patients, 76% had the X-linked recessive form of CGD. The mean age at diagnosis in the registry patients was 3.0 years with the X-linked form and 7.8 years with an autosomal-recessive form.[25] These ages are much higher than they should be for the sake of the patient. In rare instances, the initial diagnosis has been made in adulthood. Reviews have suggested that autosomal-recessive variants generally have clinically milder diseases.[26,27]

Although any organ may be involved with infections, two patterns have been evident in CGD populations across the world.[25–35] Tables 63.1 and 63.2 exemplify data from the United States. First, the inability of phagocytic cells to effect microbicidal activity at the interface between the host and the environment leads to infections such as pneumonitis, infectious dermatitis, and perianal abscesses. With the involvement of the mononuclear phagocyte system, deep-seated infections result in purulent lymphadenitis, hepatomegaly, splenomegaly, and hepatic and perihepatic abscesses. At all sites of infection, microbes may be sequestered and protected from intracellular killing mechanisms and antibiotics. Unable to destroy the microbes, the phagocytes die and release the organisms. Further microbial proliferation and leukocyte accumulation lead to the abscesses and granulomas that characterize the disorder. Septicemia may also occur because of the inability of phagocytes to localize microbial invasion.

Purulent rhinitis and otitis are common clinical features of this disease. With adequate antibiotic therapy, rhinitis clears slowly, only to recur within a few days after the treatment is discontinued.

The oropharynx and gastrointestinal tract are frequently infected, with ulcerative stomatitis, gingivitis, esophagitis, rectal abscesses, perianal abscesses, and fissures being common. Urinary tract infections and glomerulonephritis, renal abscesses, and cystitis have all been reported. Gonadal infections are rare but have been described. Osteomyelitis is common; the most frequent sites include metacarpals, metatarsals, spine, and ribs.

Lymphadenitis, a characteristic clinical feature, occurs in the majority of patients during the course of the disease. It is typically chronic, suppurative, and granulomatous and very often requires surgical drainage. Cervical, axillary, and inguinal nodes are usually involved, but hilar and mesenteric lymph nodes are also commonly enlarged.

Skin lesions include impetiginous eruptions that progress slowly to suppuration. The healing process can be slow, resulting in granulomatous nodules that persist for months. These lesions may be found in any part of the body, the face and neck being the most frequent sites. Sweet's syndrome (acute febrile neutrophilic dermatosis)[36] has been associated with CGD. Furunculosis and subcutaneous abscesses may be chronic problems. Eczematoid dermatitis can be seen early in the diagnosis.

Carriers of X-linked CGD can have discoid lupus, aphthous ulcers, and systemic lupuslike symptoms.[37,38] If X-linked inactivation is skewed so that less than 10% of neutrophils express the normal NADPH oxidase, carrier females can have clinical CGD.[39–42] The progressive skewing of the X chromosome that occurs with age can result in adult-onset CGD in these carriers.[42]

While the major problems of patients with CGD are related to infections, these individuals can also be afflicted with a number of conditions reflecting a vigorous inflammatory response without a clear infectious cause.[27,28] Pyloric stenosis, with associated decrease in gastric emptying, is common, and sterile granulomas can be found in the pyloric antrum. Similar lesions in the small and large bowel may be associated with persistent abdominal pain, diarrhea, malabsorption, or obstruction.[43] Some of the gut lesions have been described as eosinophilic gastroenteritis, gastrointestinal dysmotility, or inflammatory bowel disease. Granulomas in the urinary bladder can result in obstructive uropathy. Pericarditis and pleuritis have been noted. Chorioretinitis was detected in 9 of 30 boys with X-linked CGD and in 3 of 15 related carriers in one clinic.[44] The single patient reported with p40phox deficiency had a partial deficiency in the respiratory burst, no severe infections, but severe and chronic granulomatous colitis.[23] Patients with CGD can also have a typical autoimmune disease, including systemic and discoid lupus, idiopathic thrombocytopenic purpura, juvenile rheumatoid arthritis, IgA nephropathy, or antiphospholipid syndrome.[45] It seems likely that there is a common mechanism for this spectrum of inflammatory conditions, perhaps related to the fact that CGD neutrophils do not undergo normal cell death by apoptosis, are not cleared efficiently by macrophages, and therefore release toxic constituents into the tissues.[46,47] Whatever the mechanism, the response of pyloric and bladder granulomas to steroids is well documented.

## Pulmonary Complications

Patient surveys, as exemplified in Tables 63.1 and 63.2, show that pneumonia continues to be one of the most common types of infection, occurring in about 80% of patients with CGD.[25–35] Pulmonary disease has also become a major cause of mortality in this disease.[25] The overall pulmonary infection rate and incidence of fungal infections are increased in adults compared to children.[48] The onset of lower respiratory tract infection may be heralded by the usual clinical presentation of fever, cough, tachypnea, pleuritic pain, and abnormal auscultatory findings. However, in some patients, particularly those with a fungal infection, few if any signs or symptoms have been noted in the presence of marked infiltration on radiography. Chronic granulomatous infiltrations, bronchiolitis obliterans, pulmonary fibrosis, bronchiectasis, interstitial lung disease (ILD), and sarcoidosis have been noted in both pediatric and adult patients.[29,49,50]

The range of microbial agents causing pulmonary infections is shown in Table 63.3. Since the 1970s, the use of daily antimicrobial therapy in CGD has reduced the rate of infections due to *Staphylococcus aureus* and enteric bacteria,[51] but *Aspergillus* species has become a particularly troublesome offender.[25,52] Fungal infection of the lung can present as discreet nodular, miliary, or pan-lobular involvement. Fungi now cause a large percentage of infections in CGD; these typically cause less fever and can be hard to diagnose in early stages. Fungal lung involvement may spread to the pleura and adjacent bone and soft tissues of the chest wall.[48,53,54] Although *Aspergillus* accounts for most of the fungal agents (>80%), other agents such as *Acremonium striatum, Candida albicans, Pneumocystis carinii,* and *Paecilomyces* species may also be isolated from infected lungs.[25,28,52] *Aspergillus* pneumonia, with or without dissemination, was the leading cause of death in the 368 registry patients (23 of 65 total deaths). *Nocardia,* atypical mycobacteria, and the bacillus Calmette-Guérin vaccine strain of mycobacteria can also cause pulmonary disease.[35]

## Table 63.3

## Most Common Infecting Organisms in the 368 Patients in the Chronic Granulomatous Registry

| Type of Infection | Organism | Percentage of Patients[a] |
|---|---|---|
| Pneumonia | *Aspergillus* species | 33 |
| | *Staphylococcus* species | 9 |
| | *Burkholderia cepacia* | 7 |
| | *Nocardia* species | 6 |
| | *Serratia* species | 4 |
| Abscess—subcutaneous, liver, and/or perirectal | *Staphylococcus* species | 26 |
| | *Serratia* species | 3 |
| | *Aspergillus* species | 3 |
| Abscess—lung | *Aspergillus* species | 4 |
| Abscess—brain | *Aspergillus* species | 2 |
| Suppurative adenitis | *Staphylococcus* species | 14 |
| | *Serratia* species | 5 |
| Osteomyelitis | *Serratia* species | 7 |
| | *Aspergillus* species | 5 |
| Bacteremia/fungemia | *Salmonella* species | 3 |
| | *Burkholderia cepacia* | 2 |
| | *Candida* species | 2 |

[a] Percentage of the 368 patients who had this organism isolated at least once from the infection shown.

Data from Winkelstein JA, Merino MC, Johnston RB Jr, et al. Chronic granulomatous disease. Report on a national registry of 368 patients. *Medicine*. 2000;79:155.

Pulmonary lesions on x-ray include extensive infiltration of the lung parenchyma and prominent hilar adenopathy (Fig. 63.1). Bronchopneumonia, lobar pneumonia, extensive reticulonodular infiltration, pleural effusion, pleural thickening, pulmonary abscess, and atelectasis (especially of the right middle lobe) have been described.

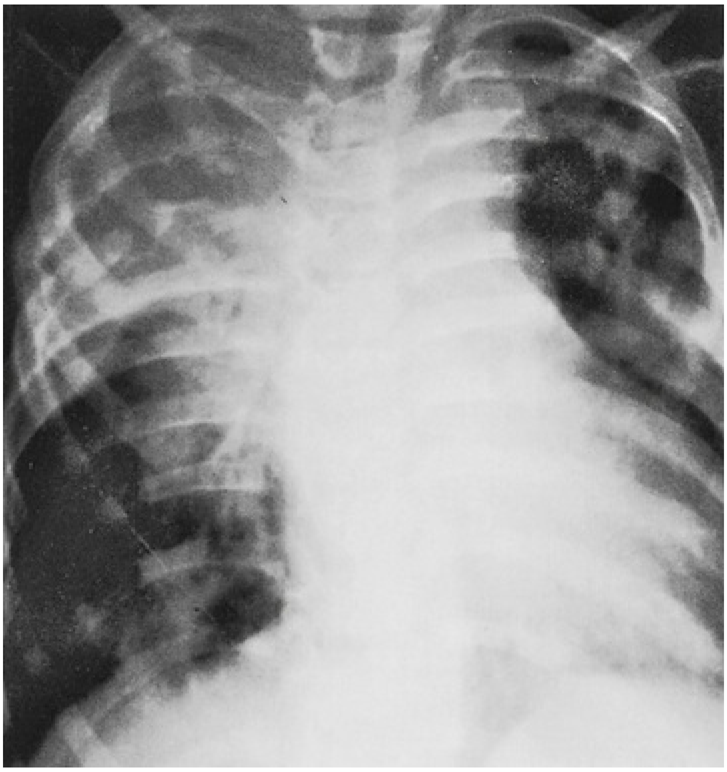

**FIG. 63.1** A chest roentgenogram from a patient with chronic granulomatous disease, showing extensive bilateral lung involvement. This patient died of the overwhelming infection.

In spite of extensive antibiotic treatment, the various expressions of CGD pulmonary disease often regress slowly over a period of weeks to months, or they can progress to involve an entire lobe. An unusual manifestation of pulmonary involvement observed in these patients is so-called encapsulated pneumonia.[55] This pneumonia is characteristically seen on roentgenography as a homogeneous, discrete, relatively round lesion; it may occur singly or in groups of two to three infiltrates (Fig. 63.2). The size and contour of the lesions may change over days or weeks or remain unchanged. Histologically, they take the form of caseating granulomas (Fig.

63.3). A homogeneous "shot-gun" distribution of small granulomatous lesions can occur, which gives the radiographic appearance of miliary tuberculosis. Discoid atelectasis, thickening of the bronchi, air bronchograms, "honeycombing," loss of lobar volume, and bronchiectasis associated with hemoptysis are occasionally observed.

## Laboratory Findings and Diagnosis

Except for abnormalities of phagocyte function, clinical laboratory findings reflect acute or chronic infection and inflammation. Leukocytosis with neutrophilia, elevated erythrocyte sedimentation rate and C-reactive protein, and the anemia of chronic inflammation are common. The anemia is usually not due to a deficiency of iron stores but to a decrease in iron release from the mononuclear phagocyte system and diminished utilization by the marrow.[56] It typically does not respond to iron administration but improves with resolution of infection. Evidence of hemolytic anemia with acanthocytosis suggests absence of the $K_x$ antigen on red blood cells, a trait encoded close to the gp91phox gene on the X chromosome.

Screening evaluations of various aspects of immune function are usually normal, including complement, cellular immunity, and antibody production in response to immunization in spite of recent data that the NADPH oxidase may modulate MCH class II antigen presentation by b-cells.[28,57] Polyclonal hypergammaglobulinemia is common. A deficiency of microbicidal activity against catalase-positive bacteria (e.g., staphylococci and *Escherichia coli*) and a diminished or absent respiratory burst by neutrophils and monocytes are the essential functional and biochemical findings of CGD.

Patients with CGD have a predisposition to infections with a broad variety of bacteria and fungi (see Table 63.3). The most common organisms are *S. aureus,* Serratia species and other gram negative organisms, and *Aspergillus,*[24,25,35,52] but unusual and rare pathogenic organisms may cause disease in patients with CGD. Recent studies have focused on *Burkholderia cepacia* as a significant pathogen, particularly in the lung.[27,58–60] Infection by this organism was the second leading cause of death in patients in the CGD registry. Its propensity to infect patients with either CGD or cystic fibrosis is not understood.

Microbial agents associated with pulmonary infections are the same as those that cause infections in other parts of the body. Fungal pneumonitis is frequent, especially due to *Aspergillus.* Other pulmonary pathogens include *Nocardia* species, *P. carinii, Actinomyces,* and mycobacteria. Mycobacterial disease is relatively common in patients with CGD in countries where tuberculosis is endemic, BCG vaccine is mandatory, or both.[61] Infections due to pneumococci, streptococci, and *Haemophilus* species are no more common in children with CGD than in normal children, presumably because these catalase-negative organisms cannot protect against their own $H_2O_2$ production within the phagocytic vacuole.

Tissue from infected sites shows granulomas like those typically seen with intracellular parasites such as mycobacteria. Granulomas in CGD patients include mononuclear phagocytes that can contain a tan or yellow pigmented material.[2,61] Granulomas in the presence of the pathogens noted above strongly suggest the diagnosis of CGD.

Simple screening tests for CGD are currently available. The histochemical nitroblue tetrazolium (NBT) test[62] remains a reliable screening measure. Stimulation of microbicidal activity and the respiratory burst results in the reduction of $O_2$ to $O_2^{\cdot-}$ ; NBT dye is reduced by the extra electron in $O_2^{\cdot-}$ and converted from a yellow, water-soluble dye to a purple, insoluble substance. In normal individuals, 95% or more of phagocytic cells reduce NBT; the phagocytes from patients with the common variants of CGD do not reduce NBT. Carriers of X-linked CGD exhibit two populations of cells, normal and NBT-negative.

Fluorescence-based screening assays using flow cytometry avoid the subjective element of the NBT test. Dihydrorhodamine-123 can be readily preloaded into neutrophils or monocytes, and it interacts with oxygen metabolites produced during the respiratory burst to generate products with increased fluorescence.[63] Patients' phagocytes do not shift fluorescence after stimulation. X-linked carriers have two populations. Additionally, some CGD variants, e.g., p47phox deficiency and milder variants of X-linked CGD, have very low oxidase activity in all cells, and this activity can be detected with this technique. This assay is more quantitative than the NBT test since it measures oxidase activity of the entire phagocyte population and can quantify partial reduction in the respiratory burst.

A positive screening test should be confirmed with one or more quantitative tests. Bactericidal assays with *E. coli* or *S. aureus* may be diagnostic.[8,64] Quantitative assays of $O_2$ consumption, $O_2^-$ production, or generation of $H_2O_2$ can be helpful[6,32,64,65] Finally, an analysis of the various oxidase components will define the molecular variant of CGD. Cytochrome $b_{558}$ can be quantitated spectroscopically, and the individual oxidase components can be analyzed by Western blot. Several cell-free systems that can reproduce the assembly and activation of the oxidase in intact cells with the use of plasma membrane and cytosol from neutrophils may be helpful in defining the molecular variants of CGD. Identification of the genetic mutation responsible for the protein defect may be helpful for genetic counseling, prenatal studies, and judging prognosis, and a recent review presents a flow diagram for evaluation.[66–68]

Prenatal diagnosis may be achieved with screening tests on fetal neutrophils obtained by percutaneous umbilical blood sampling. The diagnosis for some CGD variants can be made from chorionic villus or amniocyte samples using restriction fragment length polymorphism or gene analysis without the risk of fetal blood sampling.[69]

## NADPH Oxidase

The oxidase enzyme resides in the plasma membrane of stimulated cells, and through the oxidation of NADPH catalyzes the reduction of $O_2$ to $O_2^-$, the first step in production of antimicrobial oxygen metabolites. Phagocyte oxidase (phox) activity results from the interaction of several components that form an enzyme complex. In resting cells, these components reside in different compartments. With stimulation of the cell, they assemble in the plasma membrane to express oxidase activity (Fig. 63.4).[28,70–72]

**FIG. 63.4** Schematic diagram of the NADPH oxidase enzyme system, its components, and its activation. In resting neutrophils, membrane components (gp91phox and p22phox) reside in plasma membrane and specific granules. With stimulation, degranulation of specific granules expands the amount of cytochrome b558 in plasma membrane and translocation of cytosolic components (rac2, p47phox, p67phox, and p40phox) and p29 peroxiredoxin 6 (Prdx6) to the plasma membrane results in assembly of an active oxidase enzyme system that uses electrons from NADPH to reduce $O_2$ to form $O_2^-$.

The main catalytic component of the oxidase is the cytochrome $b_{558}$. In resting cells, 10%–20% of total cellular cytochrome $b_{558}$ appears to be located in plasma membrane, and 80%–90% is in the membranes of specific granules. This protein is a heterodimer composed of $\alpha$ (p22phox) and $\beta$ (gp91phox) subunits. Cytochrome $b_{558}$ binds NADPH; its flavin binding site and a heme moiety are critical to shuttling electrons between NADPH and $O_2$.[73] With stimulation, specific granule membranes fuse with plasma membrane, increasing the amount of cytochrome $b_{558}$ associated with the plasma membrane. The cytosolic oxidase components translocate to the plasma membrane and specific granules, providing an active oxidase complex that is increased in the plasma membrane.[70,71] A low molecular weight G protein, Rap1a, is associated with cytochrome $b_{558}$ and may be important in assembly and activation of the oxidase complex.[28,74]

The cytosolic oxidase components include p47phox, p67phox, and p40phox.[21,22,73] A cytosolic low molecular weight guanosine triphosphate (GTP)–binding protein, p21*rac*2, is also involved, and there may be other proteins that control GTP binding to the *rac*2 protein.[75,76] These latter elements link with receptors on the plasma membrane and help transmit and/or amplify biochemical signals (e.g., from opsonized microbes) that regulate assembly and activation of the oxidase.

p47phox and p67phox appear to exist as a complex in cytosol of resting cells.[73,77] Interactions between this complex, plasma membrane, and the cytoskeletal elements are critical for activation of the oxidase.[72] Precise details of the relevant domains for interactions of phox proteins, changes which occur during cell activation, and the relationship with signaling pathways has been under intense investigation in recent years and is summarized in a recent review.[78] The gene for p40phox (NCF4) has been cloned, and p40phox was identified as binding strongly to p67phox. More recent work suggests that p40phox function within the NADPH oxidase complex depends on its binding to phosphatidylinositol 3-phosphate.[23] An additional protein closely associated with p67phox has been described.[79] This 29-kd protein (termed p29) is categorized as a peroxiredoxin by its sequence and activity. Peroxiredoxins are a class of peroxidases that oxidize $H_2O_2$ with sulfur groups on cysteine residues.[79] Neutrophil p29 peroxiredoxin enhances $O_2^{\cdot -}$ production in subcellular systems of oxidase activity and in intact cells and translocates to plasma membrane after stimulation of the respiratory burst.[80] The p29 peroxiredoxin stabilizes and enhances the activity of the oxidase enzyme system.[80,81]

## Molecular Defects and Inheritance

Genetic testing documenting a patient/family mutation is currently available through commercial or research laboratories. In addition to confirming the correct classification of the patient and his/her prognosis, the specific defect will be important if more aggressive management strategies such as gene therapy and/or hematopoietic stem cell transplantation are considered. With the discovery of the various oxidase components over the past 15 years, the molecular basis of CGD has come into focus. Most patients express genetic or molecular abnormalities in one of the four major components of the oxidase: gp91phox, p22phox, p47phox, or p67phox (Table 63.4).[25,28,66,67] One patient has been reported with a mutation in *rac*2,[82] but no patients have been described with an abnormality of rap-1. p40phox, encoded by the NCF4 gene on chromosome 22 (22a13.1), is reported to be diminished in individuals with p67phox deficiency, and a single patient has been described with an autosomal recessive deficiency in this component, deficiency of the phagocytosis-stimulated respiratory burst, and granulomatous colitis.[23]

### Table 63.4

### Molecular and Genetic Classification of Chronic Granulomatous Disease

| **Affected Component**[a] | **Chromosome Location** | **Gene**[a] | **Inheritance**[a] | **Subtype Class**[a] | **NBT/DHR (% Positive)/$O_2^-$ Production** | **Cytochrome $b_{558}$ Spectrum** |
|---|---|---|---|---|---|---|
| gp91phox | Xp21.1 | CYBB | XL | X91° | 0/0 | 0 |

| | | | | | | | |
|---|---|---|---|---|---|---|---|
| | | | | | | | |
| | | | | X91$^{-}$ | 80%–100%/3%–30% (weak) | 3%–30% | D<br>g<br>p |
| | | | | X91$^{-}$ | 5%–10%/5%–10% | 5%–10% | D<br>g<br>p |
| | | | | X91$^{+}$ | 0/0 | 100% | N<br>a |
| p22phox | 16p24 | CYBA | AR | A22$^{\circ}$ | 0/0 | 0 | A<br>a<br>g |
| | | | | A22$^{+}$ | 0/0 | 100% | N<br>a<br>g |
| p47phox | 7q11.23 | NCF-1 | AR | A47$^{\circ}$ | 0/0%–1% | 100% | A<br>p |
| p67phox | 1q25 | NCF-2 | AR | A67$^{\circ}$ | 0/1%–1% | 100% | A<br>p |

[a] Oxidase components expressed as gp91phox, p22phox, p47phox, p67phox, and their genes as CYBB, CYBA, NCF-1, and NCF-2, respectively. Subtypes represented by letter designating type of inheritance. The superscripts designate detection of protein in patient samples. *A,* Autosomal; *AR,* autosomal-recessive inheritance; *X,* X-linked; *XL,* X-linked inheritance; *O,* absent, −, diminished, +, present.

[b] For Western blot analysis, abnormalities in specific phox proteins are noted. Other components not described are normal with this technique.

Activity measurements may be made in the cell-free system of activation.[70–71] In this system, activity is defined by both cytosol (and associated components) and membrane. Deficiencies in gp91phox and p22phox exhibit diminished or absent membrane contribution and deficiencies of p47phox and p67phox exhibit diminished or absent cytosol contribution.

Data from Roos D, Kuhns DB, Roesler J, et al. Hematologically important mutations: X-linked chronic granulomatous disease (third update). *Blood Cells Mol Dis*. 2010;45:246; and Roos D, Kuhns DB, Maddalena A, et al. Hematologically important mutations: the autosomal recessive forms of chronic granulomatous disease (second update). *Blood Cells Mol Dis*. 2010;44:29.

The most common molecular defects in CGD are related to gp91phox and account for about 70% of all cases of this syndrome.[26,28–35,66] Located on the short arm of the X chromosome (Xp21.1), defects in the gp91phox gene are inherited as X-linked recessive. In the most common variety, mutations in the gene result in the lack of gp91phox protein due to mRNA or protein instability. NADPH oxidase activity is totally absent, no cytochrome $b_{558}$ is seen spectrophotometrically, and no gp91phox is detected on Western blot. A defect in the membrane contribution to oxidase activity is documented with analysis in cell-free systems. Cytosol and its components are normal. Deletions, insertions, rare duplications and splice site, missense, and nonsense mutations have all been described and reviewed in detail.[66]

Other variants of gp91phox deficiency have been described. Some mutations have resulted in partial loss of protein expression and diminished oxidase activity in proportion to the decrease in protein content. In some, a truncated protein is expressed. Defects are found in exons, introns, intron/exon junctions, and promoters. A few cases have been described with normal gp91phox protein expression but nearly complete absence of oxidase activity. Additional variants have been reported with the inability to interact with NADPH or with p47phox and p67phox or to bind flavin adenine dinucleotide (FAD). Severity of disease in these less common genetic variants correlates with the level of cytochrome b expression and superoxide production.

Patients who lack both the respiratory burst and cytochrome $b_{558}$ and exhibit an autosomal-recessive mode of inheritance have a deficiency in p22phox, the gene for which is found on chromosome 16 (16q24). These patients account for 5%–6% of all cases. In the usual form, the deficiency in membrane contribution of oxidase activity is accompanied by absence of the cytochrome $b_{558}$ spectrum and both gp91phox and p22phox by Western blot. Analysis of cytosolic components is normal. Although fewer genetic analyses have been completed, deletion, insertion, missense, nonsense, and splice site mutations have been described.[67] In one variant, a homozygous missense mutation affects the area of interaction between p22phox and p47phox, resulting in a normal cytochrome $b_{558}$ that cannot form an oxidase complex.

Patients who exhibit an autosomal-recessive mode of inheritance but whose neutrophils contain normal amounts of cytochrome $b_{558}$ may have a deficiency of either p47phox or p67phox. The gene for p47phox falls on chromosome 7 (7q11.23), and that for p67phox on chromosome 1 (1q25). Defects in these genes account for approximately 20% and 5%–6% of CGD cases, respectively. Absent or nearly absent oxidase in whole cells is coupled with deficient cytosol contribution in the cell-free system and deficiency of the protein on Western blot. There appears to be much less heterogeneity in genetic mutations causing deficiency of p47phox than of p67phox.[67] Patients studied to date are either homozygous for a GT dinucleotide (ΔGT) deletion at the start of exon 2 of the NCF-1 gene or are compound heterozygotes with a GT deletion on one allele and a point mutation on the second allele. The reason for the homogeneity is that most normal individuals have p47phox pseudogenes, each of which colocalize with the functional gene at 7q11.23. Recombination events between the functional and pseudogenes lead to incorporation of ΔGT into the NCF-1 gene. In addition to heterozygous GT changes, missense and splice junction changes have been described. In many patients studied, normal amounts of mRNA and complete absence of p47phox are found in neutrophils, suggesting translation of an unstable protein.

Relatively few molecular defects have been characterized in patients with p67phox deficiency. As with p47phox deficiency, mRNA for p67phox is usually present, but in most cases no protein is detected. Nonsense, missense, homozygous point, splice site, insertion, and deletion mutations have been documented, as well as one duplication, suggesting a heterogeneity of genetic abnormalities for p67phox.[28,67]

A patient with *rac*2 deficiency presented with severe, recurrent perirectal abscesses and pyoderma, omphalitis, and poor wound healing.[82,83] His neutrophils exhibited a unique pattern of functional abnormalities, including markedly diminished random and directed migration, decreased ingestion and bactericidal activity, and absent degranulation of azurophilic granules. Expression of CD11b and degranulation of specific granules were normal. Production of $O_2^{-}$ in response to N-formyl-methionyl-leucyl-phenylalanine and platelet-activating factor was absent, to opsonized zymosan was decreased, but to phorbol myristate acetate was normal. *Rac*2 was 30% of control, and all other oxidase components were normal. A mutation in one nucleotide of codon 57 for one *rac*2 allele resulted in a substitution of asparagine for aspartic acid. Although both the wild-type and mutant alleles were expressed, the mutant protein had a defect in the GTP binding site, could only bind guanosine diphosphate, and had a dominant-negative effect on the wild-type *rac*2 as well as other low molecular weight GTPases.[82,83] Because of this, the oxidase as well as other neutrophil functions were affected. The patient was cured by a bone marrow transplant from his human leukocyte antigen (HLA)–identical sibling.[84]

Deficiency of glucose-6-phosphate dehydrogenase (G6PD) in leukocytes, which occurs in a small number of patients with erythrocytes deficient in this enzyme, has been considered a variant of CGD.[26,85–87] Patients whose neutrophils contain less than 5% of normal activity suffer from recurrent, sometimes fatal, infections. Their neutrophils do not exhibit a respiratory burst and exhibit a microbicidal defect against catalase-positive organisms. Deficiency of NADPH as the efficient electron donor to the oxidase may explain this disorder.[85]

## Management

The key to the successful management of CGD remains early diagnosis, prophylactic antimicrobial therapy, and rapid and vigorous treatment of infections.[28,51,52,88–94] This approach begins with prophylactic daily doses of trimethoprim-sulfamethoxazole (4–5 mg/kg trimethoprim, 20–25 mg/kg sulfamethoxazole, once or divided into two doses daily), which has reduced the incidence of severe bacterial infections by 70%. Ciprofloxacin may be used as an alternative. Interferon (IFN)-$\gamma$ given at a dose of 1.5 μg/kg (surface area $<0.5$ m$^2$) or 50 μg/m$^2$ (surface area $\geq 0.5$ m$^2$) three times weekly by subcutaneous injection also reduces the incidence and severity of infections.[89,92] Administration before bedtime along with acetaminophen reduces fever and myalgias. Daily itraconazole at 100–200 mg/day (4–5 mg/kg in two doses) taken with food has been advocated as fungal prophylaxis.[51,88] Care should be taken to avoid environmental conditions that present a high risk for exposure to *Nocardia* and fungi, especially *Aspergillus* (e.g., garden mulch, construction sites, leaves, and marijuana).

When infections develop, aggressive attempts should be made to obtain culture and antibiotic sensitivity of organisms from localized areas. Surgical drainage, including drainage of pulmonary abscesses or empyema, is also critical to treatment, since antibiotics required to resolve infection do not penetrate well into abscesses.[93,94] The infected site should be aggressively débrided with prolonged drainage to prevent loculation and sequestration of infected areas.

In patients with fever and elevated C-reactive protein and sedimentation rate but no definite locus for an infection, an empiric trial of parenteral antibiotics may be necessary. During the initiation of this therapy, definition of the infected area should be sought with routine radiographs, computed tomography, magnetic resonance imaging studies, or radionucleotide scans.

Identification of the infected site may provide clues to initial antibiotic coverage. For example, the vast majority of liver abscesses are caused by staphylococci (see Table 63.3), and vancomycin and levofloxacin might be used initially. *Burkholderia cepacia* is found in a higher incidence in the lung and *Serratia* in soft tissue and bones. For these infections, increasing the trimethoprim-sulfamethoxazole to a full therapeutic dose and adding a cephalosporin, meropenem, or levofloxacin should be considered until antibiotic sensitivities are available. Antibiotic coverage should be reorganized later in response to antibiotic sensitivities of recovered organisms. Initial parenteral treatment and oral antimicrobials for weeks or months may be required to resolve the infection.

If fungus is suspected or defined, vigorous antifungal therapy should be instituted. Although amphotericin has been advocated in the past, other agents may be required, such as itraconazole, voriconazole (6 mg/kg every 12 hours on day 1, then 4 mg/kg every 12 hours), or posaconazole (200 mg 3 times daily; currently approved only for children over 12 years old and adults).[88,95–97] Prednisone may be considered for miliary involvement. Although not proved efficacious, daily granulocyte transfusions (at least $10^{10}$ granulocytes per transfusion) have been used as a supplement to aggressive surgical and antibiotic therapy,[27,28,98] but these can cause alloimmunization, which could hamper later bone marrow transplantation.

Some patients with CGD inherit, as a closely associated X-linked allele, a deficiency in the $K_x$ antigen affecting both erythrocytes and leukocytes.[28] This results in the lack of Kell antigens on the surface of the red cells, which can be associated with a chronic hemolytic anemia. Transfusion of these patients can result in true isoimmunization for Kell antigens and the risk of immediate or delayed transfusion reactions.

Inflammatory conditions or obstructive lesions of the gastrointestinal tract (seen in up to 50% of the patients) or genitourinary tract (in up to 70% of the patients) usually respond to treatment with steroids.[43,99,100] The response may be prompt, but relapses are common.

## Hematopoietic Cell Transplantation and Gene Therapy

Hematopoietic cell transplantation has been attempted with mixed results.[101–104] Long-term engraftment and reversal of the defect has been documented. Sources of stem cells include bone marrow, mobilized peripheral blood, and umbilical cord blood. Although unrelated donors have been used, the majority of successful transplants have been completed with HLA-identical siblings.[101,103] In a series from the United Kingdom, transplantation led to resolution of colitis and catch-up growth in children with growth failure.[104] The best predictors of success have been absence of overt preexisting infection at the time of transplantation and transplantation at a relatively early age, before numerous infections and end-organ damage have occurred. A comparison of outcome for children with CGD treated with conservative medical management, compared to those treated with stem cell transplantation, documented fewer infections and better growth after transplantation.[105] However survival was 90% for both transplanted and nontransplanted groups.

Many of the centers transplanting CGD patients have used a myeloablative preparative regimen. While engraftment has occurred in a high percentage of patients, the presence of concurrent infection has presented a significant risk for severe complications, and death has been common. The National Institutes of Health published its experience using a nonmyeloablative preparative regimen with T cell–depleted peripheral blood stem cells from HLA-identical siblings.[103] After a median follow-up of 17 months, 8 of 10 patients had sufficient neutrophils to provide normal host defense and resolution of granulomatous lesions.

Another center used marrow from matched unrelated donors; 7 of 9 patients were alive and well 20–79 months after transplantation. Restrictive lung disease was resolved in two of these individuals.

A prospective study from 16 centers in 10 countries worldwide was recently published.[106] Patients with CGD received hematologic stem cell transplantation (HSCT) from matched related or matched, unrelated donors after a reduced intensity conditioning regimen, administration of unmanipulated bone marrow, or peripheral blood stem cells. Fifty-six patients were enrolled of whom 75% were judged to be high risk because of infections or inflammatory complications. With a median follow-up of 21 months, overall survival was 93% and event free survival 89%. Two-year probability of survival was 96% and event free survival 91%.

With results of reduced conditioning regimens, some have suggested that stem cell transplantation should be the preferred choice performed early if a suitable donor is available. However, conventional medical management by many groups does not include IFN-gamma in addition to prophylactic antibiotics and antifungals. A single center U.S. study of 27 patients with CGD was presented of whom which 24 were compliant on the medical management with IFN-gamma, Bactrim, and an azole antifungal.[107] One was lost to follow-up and 23 were alive after 3276 patient months of follow-up with an infection rate of 0.62/patient year. No controlled comparison of medical management with HSCT is available. Although CGD can be cured by successful hematopoietic cell transplantation, the possibility of infections, graft failure and rejection, and graft-versus-host disease remain major impediments, and the risks and benefits must be weighed carefully with each individual patient. Patient selection and timing of bone marrow transplantation are timely areas for developing research.

Since CGD arises from gene defects in a finite group of proteins expressed in myeloid cells, transfer of a normally functioning gene into the pluripotent stem cell would, theoretically, constitute definitive treatment. The groundwork for this approach was laid with experiments in which Epstein-Barr virus–transformed B-lymphocyte or myelomonoblastic cell lines from CGD patients with various molecular defects were transfected with complementary DNA (cDNA) for the missing oxidase component. Partial correction of protein expression and oxidase activity was obtained.[21,108,109] Reconstitution *in vivo*, however, would require transfection of normal genes into pluripotent stem cells. To this end, $CD34^+$ peripheral blood hematopoietic progenitor cells were transduced with cDNA for p47phox, p22phox, or gp91phox.[110,111] Murine models of CGD have also provided useful information for successful application of human gene therapy trials.[112,113]

Malech and coworkers developed a model process for CGD gene therapy and employed it in a clinical trial of five patients with p47phox-deficient CGD.[114] $CD34^+$ progenitor cells were mobilized by granulocyte colony-stimulating factor infusion, harvested by apheresis, purified, then expanded *ex vivo* in the presence of growth factors. These expanded $CD34^+$ cells were transfected with cDNA for normal p47phox in a retroviral vector. The patients received 0.1 to $4.7 \times 10^6$ transfected cells/kg. After 3–5 weeks, low levels of blood neutrophils with normal ability to oxidize dihydrorhodamine were detected; but these cells declined to undetectable numbers over 3–6 months. Although the numbers of normal cells were too small to reconstitute the defect and the effect was not long-lasting, the general principles of this approach were demonstrated.

This experience was extended by Ott and colleagues.[115] After nonmyeloablative marrow conditioning with bulsufan, two young adults with X-linked CGD were treated with autologous $CD34^+$ stem cells that had been transfected with a retrovirus vector expressing gp91phox. Substantial gene transfer occurred in both individuals, and life-threatening infections resolved within the first few months. However, the level of gene-positive neutrophils subsequently rose as a result of oligoclonal outgrowth of cells in which the vector had inserted at the site of a proto-oncogene.[116] Bone marrow exam showed myelodysplasia with monosomy 7 in both men; one died of sepsis, and the other received an allogeneic hematopoietic stem-cell transplantation.[116,117]

Based on the clearance of severe infections achieved in the otherwise failed trial of Ott et al., Kang, Malech, and colleagues treated 3 adult X-linked CGD patients suffering severe, unresolving infections with a different retroviral vector encoding gp91phox after busulfan marrow conditioning.[118] The three patients had 26%, 5%, and 4% oxidase-normal neutrophils initially, but these normal cells declined over time. One of the patients with a sustained level of 1.1% normal cells cleared treatment-intractable liver abscesses and has been free of infection for 3 years; a second patient with 0.03% sustained normal-cell levels resolved his *Aspergillus* lung infection that had extended to ribs and vertebrae. The patient with no detectable normal cells by 4 weeks died of his *Paecilomyces* lung infection.[118] With improvements in viral vector profiles, stem cell culturing techniques, new sources of stem cells including induced pleuripotent stem cells, and site-specific gene editing platforms, the field of gene therapy continues to progress.[119,120] Although gene therapy has not yet cured a patient, with CGD the field clearly holds out hope for the future.

## Common Variable Immunodeficiency Disorders

Common variable immunodeficiency disorders is now the standard term[121] for a group of disorders that is almost always associated with pulmonary complications. The group is characterized clinically by onset in the first 5–10 years of life, or in mid-adolescence to young adulthood, of recurrent bacterial infections, especially sinusitis, pneumonia, and chronic pulmonary disease. Although not common, the disorder can begin in infancy. Autoimmune disease, gastrointestinal disorders, and a predisposition to lymphoma are less commonly associated conditions. The group is characterized immunologically by decreased production of IgG in combination with low levels of IgA and/or IgM, weak or absent antibody response to immunizations, and absence of any other immunodeficiency state.

The condition was once thought of as a single entity and was initially referred to as “late-appearing (or ‘acquired’) hypogammaglobulinemia.” It was diagnosed in males and females and after infancy, and this term differentiated it from the earlier-described congenital X-linked agammaglobulinemia (XLA). As more cases were described, it was given the name “common variable immunodeficiency” (OMIM 240500). The condition is aptly named—it is common, at least among primary immunodeficiency diseases, with an estimated rate in the population of 1 in 25,000–30,000[122–125] and its clinical presentation and underlying immune cellular defects vary widely. It is apparently the expression of several different conditions with multiple underlying single-gene or polygenic defects. Although it is not clear what most of those may be, it is nevertheless appropriate that the new term for the group (used in our title) emphasizes a family of disorders. In describing the *diagnosis* applied to patients within the group, we will use the abbreviation CVID to mean a common variable immunodeficiency disorder.

## Clinical Features

Major reviews of 248 CVID patients from the United States,[124] 252 patients from France,[126] and 334 patients from the European Common Variable Immunodeficiency Disorders registry,[125] a collaborative analysis by two of the principal authors of these reviews,[127] and a review of CVID in children[128] have greatly expanded understanding of these disorders, recent summaries have broadened our current knowledge of these diseases.

The fundamental feature of CVID is insufficient production of antibodies to pathogens. Thus, almost all patients have a history of serious or recurrent infections (e.g., all but 5 of 248 patients in the U.S. cohort).[124] Table 63.5 summarizes the most common infections that occurred in the American and French cohorts, and the list reflects the experience at other centers (in particular those in references 125 and 127 and citations contained therein).

**Table 63.5**

**Summary of Most Common Infections in Two Large Cohorts of Patients With Common Variable Immunodeficiency Disorder**

| | Number of Patients of Total 248[124] (%)[a] | Number of Patients of Total 252[126] (%)[a] |
|---|---|---|
| Recurrent bronchitis, sinusitis, and/or otitis | 243 (98) | |
| Respiratory and lung infections (total) | | 240 (95) |
| Pneumonia | 190 (77) | 147 (58) |
| Chronic lung disease, including bronchiectasis | 68 (27) | 92 (37) |

| | | |
|---|---|---|
| Viral hepatitis | 16 (7) | |
| Severe or recurrent herpes zoster infection | 9 (4) | 27 (11) |
| Severe varicella infection | | 10 (4) |
| *Giardia* enteritis | 8 (3) | 35 (14) |
| *Pneumocystis* infection | 7 (3) | 2 (1) |
| *Mycoplasma* pneumonia | 6 (2) | |
| *Salmonella* or *Campylobacter* enteritis | 6 (2) | 38 (15) |
| Osteomyelitis or septic arthritis (2 each) | 4 (2) | |
| Chronic mucocutaneous candidiasis | 3 (1) | |
| Bacteremic sepsis | 3 (1) | 33 (13) |
| Bacterial meningitis | 2 (<1) | 20 (8) |

[a] Number of patients (%) with the infection among the total studied.

Adapted from references 124 and 126 and their accompanying texts. Reference 124 reports the experience of an academic medical center in New York City, U.S.A. Fifteen percent of the 248 patients developed symptoms between 2 and 10 years old (mean age 23 years for males, 28 years for females). Reference 126 reports the experience of a French national study of adults with primary hypogammaglobulinemia. Fifty-nine percent of the 252 patients developed symptoms between 4 and 10 years of age (median age at onset = 19 years).

Recurrent or chronic bronchitis, sinusitis, and/or otitis media occur in almost all patients and are the most common infections at onset of symptoms.[124–130] The microorganisms most commonly cultured before the diagnosis is made and treatment started are those that require antibody for optimal opsonization and phagocytosis, particularly pneumococci, *Haemophilus influenzae,* and streptococci. After treatment has been started with intravenous immunoglobulin (IVIG), infections are more likely to be caused by staphylococci or an enteric pathogen, fungi (e.g., *Candida, Pneumocystis, Nocardia*), a virus (varicella-zoster virus, enteroviruses, hepatitis viruses), protozoa (especially *Giardia*), or *Mycoplasma.*[123–133] In a review of 20 patients diagnosed with CVID and an enteroviral infection, 14 had ECHO or Coxsackievirus infection and 6 had poliomyelitis, particularly due to live polio vaccine.[132]

The clinical findings in 32 children with CVID[130] were very similar to those described in the large reviews of patients of all ages (see Table 63.5). Recurrent or chronic respiratory tract infections (88% of the children), sinusitis (78%), otitis media (78%), pneumonia (78%), bronchiectasis (34%), and intestinal tract infections (34%) were the most common infections. Two children had polio after live poliovirus immunization. An allergic disorder was present in 38% of the children and an autoimmune condition in 31%. The mean time between onset of symptoms and institution of immunoglobulin substitution therapy was 5.8 years.

On physical exam, evidence of complications may include growth retardation (9 of the 32 children)[130] or weight loss (adults), changes associated with chronic otitis or sinusitis, lymphadenopathy, splenomegaly, gingivitis, poor dentition, and signs of chronic pulmonary disease.[123–130]

Gastrointestinal disease occurs in roughly a quarter to a third of patients (15%–47% depending on what conditions are included),[124,126,128,134,135] perhaps especially in those who have an accompanying defect in cell-mediated immunity.[134] These may be caused by infection, cancer, or autoimmune or inflammatory disease. Chronic diarrhea is the most common symptom. The etiology is not always known, but infections with *Giardia, Salmonella or Campylobacter* (see Table 63.5, CMV, or *Cryptosporidium* have been reported.[124,126,128,135]

Autoimmune disease develops in 20%–25% of individuals with CVID, most often expressed as autoimmune hemolytic anemia or thrombocytopenic purpura, but also as rheumatoid arthritis, pernicious anemia, immune neutropenia, inflammatory bowel disease, or almost any known autoimmune condition.[124,126,136,137] Patients with CVID are at increased risk for malignancies, with particular susceptibility to non-Hodgkins lymphoma and gastric cancers, but other malignancies have been described.[123–125,128,138,139] Polyclonal lymphocytic infiltration expressed as enteropathy, persistent lymphadenopathy, splenomegaly, organ granulomas, or granulomatous/lymphocytic pulmonary disease, in various combinations, is one of the major phenotypes of CVID.[125]

## Pulmonary Complications

Lung disease is the most common serious problem in patients with CVID,[124,128,129,140–143] accounting for disabling morbidity and early mortality. In large clinical studies a quarter to about half of the patients had chronic lung disease including bronchiectasis, or restrictive or obstructive lung disease.[124,139,141,142] Bronchiectasis can be seen in children under 3 years of age as a result of infection and the inflammation it elicits; and it can be the presenting symptom of CVID at almost any age. Some patients have been tested for immunoglobulin levels as an afterthought on their way to resection of a bronchiectatic segment of lung. In children who carry a diagnosis of CVID, the almost universal presence of chronic bronchitis may delay diagnosis of a more serious pulmonary disease.

In one study of B-cell immunodeficiency in subjects over 18 years old, 75% of whom had CVID, bronchiectasis was detected by chest computed tomography (CT) exam, but not by chest radiograph in 8 of 19 patients; the presence of bronchiectasis by CT did not correlate with either the presence of clinical symptoms (cough, sputum, fever) or abnormalities on pulmonary function tests.[144]

Noninfectious pulmonary disease becomes common beginning in adolescence and early adulthood.[136] Granulomatous lung disease, lymphocytic interstitial pneumonia, follicular bronchiolitis, and lymphoid hyperplasia have been grouped in patients with CVID under the term granulomatous-lymphocytic interstitial lung disease (GLILD).[142,143,145–147] An example of radiographic findings from a patient with GLILD is included in Fig. 63.5. This CVID subgroup is at high risk for early mortality and B-cell lymphomas (median survival 14 years versus 29 years in other CVID groups in one careful study).[142] Human herpesvirus 8, a B-cell lymphotrophic virus, was isolated from 6 of 9 CVID patients with GLILD, 1 of 21 CVID patients without GLILD, and no controls; one CVID-GLILD patient later developed a B-cell lymphoma.[147] Granulomatous lung disease in CVID patients has been diagnosed as sarcoidosis.[124,144,146,148]

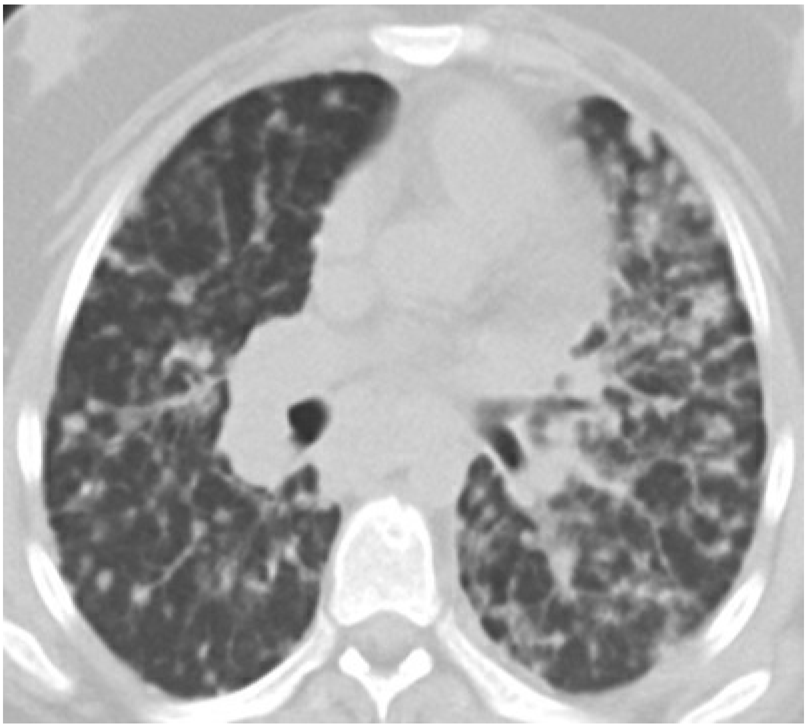

**FIG. 63.5** Computed tomography scan of a 16-year-old with biopsy proven granulomatous-lymphocytic interstitial lung disease. Extensive nodular infiltrates throughout both lung fields and interstitial thickening with associated mediastinal and subcarinal adenopathy. (Image courtesy of Robin Deterding, MD.)

## Laboratory Findings and Diagnosis

The characteristic findings in CVID are levels of IgG that are two standard deviations or more below age-adjusted means[124,128] and decreases in IgM and/or IgA meeting the same criteria. If first-drawn immunoglobulin levels are low, these should be repeated to exclude the possibilities of lab error, and the patient's response to both protein and polysaccharide vaccines should be tested. A normal response should be greater than a two-fold rise from baseline.

Most patients with CVID have normal numbers of circulating B and T lymphocytes, but some patients have decreased levels of circulating phenotypic memory (CD27+) B cells or isotype-switched memory B cells (CD27+ IgD− IgM−).[149–151] Some have mildly abnormal T-lymphocyte function or phenotypic T-cell markers, including T-lymphocyte proliferation in response to standard mitogens and antigens, decreased CD4+ cells and thus CD4/CD8 ratio, reduced numbers of T-regulatory cells, reduced CD19+ B cells, altered expression of interleukin (IL)-2 and other cytokines, defective T-cell receptor signal transduction, and defective Toll-like receptor (TLR) 7 and 9 function in lymphocytes and dendritic cells.[124,125,128,149–158] These phenotypic and functional lymphocyte abnormalities are rarely needed to make the diagnosis of CVID, but they are becoming increasingly important in understanding clinical phenotype and prognosis,[150–154] and they will become even more important as genetic defects are matched with these abnormalities. For example, 9% of 313 CVID patients in the French national registry presented with late-onset combined immunodeficiency associated with opportunistic infections, marked decrease in CD4+ T cells, and increased risk of granulomatous disease, gastrointestinal disease, and lymphoma.[159]

Because CVID is a diagnosis of exclusion, other conditions that may have an almost identical phenotype in some cases must be considered. These include XLA, hyper-IgM syndromes, and transient hypogammaglobulinemia of infancy. In the last case, cellular immunity (abnormal in about 40% of CVID patients) and response to immunization (abnormal by definition in CVID) are typically normal, and the condition is usually gone by 24 months. XLA results from any of several hundred mutations in the gene *Btk*, and the condition typically presents with absence of B cells and infections within the first 2 years of life. However, hypomorphic *Btk* mutations can allow some B-cell formation and IgG levels that are only moderately depressed or even normal.[42,160,161] As many as 10% of CVID patients may have decreased numbers of B cells, but these are usually well above levels in *Btk* deficiency.

## Molecular Defects and Inheritance

It is likely that CVID results from a variety of genetic defects. Most of these probably arise from sporadic mutations, but approximately 10% of patients have family members with CVID or another humoral immune abnormality.[162] Gene defects associated with CVID are beginning to be identified. One of these is the recessive gene for inducible costimulator of activated T-cells (ICOS) on chromosome 2q, which is thought to be important in signaling T-cells for T- and B-cell cooperation.[163–165] One patient with ICOS deficiency presented at 18 months of age, but most developed recurrent sinopulmonary infections in adolescence or young adulthood.[163] Another CVID-associated gene encodes transmembrane activator and calcium-modulator and cyclophilin ligand (TACI) found on chromosome 17p. TACI is expressed on B-cells and CD4+ T-cells and is involved in isotype switching.[166,167] Mutations in this gene are found in 8%–10% of CVID patients and are associated with susceptibility to CVID rather than directly causing it.[167,168] A defect of B-cell activating factor of the tumor necrosis factor family receptor (BAFF-R) encoded on chromosome 22q was described in siblings from one family.[169] Homozygous or compound heterozygous mutations in the gene for CD19 on chromosome 16p can be associated with a CVID phenotype.[170,171] Several other monogenetic defects can result in the phenotypic expression of CVID,[128,129] and it is likely more will be described in the future.

## Management

As with other immunodeficiency states, prompt identification of the site of infection and infecting organism and prompt administration of antimicrobial therapy will expedite resolution and reduce the chronic complications. Treatment for an extended period may be required. Administration of prophylactic antibiotics has not been studied and remains controversial. Immunizations may not be useful since these patients have poor responses, but they are still recommended.[172] Although no adverse events have been reported with live vaccines, caution should be used when considering these.

Treatment for infections should be guided by results of cultures. For acute exacerbations of bronchiectasis or sinusitis, both driven by cycles of infection and scarring, options include amoxicillin-clavulanate, cephalosporins, or fluoroquinalones (except ciprofloxacin) for 2–4 weeks. Inhaled glucocorticoids may reduce the cough and dyspnea with bronchiectasis, but they should be used sparingly, and the patient's condition should be monitored with pulmonary function testing and CT scans.

Immunoglobulin replacement has led to major improvement in the management of infections in CVID, preventing acute infections and slowing progression of chronic infections.[173] It may be given intravenously every 3–4 weeks or subcutaneously if venous access is poor, or to circumvent severe reactions to intravenous administration. The usual starting dose is 300–400 mg/kg to keep trough IgG levels (drawn just before administering the next dose) in the middle of the reference range. Higher doses, up to 1 g/kg, may be required,[174] for example, to treat development of central nervous system or systemic (muscle and liver) enteroviral infection, to which CVID patients are predisposed.[132] Immunoglobulin replacement therapy will be needed for the lifetime of the patient, monitored as IgG trough levels and adjusted as indicated. Patients with noninfectious, autoimmune disorders may require immunosuppressive therapy, but this should be undertaken cautiously. Glucocorticoids are first-line treatment for the autoimmune cytopenias; higher doses of IVIG may also be considered.[175,176] Splenectomy should be considered as a last resort, as it may increase the risk for subsequent severe infections.[177] Rituximab has been used successfully in CVID patients with cytopenia.[177,178] CVID patients should be monitored for signs and symptoms of lymphoid malignancy, gastric cancer, and other malignancies and have age-appropriate cancer screening.[124,128]

We are unaware of established treatment guidelines or controlled trials to inform optimal management of GLILD in patients with CVID. Anectdotal experience has shown general improvement in symptoms with corticosteroid treatment.[143] Exercise testing and full pulmonary function testing can be used to monitor the effects of therapy. CT radiographic abnormalities may not resolve though symptoms improve with corticosteroids. Cyclosporin and monoclonal antibody therapy against TNF-$\alpha$ or CD 20 expressed on B cells have been tried, but the experience is limited.[143]

With the advent of immunoglobulin replacement and aggressive management of infections, the risk of death from infection has been reduced dramatically. Nearly two-thirds of patients survive 20 years beyond the diagnosis.[124,128] The highest mortality rates currently are seen in patients with bronchiectasis, GLILD, and noninfectious complications.[125,142]

# Other Immunodeficiencies With Pulmonary Manifestations

The estimated worldwide prevalence of primary immunodeficiencies (PIDs) likely exceeds 1 in 1000.[179] They can affect each branch of the immune system with characteristic pulmonary manifestations both infectious and noninfectious. Adaptive immune responses are triggered by binding of microbial antigens to B-cell and T-cell receptors, which have a high degree of antigen specificity. Isolated B-cell or combined B- and T-cell immunodeficiencies develop as a consequence of abnormal B- and T-cell development. Pattern recognition receptors recognize molecular patterns of microbes with less specificity. They are expressed on innate immune cells, neutrophils, macrophages, dendritic cells, and natural killer (NK) and NKT-cells. Complement activation facilitates elimination of microbes by phagocytes and links innate and adaptive immune responses.[180] Primary immunodeficiencies that also present with characteristic pulmonary manifestations are B-cell deficiencies in general, not only CVID, combined cellular and humoral immunodeficiencies, and deficiencies of the innate immune system.

## B-Cell Immunodeficiencies

Primary B-cell immunodeficiencies with antibody deficiency are most common and affect 65% of all patients with PID.[181] They include milder forms such as transient hypogammaglobulinemia of infancy (6.8%), selective IgA deficiency (18.7%), IgG subclass deficiency (12%), specific antibody deficiency (1.2%), and more severe forms such as CVID (37.5%) and agammaglobulinemia (10.7%).[182,183] The onset and severity of infections are dependent on the underlying defect. Pulmonary infections and complications that may occur later in life can be similar to those described for CVID. Children with profound or absent antibody deficiency as in XLA usually present with severe bacterial infections after 3–6 months of life when *in-utero* acquired maternal IgG antibodies decline. During infancy, *Pneumocystis jiroveci* pneumonia has been described. In contrast to infants with severe combined immunodeficiency (SCID), infants with XLA show a normal thymic shadow on chest x-ray.[184]

The initial diagnostic workup for all suspected antibody deficiencies includes a complete blood cell count (CBC), lymphocyte phenotyping to determine the number and percentage of CD19 and/or CD20-positive B-cells, measurement of serum immunoglobulins and specific antibody concentrations to protein and polysaccharide vaccines that should be remeasured 4 weeks after revaccination, and IgG subclasses as indicated. In XLA and other antibody deficiencies with profound reduction in all serum immunoglobulin classes, B-cells are severely decreased or absent. The diagnosis of XLA can be confirmed by lack of *BTK* protein expression in monocytes by flow cytometry and gene sequencing. Genetic testing panels for antibody deficiencies are available for clinical use.

The mainstay of treatment for antibody deficiency is intravenous or subcutaneous immunoglobulin G substitution, antibiotic prophylaxis and therapy, and prevention of bronchiectasis and other pulmonary complications.

## Combined Cellular and Humoral Immunodeficiencies

Combined cellular and humoral immunodeficiencies include SCID, a medical emergency during infancy, and milder forms such as X-linked hyper-IgM syndrome (CD40-ligand deficiency), DiGeorge syndrome, ataxia telangiectasia (AT), and hyper-IgE syndromes.[185] Unexplained infections with opportunistic pathogens should raise concern for a combined immunodeficiency. When suspected in infancy, live vaccines are contraindicated, and only irradiated, CMV-free blood products should be used for transfusions.

## Severe Combined Immunodeficiencies

SCID present early during the first year of life with recurrent infections by bacteria, viruses, fungi, and opportunistic pathogens.[185] The incidence is estimated as 1 in 50,000 newborns. Infants present with lymphopenia and hypogammaglobulinemia. Recurrent pneumonia with *P. jirovecii,* parainfluenza 3 virus, RSV, CMV, adenovirus, or bacteria may occur, at times as simultaneous infection with multiple pathogens. Infants are affected by chronic diarrhea, failure to thrive, oral thrush, and diaper rashes. The thymic shadow on chest x-ray and lymphoid tissue are absent. As of 2014, 14 different genetic mutations causing SCID had been described, with mutations in the *IL-2RG* coding for the common gamma chain of receptors for cytokines IL-2, -4, -7, -9, -15, and -21 causing X-linked SCID being most frequent.[186] Currently, 42 states in the U.S. are conducting newborn screening for SCID by quantifying T cell receptor excision cycles (TRECs) in newborn blood.[187] TRECs are absent or significantly reduced in SCID.

Infants with SCID can present with respiratory distress due to viral and fungal, or bacterial pneumonia. On chest x-ray, a thymus is absent.[184] Hyperinflation, atelectasis, and bilateral, diffuse interstitial changes with nodular opacities may be present in viral pneumonitis.[184] Acute *P. jirovecii* pneumonia and Candida infections can also present with bilateral nodular or granular opacities.[184] Candida infections can be invasive and cause abscess formation.[184] Autosomal-recessive adenosine deaminase (ADA) deficiency is associated with chondro-osseous dysplasia, and flaring of the costochondral junctions can be seen on chest x-ray.[184,188] Interstitial inflammatory infiltrates can occur in ADA deficiency due to the metabolic defect and not related to infection.[189]

The diagnostic workup for suspected SCID includes a CBC, lymphocyte phenotyping to determine the number of T-cells, recent thymic emigrant T-cells (CD4/CD45RA/CD31-positive), naïve (CD4/CD45RA-positive) and memory (CD4/CD45RO-positive) T-cells, lymphocyte function testing with mitogen and antigen stimulation, and measurement of serum immunoglobulins. T-cells are usually low or absent, and B-cells are dysfunctional. The presence or absence of B- and/or NK-cells directs the initial genetic workup. In the absence of T-, B-, and NK-cells and suspected ADA deficiency, one of the most severe forms of SCID, ADA catalytic activity can be measured in hemolysates and peripheral blood mononuclear cells (PBMC), and is usually less than 1% of normal activity. Genetic testing for single gene defects and SCID-gene panels are available to determine the underlying defect. If a diagnosis cannot be confirmed, whole exome or genome sequencing should be considered.[190]

Treatment for SCID includes prevention of viral, fungal, and bacterial infections with antimicrobial therapy, immunoglobulin G replacement, HSCT, and in selected cases, e.g. ADA deficiency, enzyme replacement therapy. Bone marrow transplantation during early infancy without prior infections have resulted in greater than 90% survival of infants with SCID.[191]

## Ataxia Telangiectasia

AT is an autosomal recessive inherited neurodegenerative disease with associated combined immunodeficiency due to mutations in the *ATM* gene, which codes for a protein relevant for DNA repair. Patients present during childhood with progressive loss of motor function and telangiectasias visible on sclerae and skin.

Pulmonary manifestations of AT include recurrent upper and lower respiratory infections complicated by bronchiectasis, ILD, and respiratory symptoms related to neuromuscular and bulbar abnormalities.[192] Often a combination of these phenotypes occurs. The progressive neurodegenerative process contributes to a weak cough and respirations, which decrease effective clearance of respiratory secretions. Coughing and choking during meals increase the risk of aspiration. ILD should be considered in patients with a chronic nonproductive cough, dyspnea, crackles on exam, and fever in the absence of viral or bacterial infections.[192,193] In a retrospective chart review by Schroder et al., ILD was described as a poor prognostic factor.[193] Nineteen of 25 patients with AT and ILD died within 2 years.[193] Eleven of these 25 had developed pneumothoraces as a complication of ILD. Six patients with pneumothoraces refractory to therapy died within 6 months after diagnosis.[193]

The diagnostic workup of cellular and humoral immunity in AT includes a CBC, lymphocyte phenotyping, assessment of lymphocyte function by stimulation of PBMC with mitogens and antigens, serum immunoglobulins and specific antibody titers to vaccines; it may show a varying pattern of cellular and humoral immunodeficiency. Regular lung function testing is advised to follow the restrictive lung disease process. Due to increased radiosensitivity, imaging that exposes patients to ionizing radiation should be minimized. A chest CT can be helpful when concern about bronchiectasis or ILD arise.

Therapy for pulmonary manifestations in AT include oral or intravenous antibiotics for respiratory infections, immunoglobulin G substitution when indicated, airway clearance assistance, speech therapy and other interventions to minimize airway aspiration, supplemental oxygen, and noninvasive respiratory support. A trial of oral corticosteroids may be helpful for ILD.

## Hyper-Ige Syndromes

Hyper-IgE-syndromes (HIES) share as common features an elevated serum IgE, eosinophilia, eczema, and sinopulmonary infections. Mutations in the genes coding for signal transducer and activator (STAT) 3, dedicator of cytokinesis 8 (DOCK8), and nonreceptor tyrosine-protein kinase 2 (Tyk2) have previously been described to cause HIES phenotypes; more recently mutations in *PGM3* (phosphoglucomutase 3) have been added.[194,195] Autosomal dominant HIES or classical Job syndrome presents in infancy with a pustular rash or later with skeletal, connective tissue, and vascular abnormalities, which include a characteristic facies, retained primary teeth, recurrent fractures, and scoliosis. Characteristic pulmonary manifestations include recurrent bacterial pneumonia with predominantly *Staphylococcus (S.) aureus,* formation of pneumatoceles due to abnormal healing and bronchiectasis, and superinfection with gram-negative bacteria, nontuberculous mycobacteria, and fungal infections after parenchymal damage has occurred. *P. jirovecii* pneumonia may occur in infancy. STAT3 deficiency affects different signaling pathways, which helps explain abnormal healing and a lack of systemic inflammation during bacterial infections.[196] Autosomal recessive DOCK8 deficiency presents with significant cutaneous viral infections and pulmonary infections complicated by bronchiectasis.[197] The rare form of autosomal recessive Tyk2 deficiency is associated with mycobacterial infections due to an associated defect in the IL-12, IFN-$\gamma$, STAT1 pathway.[198] Neurologic abnormalities, cytopenias, and pulmonary infections with bronchiectasis are characteristic of

PGM3 deficiency.

The diagnostic workup includes a CBC with differential cell count, lymphocyte phenotyping with assessment of memory T and B cells, measurement of serum immunoglobulins, and specific antibody concentrations. Eosinophilia is common, memory T and B cells are decreased with normal lymphocyte numbers, and serum IgE is increased with usually normal IgM, IgG, and IgA; specific antibody concentrations can be low. Genetic testing panels for HIES are available.

Therapy is mainly supportive in autosomal dominant HIES with targeted antimicrobial therapy, antibiotic prophylaxis for *S. aureus* and fungal infections, reduction in *S. aureus* skin colonization with bleach baths, and immunoglobulin G replacement therapy in patients with relevant antibody deficiency. Successful HSCT has been conducted in DOCK8 deficiency.[199]

## Deficiencies of the Innate Immune System

Rare deficiencies of the complement system, impaired signaling though nuclear factor kappa-light-chain enhancer of activated B cells (NFκB), and Mendelian susceptibility to mycobacterial infections present with characteristic pulmonary infections.

Deficiencies of early complement components (C1–C4) increase susceptibility to pyogenic infections, including recurrent pneumonia similar to antibody deficiency.[200] Decreased total complement activity (CH50) with normal alternative complement pathway activation (AH50) points towards an early complement deficiency. Mannose-binding lectin (MBL) deficiency has also been associated with a predisposition to more severe respiratory tract infections.[201] In patients with recurrent and severe respiratory infections and normal cellular and humoral immunity, a complement screen with CH50 and AH50 should be considered; MBL serum concentrations can also be measured.

Innate immunodeficiencies with impaired signaling through NFκB will decrease the cellular immune response that would otherwise be initiated by engagement of all Toll-like receptors (TLRs; except TLR3) and several other immune receptors including IL-1, T-, and B-cell receptors.[202] Autosomal deficiencies in interleukin-1 receptor-associated kinase 4 (IRAK-4) and myeloid differentiation primary response protein 88 (MyD88), which are essential for TLR signaling, present during early childhood with invasive bacterial infections and bacterial pneumonia with predominantly *Streptococcus pneumoniae,* in the absence of fever or an increase in C-reactive protein. The severity of infections decreases over time as adaptive immunity improves. Patients with immunodeficiency due to mutations in the gene for NFκB, essential modulator (NEMO; *IKBKG* gene) and deficiency in NFκB inhibitor alpha (IκB$\alpha$; NF-κBIA gene) present similarly, but are also affected by mycobacterial, opportunistic, and severe viral infections. Anhidrotic ectodermal dysplasia occurs in greater than 90% of patients with NEMO. TLR function can be assessed by measuring cytokine production (e.g. IL-1, IL-6, TNF-$\alpha$) by PBMC after stimulation with TLR-specific ligands; absent cytokine production raises concern for immunodeficiency related to impaired NFκB signaling. Genetic testing will aid in determining the underlying defect.

Mendelian susceptibility to mycobacterial disease (MSMD) is caused by deficiencies in the IL-12/IL-23/IFN-$\gamma$ pathway involving macrophages, T-, and NK-cells. Children may present early in life with mycobacterial and Salmonella infections due to inadequate production of IFN-$\gamma$ or insufficient responses to IFN-$\gamma$. Relevant autosomal recessive and dominant mutations have been described in 10 genes, including *IL12B, IL12RB1, IFNGR1, IFNGR2, STAT1, NEMO, CYBB, TYK2, IRF8,* and *ISG15.*[203,204] The diagnostic workup, which is offered in select laboratories, includes measurement of IFN-$\gamma$ and IL-12 serum concentrations, IFN-$\gamma$ receptor expression on lymphocytes, IL-12 receptor expression on PBMC after stimulation with phytohemagglutinin (PHA), STAT1 expression in monocytes, and sequencing of respective genes. Depending on the underlying defect, therapeutic options include therapy with recombinant IFN-$\gamma$ or HSCT.[204]

# Pulmonary Disease in the Pediatric Patient With Acquired Immunodeficiency States

*Jonathan Spahr MD, Daniel J. Weiner MD, Dennis C. Stokes MD, Geoffrey Kurland MD*

## Introduction

Acquired immunodeficiency in children can be the result of a variety of diseases or their treatments. The majority of acquired immunodeficiency states, however, are the result of medical treatments that include pharmacologic, surgical, and radiotherapeutic regimens for the treatment of oncologic diagnoses. In addition, the expanding population of children receiving solid organ transplants is exposed to immunosuppressive medications to prevent graft rejection. Ablation chemotherapy combined with radiation used to prepare patients for hematopoeitic stem cell transplantation (HSCT) can produce direct toxicity to the lungs while rendering these patients temporarily pancytopenic and thus at risk for infectious complications. As a result, pulmonary disease in these patients is relatively common, and often results in significant morbidity and mortality.

This chapter will discuss pulmonary complications of solid organ transplantation, HSCT, and treatment of childhood oncologic disease. Included in these potential complications are pulmonary infections, and this will be the focus of the initial portion of this chapter. In addition, there are important noninfectious complications that will be addressed; some of these are specific to underlying conditions and their treatments.

Pulmonary complications of lung transplantation, human immunodeficiency virus (HIV)–associated acquired immunodeficiency syndrome (AIDS), and congenital immunodeficiencies are discussed in separate chapters (Chapters 67, 66, and 63, respectively). Lung injury caused by pharmacologic agents, including chemotherapeutics, is discussed in Chapter 59.

## Pulmonary Infections in the Immunocompromised Pediatric Host

Immunocompromised pediatric patients include patients with congenital defects of innate host defenses including neutrophil abnormalities, defects affecting lymphocyte function, and defects of humoral immunity. The number of entities leading to such defects is rapidly expanding, with improved recognition of the nearly 300 clinical phenotypes associated with single-gene mutations affecting immune function.[1] The major expansion of the population of immunocompromised children, however, has occurred with increased human stem cell and solid-organ transplantation, successful treatment of childhood malignancies, the AIDS epidemic, and the use of biologic agents such as inhibitors of tumor necrosis factor (TNF)-alpha for a variety of autoimmune diseases of childhood. In addition to increasing the at-risk population, these developments have also led to an increase in the number of identifiable pathogens. The term *opportunistic pathogen* is usually reserved for an organism typically infecting a patient with abnormal host defenses. The terms *immunodeficiency* and *compromised host* were first used in the 1960s and 1970s, for patients with primary immunodeficiency and for those patients who survived childhood malignancies.[2] This portion of the chapter will review some of the more common pulmonary infections in this patient population.

## Clinical Presentation of Pulmonary Infection in the Immunocompromised Child

The clinical presentations of pulmonary infection in the immunocompromised child are often nonspecific, and a high index of suspicion for atypical or opportunistic pathogens is required. Childhood cancer therapy, HSCT, solid organ transplantation, primary immunodeficiencies, and AIDS are each associated with specific pulmonary pathogens (Table 64.1).

**Table 64.1**

**Typical Pulmonary Pathogens Associated With Acquired Immunodeficiency States**

| | Bacterial | Fungal | Viral/Protozoal/Other |
|---|---|---|---|
| **NEUTROPENIA** | | | |
| Chronic | *Haemophilus influenzae*, *Streptococcus pneumoniae*, *Staphylococcus aureus*, *Klebsiella* spp. | — | — |
| Acute | *S. aureus* | — | — |
| Immunosuppressive Therapy | *S. aureus*, *Listeria* spp., *Mycobacterium tuberculosis* | *Aspergillus* spp., *Mucor* spp., *Histoplasma* spp., *Pneumocystis jirovecii* | Cytomegalovirus (CMV), VZV, *Toxoplasma* spp., Herpes simplex virus, *Cryptococcus* spp. |
| **BONE MARROW TRANSPLANT** | | | |
| Early (<30 days) | *Pseudomonas* spp., other gram-negative and gram-positive spp. | *Candida* spp. | — |
| Late (>30 days) | *S. aureus* | *Aspergillus* spp., *P.* | CMV, *Toxoplasma* spp., |

|  |  |  |  |
|---|---|---|---|
|  |  | *jirovecii* | VZV, Epstein-Barr virus, adenovirus |
| Late (>100 days) | Encapsulated Gram-positive *(H. influenzae, S. pneumoniae)* | — | VZV |

In addition, these patients often have an atypical or more severe course even when infected with a "usual" childhood respiratory pathogen.[3] For example, viruses such as varicella-zoster, influenza, and measles are all capable of leading to devastating pulmonary infections in the immunocompromised host. Although adenovirus (AdV) can cause diffuse pneumonia in any child, it can be particularly common[4] and catastrophic in immunocompromised hosts.[5–7]

The clinical course of opportunistic infections is variable and affected by the type and degree of remaining host defenses. For example, fungal pulmonary infections in patients with chemotherapy-induced neutropenia and defective cell-mediated immunity are often associated with mild clinical symptoms and radiographic findings until the normalization of peripheral blood neutrophil counts leads to significant inflammation, lung destruction, pulmonary cavitation, and clinical deterioration. The interplay of fungal pathogens with the innate and adaptive immune systems is still under investigation. It is clear that fungi can both subvert and exploit the host immune response, allowing for chronic carriage or pathogenicity. This complex response is likely mediated by various molecular interactions involving cytokines as well as cellular elements.[8–11]

## Infectious Risks Shared by Malignancy, Solid Organ Transplantation, and Stem Cell Transplantation

The immune system has multiple components. Disorders of the immune system can be divided into those involving *innate* and *adaptive* components.[1] There are physical barriers to infectious agents, including skin and airway epithelial cells. Humoral components of the immune system include immunoglobulins, complement, and other nonspecific antibacterial molecular species (e.g., defensins) important to innate pulmonary defenses.[12] Cellular components include phagocytic cells, particularly neutrophils, and lymphocytes. A more complete description of the development, interactions, and defects of each of these components is presented in Chapters 8 and 63.

Patients undergoing treatment for malignancy, HSCT, or solid organ transplant have periods of immunosuppression that vary in length and severity. The recovery of the immune system after myeloablative conditioning followed by HSCT, for example, can be divided into three phases. The *preengraftment or early phase,* from day 0 to day 30 or sooner, encompasses the time of marrow recovery leading to normalization of the peripheral neutrophil count; the *postengraftment phase* is considered day 30 to day 100 after HSCT; and the *late phase* follows day 100 post HSCT. For patients with HSCT, each phase is characterized by a susceptibility to certain types of infections correlating with the status of the immune system at that time point.[13] Following solid organ transplantation, many patients initially receive intensive immunosuppressive therapy, leading to a more immunosuppressed state early in the posttransplant period. Patients with malignancies often receive chemotherapy in a cyclic pattern, leading to periods of severe marrow suppression followed by periods of recovery.

Fig. 64.1 demonstrates different phases of immunodeficiency in which certain infectious organisms may predominate. As occurs with individuals who are not immunosuppressed, respiratory viruses and community-acquired bacteria are quite common in the individual who is immunosuppressed. Those who are immunosuppressed, however, have a greater propensity for infection, with a wider variety of organisms (the opportunistic infections). A recent publication reviews radiological findings in children with acquired immunodeficiency states following cancer chemotherapy and is a useful reference for the evaluation of these patients.[14]

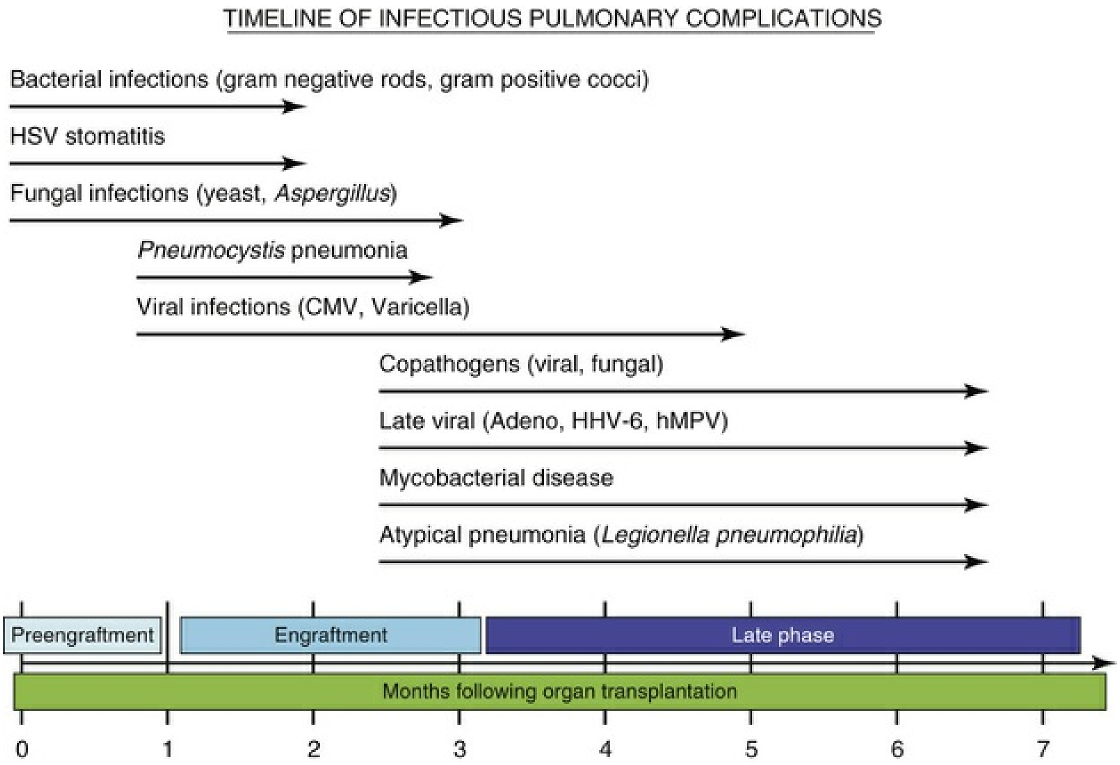

**FIG. 64.1** Timeline of infectious pulmonary complications following solid-organ transplantation. *CMV,* Cytomegalovirus; *HHV-6,* human herpesvirus 6; *hMPV,* human metapneumovirus; *HSV,* herpes simples virus.

# Common Pulmonary Infectious Agents in the Immunocompromised Pediatric Host

## Viral Pathogens (See Also Chapter 25)

### Cytomegalovirus

Cytomegalovirus (CMV) is a common herpesvirus infection of both neonates and older immunocompromised children.[15,16] Viral carriage does not always lead to disease, however, and the progression from carriage to disease depends on many factors, including the age and the immune status of the infected individual. The organism can be acquired *intrapartum* or from breast milk, saliva, or blood (via infected white cells). CMV infection in the immunocompetent hosts rarely results in overt disease, and humoral and cellular immune mechanisms are important in limiting the infective capabilities of CMV. Such hosts that have latent CMV are seropositive, rendering them at-risk for viral reactivation in the event of immunocompromise. Individuals who are CMV-seronegative prior to either immunosuppression following transplantation or chemotherapy are at increased risk of CMV disease through CMV acquisition from de novo infection, from blood products containing virions, or from transplanted organs from CMV-seropositive individuals.

CMV-infected cells typically contain basophilic nuclear inclusions surrounded by a clear halo, giving an "owl eye" appearance; such inclusions are typically seen in alveolar cells. The pathology of CMV pneumonitis varies from diffuse, discrete parenchymal hemorrhagic nodules to diffuse alveolar damage, or chronic interstitial pneumonitis. The radiographic pattern of CMV pneumonia is usually a diffuse reticulonodular pattern that is less "alveolar" than is seen in pneumonia caused by *Pneumocystis jirovecii* (described later). High-resolution computed tomography (CT) of the chest most commonly reveals patchy or diffuse ground-glass attenuation, and more diffuse pulmonary involvement may be predictive of the progression of disease.[17]

Prior to the availability of effective antiviral therapy, approximately 50% of patients with aplastic anemia or hematologic malignancy treated by allogeneic HSCT developed CMV infection and CMV pneumonia,[18] with up to 90% mortality. CMV may also be a copathogen with other opportunistic organisms, including *P. jirovecii,* Epstein-Barr virus (EBV) and *Aspergillus.*

The diagnosis of CMV pneumonia is usually made by demonstration of typical inclusions in lung tissue. Urinary excretion of CMV can be coincident, but not necessarily causally related to disease. The most important methods for the detection of CMV in blood and potentially other fluids such as bronchoalveolar lavage (BAL) are those that estimate the quantity of virus or viral DNA. Of these, determination of CMV DNA using the polymerase chain reaction (PCR) is quite sensitive and widely available.[19] Determination of the presence of the CMV protein pp65 within peripheral white blood cells is also useful to identify those patients harboring the organism. PCR for CMV detection in the blood has become a more commonly used noninvasive test to follow at-risk patients following HSCT, or solid organ transplant recipients, to more accurately predict the development of CMV disease. New standards for measuring the viral load of CMV in body fluids (including BAL) allows for more precision in following the course of the disease.[20] PCR detection of CMV precedes culture isolation of CMV and persists longer than culture-positivity. Other techniques for identifying CMV in BAL include immunofluorescence, DNA hybridization, or microplate culture, combined with CMV antigen detection using monoclonal antibodies. All the techniques described, though highly sensitive, must be interpreted cautiously, since CMV can be a commensal and may be coincidentally present without being the cause of disease. Characteristic pathologic findings as well as a clinical scenario consistent with CMV disease are very important in deciding upon therapy.

The use of CMV-negative blood products has reduced the incidence of CMV pneumonia in seronegative transplant patients. Prophylactic and preemptive strategies for patients at risk utilizing ganciclovir, foscarnet, and high titer anti-*CMV* IgG have led to a substantial reduction in the incidence and mortality of *CMV* disease.[13,21,22] Valganciclovir, the L-valyl ester and prodrug of ganciclovir, has improved oral bioavailability compared with ganciclovir, and is now the preferred drug for the prevention and treatment of *CMV* disease.[23]

"Late" CMV has been observed in HSCT recipients with active graft-versus-host-disease (GVHD) who are receiving high doses of steroids (>1 mg/kg per day of prednisone), with low CD4 counts, and with history of prior CMV reactivation or extended use of anti-CMV treatment or prophylaxis.[24] Reduced intensity conditioning regimens for HSCT, or so-called mini-transplants with fludarabine, single-dose radiation, and posttransplant cyclosporine and mycophenolate mofetil, is an emerging treatment for patients who are not candidates for standard myeloablative conditioning.[25] These patients have shorter periods of neutropenia and lowered risk of CMV disease and viremia during the first 100 days, but may subsequently be faced with a delayed onset of CMV disease. Unlike early-onset disease, which is characterized mainly by interstitial pneumonitis,[26] late CMV manifestations include retinitis, marrow failure, and encephalitis.[24,27]

The interaction of CMV disease and allograft survival has been of particular interest to the lung transplant community, with reports of an increased incidence of bronchiolitis obliterans following CMV infection in lung allograft recipients.[28–30] The precise mechanism leading to chronic lung allograft dysfunction (CLAD) in lung recipients remains unclear, although immunological mechanisms possibly targeting usually hidden potential antigens resulting in the production of auto-antibodies continue to be a target of investigation.[31] The role played by CMV in the context of this immunologic dysregulation is still under investigation.

## Respiratory Syncytial Virus and Other Common Respiratory Viruses

Respiratory syncytial virus (RSV) and other common respiratory viruses such as parainfluenza, influenza, bocavirus, and rhinovirus have long been recognized as important pathogens in adult recipients of HSCT as well as pediatric leukemia patients.[32] Although usually causing upper respiratory tract infections, they commonly progress to involve the lower respiratory tract, carrying significant morbidity and mortality.[33] In addition, RSV and other community-acquired respiratory viruses have been implicated in the subsequent development of CLAD in lung transplant recipients.[34]

With community acquired respiratory viral infections, chest radiographs may have diffuse but nonspecific densities. Nasopharyngeal swabs or washings with cultures or enzyme immunoassays (EIA) are the most commonly used diagnostic tools for most viral pathogens, including RSV. Newer technologies, including reverse-transcriptase PCR (RT-PCR) and direct immunofluorescence assays, may prove to be specific, sensitive, and more rapid for detection,[35] although further clinical studies will be required. Studies of the use of the antiviral agent ribavirin in treating adult recipients with RSV have suggested that early administration of aerosolized ribavirin, before significant lower respiratory disease develops, is superior to treatment with intravenous (IV) ribavirin.[33] However, oral ribavirin, which is much less expensive than aerosolized or IV ribavirin, has been shown to be effective in the treatment of RSV.[36] There is also support for the use of the monoclonal anti-RSV antibody known as palivizumab in patients who develop RSV following HSCT, although the largest study was in adults, and all patients also received inhaled ribavirin.[37] While there is less published data concerning these pathogens in pediatric HSCT recipients, the increased likelihood of childhood exposure in schools and other environments should lead the clinician to consider such pathogens when evaluating an immunosuppressed child with upper or lower respiratory illness of uncertain etiology.

## Varicella-Zoster Virus and Herpes Simplex Virus

Varicella-zoster virus (VZV) and herpes simples virus (HSV) are DNA viruses that typically cause infections of the skin and mucous membranes. However, in certain high-risk groups, including neonates, patients with cancer, AIDS, congenital defects of cell-mediated immunity, and recipients of solid organ transplants or HSCT, VZV and HSV can lead to visceral dissemination and pneumonia.[38] Before the availability of specific antiviral therapy, VZV pneumonitis occurred in approximately 85% of cancer patients with visceral dissemination, with a resultant mortality of 85%. Pneumonitis is much less common with reactivation of herpes zoster and HSV, but it is a potentially serious infection following HSCT and in oncology patients.

The clinical presentation of VZV or HSV pneumonitis is nonspecific and includes fever, cough, dyspnea, and chest pain. Patients with VZV who have an increasing number of skin lesions, abdominal or back pain, or persistent fevers should be considered at high risk for dissemination. HSV pneumonitis may be more subtle in its presentation, and pneumonitis can occur in the absence of mucocutaneous lesions in newborns and HSCT recipients. Chest radiographs of herpesvirus pneumonias typically show ill-defined, bilateral, scattered nodular densities, first seen in the peripheral lung fields, with subsequent coalescence into more extensive infiltrates. Microscopically, the infection involves alveolar walls, blood vessels, and small bronchioles. Electron microscopy shows intranuclear viral inclusions. Hemorrhage, necrosis, and extensive alveolar edema are seen in severely affected areas of the lung; hemorrhagic tracheitis and bronchitis can also be seen. Secondary infections with bacterial pathogens were more commonly seen in the preantibiotic era, but with the emergence of resistant organisms such as methicillin-resistant *Staphylococcus aureus,* this remains a worrisome complication. Interstitial lung disease secondary to HSV infection has been reported following HSCT, but this is relatively rare[39] and far less common than CMV-related interstitial lung disease in this population.

Varicella-zoster immune globulin can modify or prevent VZV infection in high-risk hosts exposed to the virus if given within 48–72 hours of exposure. VZV immune globulin, antiviral therapy with acyclovir and related drugs, and routine varicella vaccination have been effective in reducing the incidence of serious VZV pneumonias in immunocompromised hosts. However, a single varicella vaccination given prior to an acquired immunocompromised state may be insufficient to prevent disseminated VZV.[40] In the case of HSV pneumonitis, acyclovir may not always be protective against respiratory complications. *In vitro* testing for antiviral sensitivity and the administration of alternative antiviral treatment may be warranted when proven *HSV* pneumonitis occurs.[41]

## Herpesvirus Type 6

Human herpesvirus 6 (HHV-6) is a DNA virus and is the etiologic agent of roseola. It can persist in normal hosts following infection and has been shown to integrate into the host genome in 0.2%–2% of the population.[42,43] Immunosuppression can lead to reactivation of HHV-6, resulting in fever, hepatitis, bone marrow suppression, encephalitis, and interstitial pneumonia.[44,45] HHV-6 may also be associated with coinfection by CMV and other pathogens. Antiviral compounds with activity against CMV, such as ganciclovir, foscarnet, and cidofovir, are also active against HHV-6,[46] although increasing resistance to these agents by HHV-6 and other herpesviruses is becoming increasingly common.[47]

## Human Metapneumovirus

Human metapneumovirus *(hMPV)* accounts for a large proportion of cases previously relegated to “undiagnosed” respiratory infections, particularly in young children.[48,49] Its epidemiology is similar to that of *RSV*—that is, winter epidemics—with variation in severity from year to year. Martino and colleagues[50] recently described isolation of *hMPV* as a primary pathogen in 11/177 (6.2%) of nasopharyngeal aspirates from symptomatic adult HSCT recipients. An additional five patients had *hMPV* as a copathogen, one with *Aspergillus*, one with *Aspergillus* and *CMV*, and three with other respiratory viruses (*AdV*, *RSV*, or *influenza*). Fifty percent of the infections were considered nosocomial; pneumonia complicated *hMPV*-upper respiratory tract infections in four (44%) of nine and one (14%) of seven allo-HSCT and auto-HSCT recipients, respectively. More worrisome, Englund and coworkers[51] reported real-time PCR evidence of metapneumovirus in 5 of 163 (3%) of BAL samples obtained in HSCT recipients experiencing respiratory disease. Of these five patients, four died of respiratory failure and most carried a diagnosis of “idiopathic pneumonia syndrome” (IPS; discussed further in this chapter). Evashuk and colleagues reported metapneumovirus infection leading to severe respiratory failure in an infant recovering from liver transplantation.[52] More recently, an outbreak of *hMPV* affecting 15 immunocompromised adults with hematologic malignancies that led to respiratory failure in 33% and death in 26.6% was reported, highlighting the potential virulence of this particular pathogen.[53] It is likely that further investigations will underscore the importance of *hMPV* as a viral pathogen in immunocompromised adults and children.[54]

## Adenovirus

*AdV* is a DNA virus that is a common cause of community-acquired lower respiratory tract disease. Serotypes 3 and 7 are associated with epidemics of bronchiolitis and pneumonia in the general population. In immunocompromised patients such as HSCT recipients, AdV infections can lead to gastrointestinal, urologic, and pulmonary morbidity with disseminated disease that is associated with a high mortality.[7] AdV typically causes fever, pharyngitis, cough, and conjunctivitis. Pneumonia is usually mild in normal hosts, but rapid progression, with necrotizing bronchitis and bronchiolitis, can occur in immunocompromised patients. The radiographic picture is nonspecific and resembles other causes of diffuse pneumonia. Failure of pneumonia to respond to standard therapy, particularly in the setting of epidemic acute respiratory disease in the community or hospital staff, should raise suspicion of AdV involvement.

The diagnosis is usually made by lung biopsy or brushings demonstrating typical adenoviral inclusions, or by culture, but institution of empiric antibiotic and antifungal therapy leading to delay in invasive procedures may delay the diagnosis. PCR to quantify adenoviral DNA in blood or other fluids[55,56] may be useful as a screening tool. The antiviral agent Cidofovir has been shown to have activity against AdV, but more study is needed before it can be universally recommended.[57] Because very low T-cell counts in HSCT recipients are a major risk factor for disseminated disease in those patients found to harbor AdV, and because PCR is quite sensitive, algorithms have been proposed for determining which patients might benefit from antiviral treatment with agents such as cidofovir.[58,59] Meanwhile, supportive therapy for affected patients includes oxygen, treatment of bacterial superinfections, IV immunoglobulin, and assisted ventilation. A novel approach to treatment of refractory *AdV* (and other viral) infections in immunocompromised patients involves the production of multivirus-specific T-cells using overlapping peptide libraries incorporating antigens from a variety of pathogenic viruses to stimulate peripheral blood mononuclear cells *in vitro*. While this technology is only recently developed, it may provide a more sustainable treatment in this patient population.[60]

## Fungal Pathogens (See Also Chapter 31)

### *Pneumocystis jirovecii* (Formerly *P. carinii*)

*Pneumocystis* has been an organism of uncertain taxonomy and was regarded as a parasite because of its resemblance to cystic spore-forming protozoa. DNA sequencing of 16S-like ribosomal RNA of *P. carinii* with phylogenetic analysis demonstrates that it is much more closely related to fungi than to protozoal organisms.[61] There are several animal models for infection with *Pneumocystis,* with no evidence of infection transmission across species. The nomenclature

*P. carinii* is now reserved for the organism infecting rats, while *P. jirovecii* is the organism isolated in humans.[62] The term PCP, initially an acronym for *P. carinii* pneumonia, is retained with *P. jirovecii* pneumonia, now indicating *Pneumocystis* pneumonia.

The organism exists in two forms in tissues: the more common trophic, or trophozoite, and the cystic form containing sporozoites.[63] The trophozoites measure 2–5 μm and stain best with Giemsa stains or fluorescein-conjugated monoclonal antibody but are not visible with Grocot-Gomori methenamine-silver nitrate or toluidine blue O stains, which stain the 5–8-μm cyst forms. The cysts are spherical or cup-shaped and often appear to contain up to eight 1–2 μm sporozoites within the cyst wall. The organism cannot be cultured from routine clinical specimens and must be identified in tissue, sputum, or alveolar lavage. The trophozoites appear to attach to type I cells through surface glycoproteins related to lectins and there undergo encystation. This interaction directly or through soluble factors leads to cell injury. The alveoli of lungs infected with *P. jirovecii* are filled with trophozoites and protein-rich debris, and the altered permeability produced by the organism contributes to the development of pulmonary edema and surfactant abnormalities, which lead to decreased pulmonary compliance and altered gas exchange. Latent infection with *P. jirovecii* was thought to be common, since serologic studies indicated that 40% of children had antibodies to the organism, and more recent studies using sensitive PCR assays have found evidence of *P. jirovecii* in the nasopharynx and lungs of normal infants. Colonization appears to be common in immunocompromised patients but less common in normal hosts, and there is some evidence of patient-to-patient transmission. Reactivation of latent infection in the immunocompromised host, previously felt to be the most likely explanation for disease, has been called into question by epidemiologic data, suggesting new acquisition of airborne organisms.[63]

In patients with congenital or acquired immunodeficiency, the clinical features of PCP are nonspecific and include dyspnea, tachypnea, fever, and cough. Cyanosis occurs later, but early hypoxemia with a mild respiratory alkalosis is common. The most common chest radiographic finding is diffuse bilateral infiltrates.

*P. jirovecii* pneumonia can be treated with several medications, although trimethoprim-sulfamethoxazole (TMP-SMZ) is the preferred agent for both prophylaxis and treatment in children as well as adults.[63] The earliest drug available for PCP was the dihydrofolate reductase inhibitor pentamidine, which was associated with a high rate of immediate adverse reactions including hypotension, tachycardia, and nausea as well as hypoglycemia and nephrotoxicity. Pentamidine may be administered by the aerosol route for treatment or prophylaxis in at-risk patients to prevent PCP, but its effectiveness is highly dependent on the delivery system used. Other "second-line" medications that have activity against *P. jirovecii* include combination therapy of clindamycin and primaquine, dapsone (sometimes combined with trimethoprim), and atovaquone.[63–65] Limited studies and case reports of the use of the antifungal agent caspofungin have shown some promise, but further study is necessary.[66,67] A newer form of combination therapy, reported for patients with AIDS, is trimetrexate-folinic acid,[68] but this will also require further evaluation. For proven PCP infection with moderate to severe hypoxemia, high-dose TMP-SMX with adjuvant glucocorticoid therapy remains the treatment of choice.[63,69]

Patients at known risk for *P. jirovecii* generally receive prophylaxis. For pediatric oncology and immunocompromised patients, oral TMP-SMZ given 3 days per week is effective. However, if patients or parents are noncompliant, there is a risk of breakthrough pneumonias on this schedule. For most patients, TMP-SMZ remains the drug of choice, but other prophylactic regimens have been used, including IV pentamidine.[63,70]

## *Aspergillus* Species

*Aspergillus* is a group of ubiquitous fungal organisms found in soil and other settings, including the hospital environment. *Aspergillus fumigatus* is the most common species to cause pneumonia in immunocompromised hosts, but other pathogenic species include *A. niger* and *A. flavus*.[71] Invasive *Aspergillus* is most common in pediatric patients with malignancy (especially acute myelocytic leukemia) and HSCT.[72]

In tissues, the organisms are seen as septate hyphae with regular

45-degree dichotomous branching, best seen with methenamine silver staining (Fig. 64.2). Novel PCR-based detection methods for *Aspergillus* (and other fungal pathogens) in BAL samples are being developed but require further testing.[73] *Aspergillus* causes both acute invasive pulmonary aspergillosis and a more chronic necrotizing form. The former occurs most commonly in patients undergoing cancer therapy, as well as other immunocompromised patients, such as those with aplastic anemia. Aspergillosis of the lung is often preceded by or accompanied by invasion of the nose and paranasal sinuses in susceptible hosts. Confirmed risk factors for aspergillosis include prolonged neutropenia, concurrent chemotherapy and steroid therapy, and broad-spectrum antibiotic therapy. Cutaneous aspergillosis is often observed in patients with disseminated disease. The killing and/or clearance of *Aspergillus* by neutrophils and alveolar macrophages are partly dependent on intracellular calcineurin, which itself is a target of widely used antirejection medications. This suggests another reason why transplant recipients are more susceptible to invasive *Aspergillus* infections.[74,75]

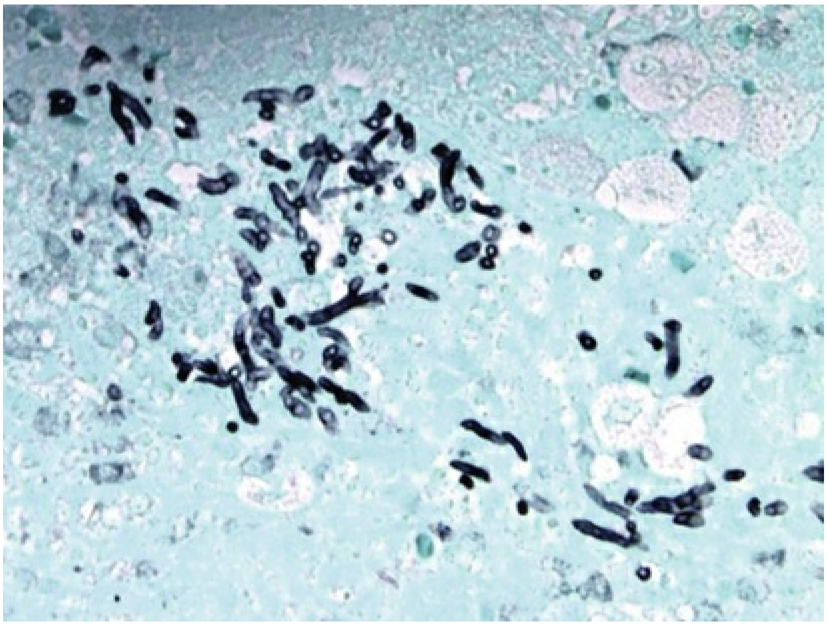

**FIG. 64.2** Invasive aspergillosis seen in a patient with pulmonary complications posthuman stem cell transplantation. Methenamine silver stain, 400×.

In the lungs, *Aspergillus* can cause tracheobronchitis, pneumonia, abscesses, cavity formation, and diffuse interstitial pneumonia. The organisms often extend along blood vessels, and nodular lesions of necrosis surrounded by air often develop within an area of pneumonia, leading to the typical air crescent sign, seen on CT scan of the chest. This finding is more common in adults, rather than pediatric, immunocompromised patients,[14] and while strongly suggestive of *Aspergillus* infection, is usually seen early in the disease process, and later it is replaced by nodular infiltrates with or without cavitation. CT scanning of the chest is much more sensitive than plain radiographs and can reveal early evidence of cavitation.

The diagnosis of *Aspergillus* pneumonia is generally made by tissue examination, but this has limitations, as several other fungal species can histologically mimic *Aspergillus* histologically. *Aspergillus* can be isolated from BAL in approximately 50% of cases, and needle aspiration biopsy of peripheral lung lesions can also demonstrate typical fungal lesions.[76] Although direct tissue sampling by needle biopsy or transbronchial biopsy is recommended for diagnosis, the angioinvasive nature of *Aspergillus* increases the risk of bleeding or secondary infection following such procedures.[77] Isolation of *Aspergillus* from a nasal culture in a patient with typical clinical risk features (prolonged neutropenia, progressive nodular infiltrates, cavitary lesion) may be helpful, but negative cultures do not exclude *Aspergillus.*

Galactomannan, a polysaccharide consisting of a mannose backbone linked to galactose side groups, is a component of the cell wall of *Aspergillus* that is released with growth. It can be detected in blood, BAL fluid, and cerebrospinal fluid in patients with invasive aspergillosis.[78] Although most of the studies using galactomannan as a biomarker for invasive fungal disease have been in adult patients, it has gained favor in the pediatric population.[79] *Aspergillus* galactomannan antigen detection in blood and BAL fluid as well as other noninvasive tests such as fungal-specific PCR-based diagnostics under development[80] offer the promise for accurate diagnosis without more invasive procedures such as needle biopsy or transthoracic lung biopsy.[81,82] Further studies to demonstrate utility in clinical practice will be necessary.[82–84]

Although initially amphotericin B was the sole antifungal agent with activity against *Aspergillus*, newer agents are available and include the orally available itraconazole and voriconazole, which have excellent activity against *Aspergillus;* of these, voriconazole is the treatment of choice for invasive aspergillosis.[85–87] Alternative therapies for aspergillosis include lipid formulations of amphotericin B, caspofungin or other echinocandins, or itraconazole. The utility of surgical excision of *Aspergillus* lesions is somewhat controversial. Invasive pulmonary aspergillosis during treatment of hematologic malignancy is generally considered a contraindication to subsequent BMT, but adult patients treated with amphotericin B and surgery have survived free of disease and without reactivation of *Aspergillus* following BMT. The outcome of *Aspergillus* pneumonia depends primarily on host factors, including degree of immunosuppression and recovery of neutrophil counts, as well as early diagnosis and treatment.[88]

## *Mucor* and *Rhizopus*

Mucormycosis includes fungal disease caused by organisms in the order Mucorales, including a variety of species in the genera *Rhizopus, Mucor,* and *Cunninghamella.*[89] In tissues they are differentiated from *Aspergillus* by their broad, nonseptate hyphae that branch at angles up to 90 degrees and have an appearance of “twisted ribbons.” *Rhizopus* organisms cause disease only in patients who are immunosuppressed or who have an underlying disease, especially diabetes. In adults, it is associated with chronic or recurrent acidosis, such as uncontrolled diabetes mellitus with ketoacidosis. Most pediatric cases of pneumonia occur in the oncology population, where the organism affects the same risk groups as *Aspergillus.*

Pneumonia due to *Rhizopus* is usually an insidious segmental pneumonia that is slowly progressive despite antifungal therapy. Persistent fever, chest pain, hemoptysis, and weight loss are typical. Cavitation may occur, and dissemination to brain and other sites occurs because of the propensity of the organism to invade blood vessels. Death may occur suddenly with massive pulmonary hemorrhage, mediastinitis, or airway obstruction. The specific diagnosis usually depends on demonstration of the organism in specimens obtained by open, transbronchial, or needle-aspiration biopsy. As with *Aspergillus,* treatment with amphotericin B and possibly surgical resection as early as possible is critical to achieving a cure. Posaconazole has good activity against mucormycosis, which can be aggressive and relatively resistant to voriconazole.[90,91] Correction of chronic acidosis, if present, also appears to be important in some forms of *Rhizopus* disease.

## *Candida* Species

Though important as a cause of fungal sepsis and secondary hematogenous pulmonary involvement, primary *Candida* pneumonia is unusual. *Candida albicans* and *C. tropicalis* are the most important causes of fungal sepsis and secondary pulmonary involvement. Neutropenic children colonized with *C. tropicalis* are at a 10-fold higher risk for dissemination than children colonized with *C. albicans.* Patients with HIV infection, primary immunodeficiencies, or prolonged neutropenia are at greatest risk, but other predisposing conditions include diabetes, corticosteroid administration, broad-spectrum antibiotic treatment, IV hyperalimentation, and the presence of deep venous access devices (conditions common to the patient with solid organ or HSCT).

In tissue, silver stains show oval budding yeasts 2–6 μm in diameter with pseudohyphae. The prominent histologic features of primary *Candida* pneumonia include bronchopneumonia, intraalveolar exudates, and hemorrhage. Amphotericin B is usually the treatment of choice for invasive *Candida* infections, along with flucytosine if synergism is desired. The imidazole antifungal agents, including ketoconazole, fluconazole, and itraconazole, have activity against *C. albicans* and have been used successfully. Although fluconazole prophylaxis, as well as the use of hematopoietic growth factors, has led to a reduction in the frequency of early *Candida* infections in patients at risk, many institutions have experienced an increase in azole-resistant *nonalbicans Candida* infections.[92–98] In response to this, caspofungin appears to be an excellent alternative, with less toxicity than amphotericin B and improved coverage against systemic *Candida* infections when compared with fluconazole.[99,100] A Cochrane review of various antifungal treatments points out the relative benefits of liposomal

Amphotericin as well as the need for further controlled clinical trials to determine the optimal treatment for deep fungal infections in the pediatric host.[101] There is increasing interest in the use of combination therapies to improve the treatment of *Candida,* as well as other fungal pathogens. Such combination therapies take advantage of different therapeutic targets of the various antifungals, possibly reducing the emergence of resistant organisms.[102]

## Histoplasmosis and Blastomycosis

*Histoplasma capsulatum* and *Blastomyces dermatitidis* are ubiquitous soil fungi endemic to the eastern and southeastern United States. Histoplasmosis is especially associated with exposure to bird or bat fecal material[103]; as a result, it is a fairly common infection in immunocompetent children and may be asymptomatic or lead to an acute pneumonia with fever, hilar adenopathy, and pulmonary infiltrates. Blastomycosis is a less common but more serious infection. Both can cause chronic granulomatous pulmonary disease and lead to extrapulmonary dissemination.

In the immunocompromised patient, particularly pediatric oncology patients, histoplasmosis may present as an acute illness with fever, cough, and diarrhea, or in a disseminated form with additional features of hepatosplenomegaly, fevers, and adenopathy.[104] Progressive disseminated histoplasmosis is a rare (<0.1% of cases) complication of primary infection, but it is much more common in immunocompromised patients.[105] Interestingly, neutropenia is not always associated with *H. capsulatum* infections. Chest radiographs or CT scans usually demonstrate hilar adenopathy and nodular parenchymal disease in both forms of the disease. Blastomycosis is much less common in adult or pediatric oncology patients, and may be associated with dermatologic manifestations such as skin ulcers, in addition to diffuse chronic pulmonary infiltrates.[106]

Amphotericin B is indicated for both histoplasmosis and blastomycosis in immunocompromised hosts. Itraconazole is also effective for histoplasmosis and moderate blastomycosis without central nervous system involvement.

### *Cryptococcus Neoformans*

*Cryptococcus neoformans* is a yeast that causes protean clinical manifestations in immunocompromised patients, often involving the meninges, endocardium, skin, and lymph nodes.[107] The lungs are the portal of entry for *C. neoformans,* and pulmonary involvement may be minimal if dissemination occurs quickly. Pneumonia typically causes chest pain, fever, and cough. The diagnosis of cryptococcosis relies on demonstration of the organism histologically, in biopsy tissue or pleural fluid,[108] or by culture methods.[109] Although controlled trials are lacking, treatment of cryptococcosis in immunosuppressed patients with IV amphotericin B and oral flucytosine followed by fluconazole is recommended.[109,110]

### Rarer Fungal Pneumonias

Several recent trends have been noted in fungal infections, among them increased identification of rarer fungal pathogens, including saprophytic fungi such as *Trichosporon beigelii* and *Fusarium* sp. These fungi cause skin and soft tissue infections and occasionally invade the lungs and sinuses. For example, *Scedosporium apiospermum* (formerly *Pseudallescheria boydii*) causes invasive disease in solid-organ transplant patients, with lung involvement in 50%[111]; it is difficult to distinguish histologically from *Aspergillus.*[112,113] These fungi are thus often difficult to diagnose, and unlike *Aspergillus,* their response to therapy with amphotericin B and echinocandins (e.g., Caspofungin) may be very poor.[114] Newer azole agents such as posaconazole and voriconazole have activity against *Fusarium* spp. and *Scedosporium* spp. and should be considered if these species are isolated from immunosuppressed patients. Other rare fungal pathogens seen in immunocompromised patients include filamentous fungi of which there are several species, including *Dactylaria gallopava, Cladophialophora bantiana,* and *Exophiala.* Several of these have a proclivity for infecting the CNS, but soft tissues and lungs may also become involved with cavitary lesions.[115]

## Bacterial Pathogens (See Also Chapter 25)

The bacterial pathogens associated with pneumonia in immunocompromised hosts include those pathogens typically associated with pneumonia in children, such as *S. aureus* (particularly methicillin-resistant strains), *H. influenzae,* and *S. pneumoniae. Pseudomonas aeruginosa* is an additional important cause of pneumonia and sepsis in hospitalized immunocompromised children. Significant risk factors for bacterial infections include neutropenia, the presence of indwelling venous catheters, and perineal skin lesions. More unusual bacterial causes of pneumonia include *Listeria monocytogenes,* a gram-positive rod that causes primarily septicemia in immunocompromised patients, with subsequent pulmonary involvement. Corynebacteria (commonly called diphtheroids) are gram-positive bacilli or coccobacilli that exist as saprophytes on mucous membranes and skin. *Corynebacterium jeikeium* is a strain from this group that may lead to sepsis and pneumonia in oncology and HSCT patients.[116] *Listeria* can be successfully treated with ampicillin plus an aminoglycoside, but newer cephalosporins are not active against *Listeria. C. jeikeium* is resistant to most antibiotics except vancomycin. Other rare Gram-negative organisms that cause pneumonia in the immunocompromised host include *Legionella pneumophila* and *Capnocytophaga* sp. It is important to realize that factors such as geographic location, changes in infection control, prophylactic antimicrobial protocols, and technological advances all have an effect on microbial predominance.[117,118]

## Mycobacteria (See Also Chapters 29 and 30)

With the onset of the AIDS epidemic, disease due to both *Mycobacterium tuberculosis* and atypical strains such as *M. avium-intracellulare, M. kansasii, and M. abscessus* have been increasingly recognized in both AIDS and non-AIDS immunodeficient populations.[119,120]

The development of disseminated *M. tuberculosis* following HSCT is a serious and often fatal complication (Fig. 64.3).[121] Based on data from developed countries, *M. tuberculosis* infections are rare in HSCT recipients.[122–124] However, the incidence of tuberculosis in the HSCT population directly reflects its incidence in the general population. In Turkey, where tuberculosis is endemic (35/100,000 population vs. 7/100,000 in the United States), tuberculosis was 40 times more common in allo-HSCT patients than in the general population.[125] The presence of multidrug-resistant strains of *M. tuberculosis* (indirectly related to treatment of HIV disease) is of great concern[126] and has led some programs to maintain a high index of suspicion for tuberculosis and to treat HSCT recipients with this complication for longer periods of time, often with multidrug regimens.[127]

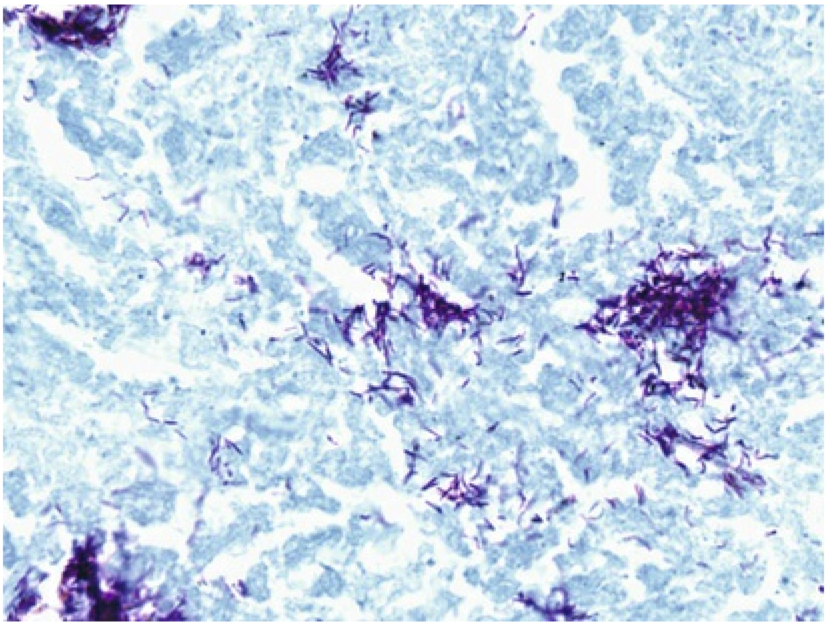

**FIG. 64.3** Acid-fast organisms in a patient with end-stage lung disease following human stem cell transplantation. Acid-fast stain, 1000×.

Nontuberculous mycobacterial (NTM) infections can be either catheter-related or respiratory infections.[127] Mere isolation of NTM on BAL may not be of pathogenic significance, unless there is evidence of tissue invasion or concomitant bacteremia is present. Treatment requires 2–4 antimicrobials guided by in vitro susceptibility testing, and removal of indwelling catheters (if contaminated), as well as surgical debridement of subcutaneous tunnel infection sites.[127]

## *Legionella Pneumophila*

Patients undergoing bone marrow and solid organ transplantation are particularly susceptible to *Legionella* infections due to prolonged neutropenia and abnormalities in cell-mediated immunity. Legionnaires' disease (LD) can be acquired by inhalation of aerosols containing *L. pneumophila,* or by microaspiration of contaminated drinking water.[128] LD should always be in the differential diagnosis of pneumonia among HSCT recipients. Appropriate tests to confirm LD include culturing sputum, BAL, and tissue specimens; testing BAL specimens for *Legionellae* by direct fluorescent antibody (DFA), as well as examining for *L. pneumophila* serogroup 1 antigen in urine and performing testing for 5S rRNA PCR of BAL, urine, or serum samples.[129,130]

## Parasitic Agents (See Also Chapter 33)

### *Toxoplasma Gondii* and *Cryptosporidium Parvum*

*Toxoplasma gondii* infects cats and other animals and secondarily infects humans, causing congenital toxoplasmosis during intrauterine infection. Primary infection later in life usually causes only lymphadenopathy and mild systemic symptoms.[131] *Cryptosporidium parvum* infects a variety of hosts, including immunosuppressed individuals. Its usual routes of transmission are water- or food-borne, but person-to-person transmission is possible.[132] *Toxoplasma* primarily causes central nervous system disease, but disseminated disease with secondary pulmonary involvement can occur, presenting with shortness of breath, cough, fever, and bilateral interstitial infiltrates.[133] *C. parvum* causes severe diarrhea, but disseminated disease with pulmonary involvement can occur. Treatment of *T. gondii* is with pyrimethamine-sulfadiazine, while treatment of *C. parvum* is rapidly evolving, with combination therapy of azithromycin-paramomycin[134] being supplanted by the more effective nitazoxanide in many parts of the developing world.[135]

## Pulmonary Coinfections

Late after solid organ transplantation or in the late phase infections following HSCT, it is common to find copathogens—that is, isolation of more than one pathogenic species of bacteria, fungus, or opportunistic virus from BAL or lung biopsy specimens. For example, pulmonary copathogens may be isolated in as many as 53% of patients with *parainfluenza* pneumonia.[136] HSCT recipients with *CMV* disease or respiratory viral infections are more susceptible to invasive fungal infections, especially *Aspergillus*.[137] Alangaden and colleagues described the occurrence of gram-negative bacilli and *Aspergillus* infections among allogeneic BMT recipients with chronic GVHD requiring long-term steroid use.[138] Chronic colonization of the airways of patients with GVHD may be analogous to colonization of the respiratory tract, with *Pseudomonas* and *Aspergillus* species in patients with cystic fibrosis, possibly suggesting an alteration in the homeostasis of the respiratory mucosa, mucociliary clearance, and airway surface liquid. Recovery of bacteria from respiratory secretions in this scenario may represent airway colonization rather than invasive parenchymal disease.

# Pulmonary Complications Following Solid-Organ Transplantation

This section will refer mainly to pulmonary complications of nonlung, solid-solid organ transplantation, as lung transplantation and its complications will be discussed in Chapter 67.

## Pulmonary Edema, Pleural Effusions, and Acute Respiratory Distress Syndrome

Pulmonary edema can occur posttransplant because of increased hydrostatic pressure (e.g., caused by fluid and blood product administration or poor left ventricular function) or decreased oncotic pressure (e.g., caused by hypoalbuminemia), or because of increased vascular permeability (e.g., caused by immune-mediated transfusion-related acute lung injury [TRALI]).

Pleural effusions may also occur as a result of increased hydrostatic or decreased oncotic pressure. Lymphatic vessels that drain the lungs can be overwhelmed or disrupted in transplantation. Infection or injury in the thoracic, mediastinal, or abdominal cavity can lead to sympathetic effusions or empyema. Finally, abdominal ascites fluid (i.e., in patients with liver or kidney disease) can translocate through pores in the diaphragm and enter the pleural space.

Pleural effusions can occur in up to 40% of children who undergo liver transplantation,[139] are predominantly right-sided, and are thought to occur as a result of disruption of diaphragmatic lymphatic channels.[140] Effusions exclusively in the left pleural space following liver transplantation should prompt evaluation for other causes. Generally, pleural effusions following liver transplantation will enlarge over the first week following transplantation and then resolve over the ensuing 3–4 weeks. Between 14% and 25% of pediatric patients require pleural drainage because of significant respiratory compromise.[141,142] Not surprisingly, pleural effusions significantly increase the duration of mechanical ventilation and ICU days.[142] Persistent pleural effusions may be a sign that acute rejection of the liver allograft is occurring.[143]

Acute respiratory distress syndrome (ARDS) is a devastating complication in up to 15% of liver transplant recipients in the immediate postoperative period. This is primarily caused by sepsis, but in the case of liver and small bowel transplantation, other risk factors should be considered as potential causes (e.g., severe malnutrition of the recipient, the extensive and prolonged abdominal surgery, massive intraoperative blood transfusion, and aspiration in the early posttransplant period).[144]

## Impairment of Respiratory Mechanics

The extensive surgery in the upper abdomen that occurs during orthotopic liver transplantation can have significant effects upon diaphragmatic excursion, especially on the right side. Diaphragmatic dysfunction can also occur in heart, kidney, and small bowel transplantation, but to a lesser degree than after liver transplantation. Poor excursion of the diaphragm can lead to impaired cough and airway clearance, resulting in atelectasis and pneumonia. Diaphragmatic function can be impaired by swelling in the subdiaphragmatic area, as well as phrenic nerve injury when the suprahepatic vena cava is clamped during liver transplantation.

Diaphragmatic dysfunction or paralysis can be found in 8%–11% of pediatric liver transplant recipients,[142,143] and with more sensitive techniques, phrenic nerve conduction abnormalities are seen in up to 80% of adult liver transplant recipients.[145] For adults, the injury to the right phrenic nerve does not seem to have significant impact on recovery, as determined by the duration of mechanical ventilation or hospital stay. In infants and small children, compromise of one diaphragm can lead to more respiratory distress, atelectasis, and pneumonia, as well as longer duration of mechanical ventilation and ICU stays.[142]

Recruiting atelectatic lung and performing adequate airway clearance in the postliver transplant period can be challenging because of pain and the "fresh" surgical sites. This is especially true for patients in whom the abdomen is not completely closed in the immediate postoperative period. In this situation, the important abdominal muscles that are needed for cough are impaired. Patients may require noninvasive positive pressure ventilation (NIPPV) after extubation. Airway clearance and the use of a mechanical in-exsufflator (cough assist device) can help clear secretions and prevent atelectasis in the immediate postoperative period. Since physiotherapy to the chest wall may be painful after sternotomy, oscillating positive expiratory pressure devices and incentive spirometry (in patients who can cooperate) and intrapulmonary percussive ventilation (in those that cannot cooperate) can be invaluable in the postoperative period. When diaphragmatic dysfunction or paralysis is present, plication of the diaphragm can be considered (utilized in up to 25% of patients with diaphragm paralysis).[143] However, plication should only be considered if phrenic nerve function has not returned after a period of observation with noninvasive management of at least 90 days, or if the patient develops clinical respiratory deterioration.

## Medication Toxicity

Early infusion of cyclosporine has been reported to cause ARDS in patients receiving liver transplantation.[144] Fortunately, most medications used for immunosuppression in the postorgan transplantation period do not have direct toxicity to the lung. Two exceptions are the mammalian targets of rapamycin (mTOR) inhibitors, sirolimus (rapamycin) and everolimus. Both are potent immunosuppressants that confer less nephrotoxicity than calcineurin inhibitors. They have been increasingly popular because of their overall favorable side-effect profile. However, sirolimus and everolimus cause interstitial pneumonitis at both therapeutic and supratherapeutic drug levels.[146–151] Incidence of this complication ranges from 0.4% to 2.9%.[148,152] Sirolimus-induced interstitial pneumonitis can occur acutely, but the onset is usually insidious. Patients usually present with dyspnea on exertion (66%–90%), dry cough (75%–100%), and fever (60%–87%). Lung function testing may reveal a restrictive defect. Plain films and CT scans of the chest might reveal an interstitial pattern with interstitial infiltrates, consolidation, or ground-glass opacification with lower lobe predominance. BAL and biopsy specimens can show patterns of lymphocytic alveolitis, pulmonary hemorrhage, or organizing pneumonia.[147,148] Treatment requires discontinuation of the causative medication, and resolution is generally prompt, although radiographic abnormalities may persist. Corticosteroid use should be considered and may be effective, although supportive data are limited.[148]

## Posttransplant Lymphoproliferative Disease

The immunosuppression required for solid-organ transplant recipients places them at increased risk for developing posttransplant lymphoproliferative disease (PTLD).[153] PTLD typically stems from an immunosuppressive regimen that causes T lymphocyte depletion, which then leads to uncontrolled EBV-driven B cell proliferation. This unregulated growth of B cells can range from benign polyclonal B lymphocyte expansion to aggressive immunoblastic B cell lymphomas.[154] Less frequently, PTLD also can result from T cell or natural killer (NK) cell proliferation.[155,156] PTLD occurs in approximately 3%–9% of heart transplant recipients[155,157,158] and up to 20% of intestinal transplant recipients.[159] PTLD can occur following kidney and liver transplantation as well, but less frequently. PTLD arising in the lung is much more common following heart, lung, and heart-lung transplantation than following transplantation of abdominal organs. The median onset of PTLD is typically within 24 months following solid-organ transplantation.

A significant risk factor for PTLD is seroconversion of an EBV-naïve recipient, either by primary infection in a previously uninfected recipient or by transplantation of a graft from an EBV-seropositive donor. Other risk factors include Rh factor negativity, Rh mismatch, and recipient CMV seronegativity, and a high degree of immunosuppression, although induction immunosuppression does not appear to appreciably increase the risk of PTLD.[157,158,160–162] Shortness of breath, cough, and upper airway obstruction were the most common symptoms in those with pulmonary PTLD. Because many will not have symptoms at presentation, screening of the at-risk patient population with EBV viral load may be the earliest means of detecting the presence of EBV as a marker for PTLD. A retrospective study in liver transplant recipients showed a marked reduction in PTLD and prevention of rejection in patients in the era in which EBV PCR monitoring was available (PTLD incidence decreased from 14.9% to 1.9%).[163] Increasing EBV load may signify a need to adjust the patient's immunosuppressive regimen. Because CMV may be a coinfecting agent in these patients, prophylactic antiviral therapy and CMV PCR monitoring are also recommended. In patients who present with pulmonary disease, nodular abnormalities are the most common finding (Fig. 64.4A and B), although lymphadenopathy, consolidations, or effusions may be seen on chest imaging.[164] Even when PTLD is strongly suggested by the combination of increasing EBV load and typical radiographic findings, biopsy material should be obtained to confirm the diagnosis histologically (see Fig. 64.4C) and assess for the presence or absence of EBV-early RNA (EBER)–staining cells (see Fig. 64.4D). In addition, it is useful to characterize cell surface markers such as CD20, which may guide therapy.

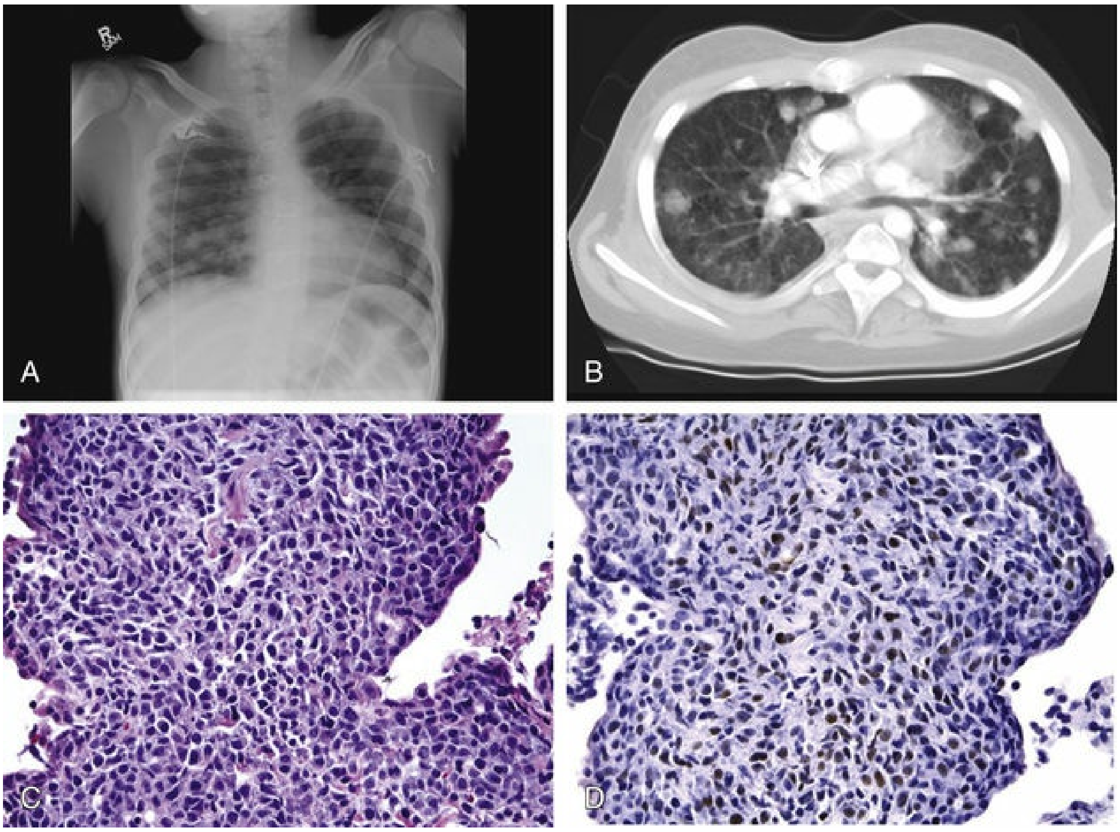

**FIG. 64.4** Posttransplant lymphoproliferative disease. (A) Anteroposterior chest radiograph. (B) Computed tomography scan. (C) Histopathology showing monomorphic clonal expansion of lymphocytes that express Epstein-Barr early RNA (D).

Initial therapy for PTLD is the reduction of immunosuppression to reduce the degree of T lymphocyte depletion. This reduction can be associated with further complications (e.g., graft rejection) and still may be insufficient for recovery.[165,166] Thus some have employed novel assays of immune function to monitor the degree of immunosuppression, while at the same time monitoring EBV viral load.[167] Antiviral agents and IV immunoglobulin, including anti–B cell immunotherapy with the monoclonal anti-CD-20 antibody (rituximab), have been attempted with varying degrees of success.[168] The main complication of rituximab therapy is prolonged B cell depletion and hypoimmunoglobulinemia.[169] Anti-CMV therapy should be continued in patients at risk for this coinfection, but it may not decrease the cellular proliferation of PTLD, because there is very little active EBV replication in these lesions.

PTLD following solid-organ transplantation confers an increase in mortality, reflecting the severity of the disease itself or its treatment, specifically the treatment effects upon the transplanted organ.

## Other Noninfectious Pulmonary Complications of Solid-Organ Transplantation

Many pulmonary complications that arise pretransplantation may not resolve completely or immediately posttransplantation. Metastatic pulmonary calcifications can occur in patients with kidney or hepatic failure, and while usually benign, can lead to restrictive lung disease. Furthermore, their nodular appearance on chest radiographs can mimic nodules from infection or malignancy (see the previous section).

Pulmonary conditions such as alveolar simplification[170] and primary ciliary dyskinesia (PCD)[171] can be associated with congenital heart disease, including those associated with heterotaxy, and they may not have been recognized before heart transplantation. These conditions should be considered if unexpected pulmonary complications including prolonged hypoxemia and recurrent atelectasis develop in the posttransplant period.

Hepatopulmonary syndrome (HPS) and porto-pulmonary hypertension (PPHTN) are two entities that occur in end-stage liver disease and can significantly improve with liver transplantation. However, improvement is not universal or even expedient. In the case of HPS, significant hypoxemia can occur because of dilation of pulmonary capillaries, and this may persist in the postoperative period, leading to prolonged mechanical ventilation and the use of supplemental oxygen. Typically, resolution of hypoxemia from HPS occurs over the initial 8 months following transplant.[172]

Severe cases of PPHTN may preclude liver transplantation since the operative mortality increases as the severity of pulmonary hypertension increases. Additionally, PPHTN can recur or occur de novo after liver transplantation. Posttransplant pulmonary hypertension (PHTN) can occur in those with pretransplant HPS, those with recurrent liver disease, and those with no apparent liver disease and isolated PHTN. Severe PHTN in either the pretransplant or the posttransplant period increases the risk of mortality.[173,174] Continuous infusion of prostaglandins can serve to lower pulmonary pressures, acting as a bridge to transplant and attenuating surgical risk.

Venous thromboemboli (VTE) can occur in the posttransplant period, thus leading to respiratory distress and hypoxemia, but they are uncommon in pediatric patients. Renal transplant patients may be at higher risk because of manipulation of pelvic veins, although this has mainly been reported in adult patients.[175]

# Pulmonary Complications of Childhood Tumors and Their Treatment

Pulmonary complications of solid organ and hematopoietic stem cell transplant may be preexisting conditions either from the underlying malignancy or from the initial treatment for malignancy.

Childhood cancers are treated with a combination of surgery (primarily for solid tumors), chemotherapy, and radiotherapy. See Chapter 59 for a further discussion of pulmonary toxicity from chemotherapy. Radiation therapy is an integral component of curative treatment for a variety of oncologic malignancies, both for the treatment of primary tumors and for those patients with distant metastases. A common site for metastases is the lung, particularly in diseases such as Wilms tumor, sarcomas, and hepatoblastoma. Whole lung irradiation (WLI) is often used as adjuvant therapy for patients with distant lung metastases. Unfortunately, lung tissue is particularly sensitive to the effects of radiation, and the untoward effects of WLI are a concern, both during and well beyond the end of therapy. In addition, total body irradiation (TBI) is commonly used as part of pretransplant conditioning regimens.

Therapeutic doses of radiation can cause acute (radiation pneumonitis) and chronic (radiation fibrosis) lung injury. The incidence of acute radiation pneumonitis is up to 15% of adults treated for breast and lung cancers and Hodgkin disease, but the incidence in pediatric patients is less well described.[176] The incidence may be dependent on the radiation dose, fractionation, and volume of lung exposed,[177] as well as concurrent chemotherapy.[178] At thoracic radiation doses approximating 1000 cGy or more, total lung capacity and diffusing capacity may be significantly impaired.[179–181] Some chemotherapeutic agents (bleomycin, dactinomycin) have additive toxicity with radiation, and others (actinomycin D and Adriamycin) can result in a "radiation recall" effect, with delayed presentation of toxicity, up to 6 weeks later.[182,183]

Acutely, radiation injury results in the release of a number of proinflammatory cytokines that can cause subendothelial and perivascular damage. Over time, this causes type II pneumocyte hypertrophy and infiltration of inflammatory cells.[184] Radiation pneumonitis typically presents 30–90 days after radiation therapy, with symptoms of cough, dyspnea, hypoxemia, and pleuritic pain. Examination may reveal crackles or a pleural friction rub, and chest radiography may show diffuse haziness or ground-glass densities. Early injury may be detected by decreases in diffusing capacity for carbon monoxide. The differential diagnosis for this presentation includes infections and other etiologies that must be excluded. Treatment of radiation pneumonitis usually involves systemic corticosteroids, based on a murine model of radiation toxicity.[185]

Radiation fibrosis may appear 6–24 months after radiation therapy. It is usually but not always preceded by symptoms of radiation pneumonitis, and itself most commonly presents with progressive dyspnea. Radiographically, there may be streaky densities, decreased lung volume or atelectasis, or pleural thickening. Pulmonary function findings include hypoxemia, a restrictive defect, and decreased diffusing capacity. Histologic findings include pleural and subpleural fibroses, interstitial fibrosis, interstitial pneumonitis, interlobular septal fibrosis, and obliteration of pulmonary vessels (Fig. 64.5). Unfortunately, there is no useful treatment for radiation fibrosis. Some patients with severe lung disease because of radiation fibrosis have undergone lung transplantation. As such, efforts should be focused on prevention (with considerations of shielding, dose, and effects of other agents) and close monitoring for patients at high risk.

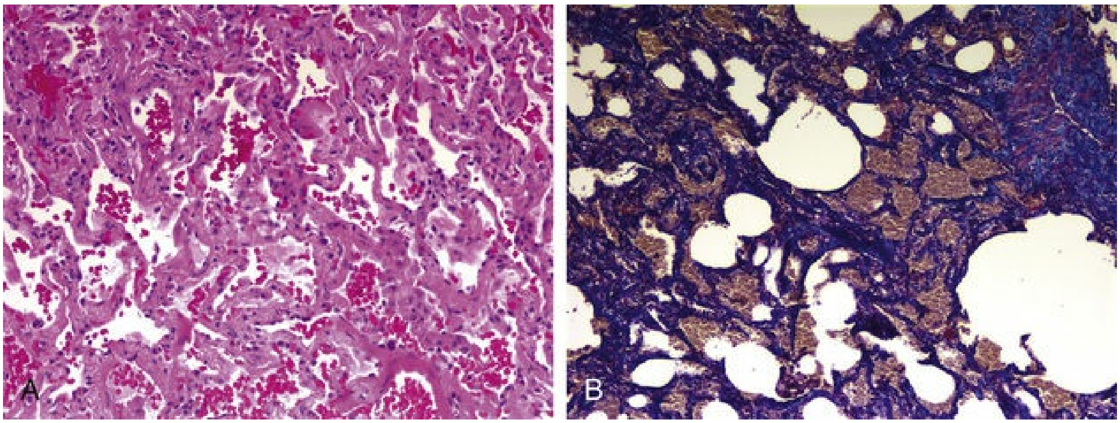

**FIG. 64.5** Radiation fibrosis. (A) Hematoxylin and eosin (H&E) stain, 20×, showing pleural, subpleural, and interstitial fibrosis; foci of chronic interstitial pneumonitis; and irregular scars within the parenchyma. The interlobular septa are fibrotic and thickened with obliteration of some of the pulmonary vasculature. (B) Trichrome stain showing significant collagen deposition.

Analysis of self-report data from the Childhood Cancer Survivor Study[186,187] cohort showed that in survivors who were more than 5 years from diagnosis and received radiation to the chest or TBI, there was a statistically significant increase in the relative risk of developing late pulmonary complications. These included lung fibrosis, emphysema, recurrent pneumonia, chronic cough, persistent shortness of breath, and abnormal chest wall development. As more children survive cancer and live well into adulthood, it is important to consider the late effects associated with WLI.[178] Beyond the lung parenchyma itself, radiation can also impair the growth of the muscle, cartilage, and bone of the thorax. Studies in adults receiving WLI suggest that mild restrictive disease usually resolves over a period of 2–4 years. However, the ongoing development of the chest wall and the lung in children makes the impact of such toxic therapy quite different. Continued alveolar multiplication occurs until 2–4 years of age, and alveolar enlargement continues for some time after that.[188] The growing chest wall may also be impacted by radiation treatment. Weiner and colleagues reported a retrospective review of pulmonary function in 30 children who had received WLI[189] for treatment of malignancy. At a median of almost 3 years post radiation, 20% of subjects had moderate or severe reduction in $FEV_1$, 43% had moderate or severe reduction in TLC, and 43% had moderate or severe reduction in diffusing capacity. At least two patients demonstrated a clear progressive decline over time. These authors suggested that recognition of early abnormalities might allow for earlier intervention for radiation pneumonitis (e.g., corticosteroid therapy) and that it cannot be presumed (as in adults) that loss of lung function after radiation is transient.

Benoist and coworkers[180] followed 48 children treated with WLI for Wilms tumor for 2–17 years following treatment. Two subjects had clinical evidence of radiation pneumonitis shortly after treatment, which resolved within 3–8 weeks. In this study, the percentage of patients with abnormal TLC or lung compliance increased over time, with reduced TLC observed in 50% at 6 months and greater than 90% at 6 years. These authors posit that early lung function abnormalities are caused by parenchymal lung injury, while later effects result from impaired chest wall growth. These findings argue for continued pulmonary follow-up of children treated with thoracic irradiation.

## Pulmonary Complications of Hematopoietic Stem Cell Transplantation

Significant advances in transplantation immunology as well as innovations in chemotherapy and irradiation have allowed HSCT to become a more viable therapy for the treatment of hematologic diseases. The science of bone marrow transplantation, which began as the allogeneic transplantation of whole bone marrow, has progressed to include allogeneic altered marrow (e.g., T cell depleted), autologous marrow, and HSCT. Despite many advances, even the most experienced transplant centers encounter significant posttransplantation morbidity and mortality. Infectious and noninfectious pulmonary complications remain common following marrow transplantation in both adults[190–192] and children.[193–196] While most studies of HSCT recipients deal with adults rather than children, many important principles apply across age barriers. Although different sources of stem cells for transplantation (e.g., allogeneic or autologous) portend different risks of particular complications, we will describe potential complications in a more general fashion and will refer to relative incidences when appropriate. In addition, we will refer to these procedures collectively as HSCT.

## Pretransplant Factors

Some preexisting diseases that themselves are treated with HSCT may have significant pretransplant pulmonary complications. For example, sickle cell disease (SCD) can be complicated by previous acute chest syndrome and pulmonary infarction,[197] and patients with underlying malignancies may have been treated with irradiation targeting the lung or with pulmonary toxic chemotherapy including bleomycin, busulfan, or cyclophosphamide. These all may affect lung function prior to HSCT.

It is critical that patients previously exposed to treatments that are potentially "pneumotoxic" have pre-HSCT pulmonary screening (Table 64.2), including the determination of lung volumes, flows, diffusing capacity, and respiratory muscle strength. The monitoring of PFTs remains useful during the posttransplantation period and can be especially important as adjuncts to radiographic evaluation of intercurrent illness affecting the lung. Recent reports suggest that pre-HSCT pulmonary function can predict post-HSCT pulmonary complications as well as survival.[198,199] Musculoskeletal weakness is both a common preexisting condition and a known complication of HSCT[200]; several relatively simple tests (6-minute walk test and respiratory muscle strength test) are useful in identifying patients at risk,[201] allowing for musculoskeletal rehabilitation and nutritional support in both the pre- and post-HSCT period.

**Table 64.2**

**Recommendations for Pulmonology Evaluation Prior to Hematopoietic Cell Transplantation**

| |
|---|
| History/physical examination |
| Chest radiograph |
| High-resolution, thin cut, computed tomography (CT) scan of chest |
| Pulmonary function testing[a]: Spirometry |
| Lung volumes |
| Transfer factor (diffusing capacity) |
| Maximal inspiratory/expiratory pressure |
| Six-minute walk test |

[a] Pulmonary function testing will depend on patient age and cooperativity.

Spirometry, plethysmographic lung volumes, and even diffusing capacity have been performed in infants and toddlers unable to cooperate with traditional testing. See Chapter 11 for a further discussion of these techniques. Whether infant lung function testing can be used to predict risk for pulmonary complications of HSCT has not been studied but is an area that requires further investigation.

The impact of some conditioning regimens on post-HSCT pulmonary complications has led to alterations in the intensity of these regimens. This approach may lead to improved survival with diminished toxicity in selected circumstances, such as in recipients with primary immunodeficiencies who are to receive HSCT from an HLA-matched unrelated donor[202] or in patients with SCD.[202,203]

There is a variety of other pre-HSCT factors that may adversely affect post-HSCT pulmonary status and complications. These consist of pulmonary infections, including viral illnesses, thoracic surgical procedures, chronic aspiration, and gastroesophageal reflux. Several lower respiratory infections, particularly invasive fungal disease, can increase the risk of both recurrent infection and pulmonary debilitation post-HSCT. The increased risk of recurrent fungal infection in patients undergoing intensive chemotherapy[204] led to more widespread use of antifungal prophylaxis to prevent recurrence following HSCT.[205] This practice has allowed consideration of HSCT in these high-risk patients.[206,207] Thoracic surgical procedures prior to HSCT may include lobectomy or wedge resection of pulmonary metastatic disease or for surgical diagnosis of localized fungal infections. The added risk of HSCT closely following thoracic surgery is unknown, but reduced lung function from surgery undoubtedly contributes to the additional risks of low pretransplant lung function.

Cytoreductive therapy and irradiation alter host defenses and disturb mucosal integrity, potentially leading to colonization with potential pathogens. Potential HSCT recipients with dysphagia or odynophagia should be evaluated for esophagitis, as the damaged esophageal mucosa, aided by neutropenia, increases the risk of esophageal colonization with organisms, including *Candida* and *Herpes simplex*. Esophagoscopy may help direct therapy for such patients.[208] In addition, gastroparesis and delayed gastric emptying resulting in nausea, gastroesophageal reflux, or decreased oral intake may be seen following HSCT.[209,210]

Malnutrition is common in pediatric patients being considered for HSCT, and accurate determination of the degree of malnutrition is important.[211] Because myeloablative and irradiative conditioning regimens can lead to mucositis affecting oral intake and because malnutrition is felt to be an independent risk factor for mortality following HSCT,[212] the use of enteral or parenteral feeding is common following HSCT.[213,214]

## Early Noninfectious Posttransplant Complications (Fig. 64.6)

### Oral and Perioral Complications

Oral mucositis affects the majority of patients undergoing HSCT[215] and can lead to dysphagia, as well as laryngeal or epiglottic edema, resulting in upper airway obstruction. It is recognized to increase the risk of infection, lengthen hospital stay, and increase the cost of care.[216] Although oral mucositis likely represents the sequelae of intensive chemotherapy and irradiation,[217] other important factors (e.g., bacterial colonization of the mucosal surface, upregulation of proinflammatory cytokines, and oxidative radical production) play an important role.[215,218,219] It is usually seen within the first week of irradiation and reaches its peak 1–2 weeks following HSCT.[220] Impaired mucociliary clearance in the nasopharynx, along with oropharyngeal mucositis, can lead to both upper and lower airway complications, including sinusitis, oropharyngeal bleeding, upper airway obstruction, stridor, and aspiration pneumonia. Advances in the understanding of the pathophysiology of oral mucositis have led to newer treatments, including dietary manipulation, mucosal administration of monochromatic light, and the administration of cytokines, such as keratinocyte growth factor.[215,221,222]

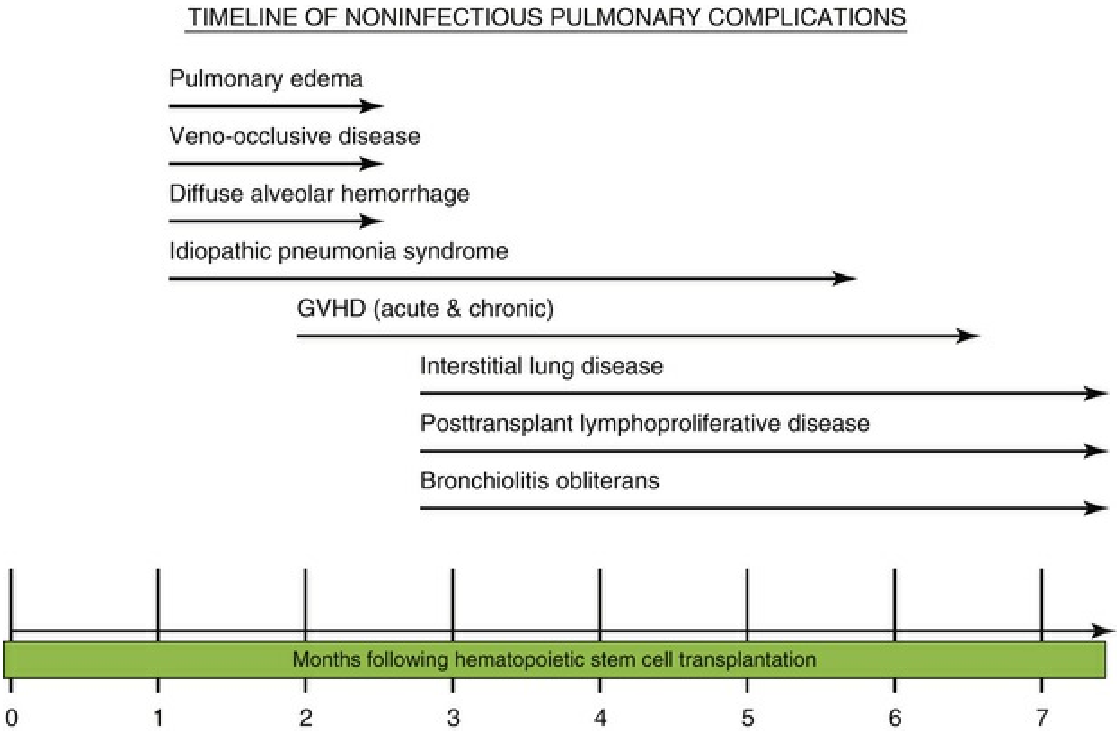

**FIG. 64.6** Timeline of noninfectious pulmonary complications following hematopoietic stem cell transplantation. *GVHD*, Graft-versus-host-disease.

## Pulmonary Edema and Capillary Leak Syndrome

Pulmonary edema in the posttransplant period is relatively common[195,223,224] and is characterized by a rapid onset, usually within the 2–3 weeks following HSCT. Potential etiologies include increased hydrostatic pressure from either overly vigorous rehydration or fluid overload via parenteral nutrition, cardiac dysfunction following the use of anthracyclines, and renal toxicity following cyclophosphamide. Other causes of increased pulmonary capillary permeability may include sepsis and direct pulmonary toxicity secondary to irradiation and chemotherapy. Clinical features may include dyspnea, tachypnea, weight gain, hypoxemia, and basilar crackles on chest auscultation. Chest radiographs often show bilateral infiltrates, and pleural effusions may be present.

Treatment usually involves vigorous diuresis.

## Peri-Engraftment Respiratory Distress Syndrome

This entity has a low incidence (~5%), and it occurs within the first 14 days following HSCT, at a time coinciding with neutrophil engraftment.[225,226] The characteristic clinical and radiographic features include hypoxemia and respiratory distress. Chest radiographic findings include diffuse edema and pulmonary infiltrates, and in some cases pleural effusions.[227] BAL and other invasive studies are consistently negative for pathogens. While its name and timing might suggest a specific pathology, there are no biochemical markers or pathognomonic histopathologic findings to distinguish it from other forms of respiratory distress in the period closely following HSCT. Therapy is supportive, and although steroids have often been utilized for treatment, their efficacy is unproven.

## Idiopathic Pneumonia Syndrome

IPS (also known as *idiopathic interstitial pneumonitis*) has a reported incidence of 5%–10% in adult HSCT recipients,[228,229] although the incidence in pediatric recipients is more difficult to assess. A National Heart, Lung, and Blood Institute Workshop[230] refined the definition of IPS and established clinical and diagnostic criteria for it. Accordingly, the clinical manifestations of IPS include dyspnea, nonproductive cough, hypoxemia, and crackles on auscultation; pulmonary function testing (PFT) reveals a restrictive pulmonary physiology, and diffuse or nonlobar infiltrates are seen on chest radiograph. In order to confirm this diagnosis, BAL cultures must be negative for bacterial, viral, and fungal pathogens; a second negative BAL is recommended 2–14 days following the initial negative BAL. Open lung biopsy is not specifically suggested, although transbronchial biopsy may be considered if the patient's condition will allow it. Pathologically, IPS can have two distinct histopathologic types: interstitial pneumonia and diffuse alveolar damage. IPS is typically an early complication of HSCT. Previous reports of IPS incidence described a bimodal pattern, with an initial peak approximately 2 weeks and a later peak 6–7 weeks post-HSCT.[230] While an entity essentially identical to IPS can be seen greater than 100 days following HSCT, the incidence of this much later complication is unknown. A review of more than 1000 HSCT recipients[229] indicated that the overall incidence of IPS was 7.3%, with no significant difference in incidence between recipients of autologous and allogeneic HSCT. Pediatric patients (<20 years of age) had a slightly lower incidence of IPS. The median time between HSCT and onset of symptoms of IPS was 21 days; the hospital mortality was 74%, and multiorgan failure rather than isolated respiratory failure was associated with mortality. Potential causes for IPS have included direct pulmonary toxicity resulting from pre-HSCT conditioning, as well as immunologically mediated factors resulting from alloreactivity.[231–234]

Treatment for IPS remains supportive; steroids, although often used, have not been shown to have a beneficial effect. The need for mechanical ventilation in these patients is associated with a poor prognosis.

## Diffuse Alveolar Hemorrhage

Robbins and colleagues are generally credited with the description of what is known as diffuse alveolar hemorrhage (DAH) in recipients of HSCT, although the syndrome has been recognized for more than 30 years.[235,236] This entity appears to be much more common in adult than in pediatric recipients of HSCT.[236,237] It usually appears within 30 days post-HSCT and coincides with marrow recovery. Of interest is the finding of relative BAL neutrophilia, despite peripheral leucopenia.[235] A retrospective analysis of pediatric HSCT recipients suggests that the incidence of DAH is approximately 5%, with allogeneic recipients being at higher risk.[238] The clinical onset is often relatively sudden and rapidly progressive, with dyspnea, hypoxemia, and crackles on auscultation. On BAL, the characteristic feature is that with each successive aliquot instilled, the effluent becomes more hemorrhagic[236]; however, the specificity and sensitivity of the findings are not completely clear. Agusti and coworkers reported on four of eight HSCT recipients who had DAH on postmortem and nonhemorrhagic BALs, while 7 of 13 patients without pathologically proven DAH had hemorrhagic BALs.[239] Thus clinical correlation, timely performance of BAL, and sampling of multiple sites may be important in establishing the presence or absence of DAH.

### Pulmonary and Hepatic Veno-Occlusive Disease

First reported by Troussard and colleagues, this entity presents as a form of pulmonary hypertension, with dyspnea, signs of right-sided heart failure, and pulmonary infiltrates on chest radiograph.[240] Children compose the most significant proportion of HSCT recipients affected by veno-occlusive disease (VOD).[241,242] Hepatic VOD, another vascular complication of HSCT, is often associated with pulmonary VOD and interstitial pneumonitis.[243] In both, small veins and venules are partially or completely occluded by intimal fibrosis. The explanation of the relatively common coexistence of hepatic and pulmonary VOD is unknown. Possibilities include coexistent underlying toxicities or genetic factors. The diagnosis of pulmonary VOD requires a high index of clinical suspicion, as many cases reported in the literature are diagnosed postmortem.[240] Some recent reports suggest that serum levels of vascular endothelial growth factor or plasma protein C activity may be useful surrogate markers for the development of VOD,[244,245] but larger controlled studies will be needed before their routine use can be recommended. Echocardiography, cardiac catheterization, BAL to rule out intercurrent infection, and transbronchial or transthoracic lung biopsy are potential clinical investigations that should be tailored to the patient's condition and the clinical circumstances. Treatment options for pulmonary VOD are few, although reports demonstrate that defibrotide, a polydisperse oligonucleotide with fibrinolytic and antithrombotic properties,[246,247] may be effective therapy for hepatic VOD.[248] There are also reports of its utility in preventing VOD in HSCT recipients at increased risk for this complication.[249]

## Pulmonary Function Following Human Stem Cell Transplantation

A significant proportion of children who undergo HSCT have abnormalities in PFT both soon after HSCT and later after engraftment has taken place.[196,198,250] Ginsberg and coworkers[198] reported a retrospective analysis of serial pulmonary function test subjects; 273 had at least one pretransplant PFT. The majority of patients had normal or mildly reduced spirometry (FVC and $FEV_1$) and lung volumes prior to transplant. In addition, the majority had a decreased diffusing capacity, with 25% having moderately or severely reduced diffusion. Following HSCT, FVC and $FEV_1$ decreased significantly over the first 6 months, improved slightly between 6 and 12 months, and remained stable at 1–2, 2–5, and more than 5 years. Diffusing capacity also decreased 6 months post-HSCT, with gradual but incomplete improvement by 5 years posttransplant. In a multivariate analysis, patient age, underlying diagnosis, and transplant type (autologous vs. allogeneic) all had independent predictive value for decline in DLCO following HSCT. Similar reports describe pulmonary function abnormalities in those who have received HSCT with TBI conditioning.[251–253] Other studies have shown that older age at HSCT,[254] female sex,[254,255] busulfan,[254] TBI,[256,257] chronic GVHD,[258] and peripheral blood stem cell graft[254] are also associated with risk for pulmonary function decline.

## Late Noninfectious Posttransplant Complications

The differential diagnosis of late-onset pulmonary complications extends from the complications listed in the early noninfectious group to include obliterative bronchiolitis (OB), also known as bronchiolitis obliterans, possibly associated with underlying chronic GVHD, cryptogenic organizing pneumonia (COP, formerly *bronchiolitis obliterans organizing pneumonia,* or BOOP) and posttransplant lymphoproliferative disorder (PTLD).[133] In addition, persistent post-HSCT pulmonary findings of VOD and IPS continue to occasionally complicate the late posttransplant course.

### Obliterative Bronchiolitis (“Bronchiolitis Obliterans Syndrome”)

Development of chronic lower airways obstruction is a common late pulmonary complication following HSCT and is most commonly associated with pathologic changes of OB.[192,259,260]

Bronchiolitis obliterans syndrome (BOS) refers to the finding of progressive obstruction, even when pathologic evidence of OB has not been demonstrated on open lung biopsy and is most commonly associated with evidence of chronic GVHD, and is much more common following allogeneic, as opposed to autologous, marrow transplantation. Additional risk factors include early posttransplant viral infection and advanced age of the recipient.[192,261] Symptoms are generally seen 12–24 months after HSCT but have been described as early as 90 days after transplantation. The primary symptoms reported at clinical presentation include dyspnea, wheezing, and nonproductive cough; fever is not common.

The chest radiograph is usually normal although hyperinflation and increased linear markings may be present. High-resolution lung CT scans performed on inspiration (TLC) and expiration (RV) in cooperative individuals or using passive lung maneuvers in pediatric patients demonstrate characteristic abnormalities and have become the standard diagnostic technique. The most common chest CT findings in BOS is a heterogeneous pattern with areas of patchy hyperaeration, areas with bronchial dilatation, and other areas characterized by hypoattenuation or increased density.[262,263] This combination of findings is often referred to as *mosaic perfusion or attenuation* and is highly suggestive for BOS (Fig. 64.7A).

characterized by areas of varying attenuation. (B) A photomicrograph of an airway demonstrating subepithelial fibrosis *(arrows).* Trichrome stain, 100×. (C) Severe lung disease following human stem cell transplantation seen on chest high-resolution CT scan. Note bronchomegaly and bronchiectasis, seen best in the right upper lobe. Additional findings included widespread fibrosis of the right upper lobe and lingula, with relative sparing of the left lower lobe, and bilateral pleural thickening.

PFT demonstrates airflow obstruction, as shown by a decrease in $FEV_1$ and a reduction of the $FEV_1/FVC$ ratio without significant reversiblity.[228] The degree of air trapping seen on CT images may correlate with the pulmonary function abnormality. Confirmatory biopsy to make the diagnosis of BOS is now rarely indicated based on the sensitivity of imaging studies.[192,264] The diagnosis of post-HSCT BOS is often made based on the clinical presentation of cough or dyspnea, and there may be changes in lung function testing when screening asymptomatic patients.[265] Overall, up to 10% of allogeneic transplant recipients will have some degree of BOS and chronic air flow obstruction.[266] If lung biopsy is performed for confirmation of the diagnosis and to exclude other causes, this will demonstrate subepithelial fibrotic changes in the airways, a common pathologic finding in OB (see Fig. 64.7B). The insidious nature of this process, together with continuing inflammatory changes involving the airways and parenchyma, can result in end-stage lung disease with diffuse areas of traction bronchiectasis and fibrosis (see Fig. 64.7C).[267]

The incidence is variable, with reports ranging from 2% to 20%.[261] The lack of direct evidence of small airway inflammation resulting in BOS leads to the implication that donor T helper cell alloreactivity causes distal airway epithelial cell injury, which in turn leads to the pathologic changes seen.[263] Patients undergoing aggressive treatment for chronic GVHD, as well as those who had specific conditioning regimens utilizing busulfan and irradiation,[266] are at most risk for BOS; however, these simply remain recognized associations, resulting in an increased incidence of airways obstruction without a defined mechanism.

Therapy for post-HSCT BOS remains controversial and has generally centered on augmenting immunosuppression. Calcineurin-inhibitors and azathioprine, as well as steroids, have reduced the decline in lung function and have shown improvement in a small proportion of subjects.[268] Azithromycin, a macrolide antimicrobial, may improve lung function in patients suffering from BO post-HSCT,[269] and has been combined with leukotriene-receptor antagonists, and combination inhalers with long-acting bronchodilators and high-dose inhaled steroids in adults with new onset BOS with modest benefit.[270] Cycled high-dose corticosteroids have been shown to increase oxyhemoglobin saturation and improve $FEV_1$ in a small cohort of pediatric patients following transplant.[271] Additional multicenter clinical trials of these and other innovative therapies for BOS in pediatric HSCT patients are clearly needed.

## Interstitial Lung Diseases

Interstitial lung disease, which presents with a restrictive pattern and diffusion impairment on PFT, has also been reported as a late posttransplant complication. Here the typical presentation is that of an asymptomatic subject, who on posttransplant monitoring is found to have a progressive decline in the vital capacity and/or diffusion capacity for carbon monoxide.[265] Whereas IPS may be the etiology for these changes, irradiation, chemotherapy, infectious pneumonitis, and BOOP could all contribute to these PFT alterations. Despite efforts to develop a good predictive model, these authors were unable to demonstrate any specific covariates that might predict development of restrictive change. This may be similar to an entity seen in adult HSCT recipients and termed *delayed pulmonary toxicity syndrome.*[272]

Although the diagnosis is often delayed if based on lung function testing alone, certain predisposing conditions should raise awareness of the potential for developing this restrictive pattern. Some of these may extend from the early posttransplant period and include infection and VOD. However, the most common cause remains pre-HSCT exposure to cytotoxic drugs or irradiation.[273,274] Although steroids may result in clinical improvement,[271] full diagnostic studies should be undertaken to rule out deterioration related to known pretransplant pulmonary causes, as well as to rule out infectious etiologies.

## Cryptogenic Organizing Pneumonia

COP, formerly known as *bronchiolitis obliterans with organizing pneumonia* or *BOOP,* differs from OB histologically, physiologically, and most significantly in its response to treatment. It is histologically distinguished by patchy areas of consolidation with polypoid plugs of loose organizing connective tissue in the respiratory bronchioles and alveolar ducts.[267,275,276] Associated inflammation may be mild to moderate, but the proliferative bronchiolitis is manifest by patchy infiltrates on chest radiograph and by restriction on PFT.[192,276] Unlike many other post-HSCT complications, COP/BOOP often improves with corticosteroid therapy. However, it is critical to rule out other post-HSCT complications, particularly infections that may cause similar symptoms and pulmonary radiographic changes. For this reason, bronchoscopies with BAL as well as open lung biopsy are often required to seek potential infectious causes as well as to document the histopathology of the lung.[264] In addition, a response to steroids will help differentiate between OB and COP/BOOP if the diagnosis is obscure, despite studies such as bronchoscopy and open lung biopsy.[277]

## Posttransplant Lymphoproliferative Disorder

PTLD can occur after HSCT, as it does after solid-organ transplantation (described earlier in the chapter). In this population, allogeneic transplants, human leukocyte antigen (HLA) mismatched transplants, T cell-depleted grafts, and Epstein-Barr virus (EBV) seronegative recipients who receive transplants from EBV seropositive donors are at increased risk.[278] The pathogenesis, monitoring, and treatment of PTLD in the HSCT recipient are similar to those described previously for the solid-organ transplant recipient. The presentation is usually within the first year following HSCT, with the peak incidence 1–5 months after transplant.

## Pulmonary Alveolar Proteinosis

Pulmonary alveolar proteinosis (PAP) has rarely been described in conditions associated with immune impairment including post-HSCT.[192,279] This condition is associated with the excessive accumulation of surfactant lipoprotein in the alveolar space and results in defective air exchange and hypoxemia. The diagnosis can be suggested on CT and is easily made on BAL, where the distinctive finding is the lipoproteinaceous milky white fluid recovered from the lower airway. This finding can be subsequently confirmed via laboratory analysis.[192] The treatment for PAP requires the physical removal of this excessive surfactant material, usually by sequential lavage.[280]

### Respiratory Failure

Chronic respiratory complications following HSCT, particularly BOS and interstitial lung disease, can lead to respiratory insufficiency and, ultimately, respiratory failure. Because of this, monitoring the pulmonary and cardiac status of HSCT recipients who have these complications will allow the clinician to intervene appropriately with treatment when possible. Unfortunately, the treatments for BOS and interstitial lung disease are often unsuccessful. For such conditions with end-stage lung disease, lung transplantation may be a treatment option.[281] As in the case of other chronic lung diseases, such as cystic fibrosis,[282,283] the use of noninvasive ventilatory support will likely play an increasingly important role in allowing patients to be "bridged" to lung transplantation. Whether a HSCT patient is a candidate for lung transplantation may depend upon the time from remission from the primary malignancy and varies from 2 to 5 years. One review of lung transplantation in HSCT patients reported that outcome of HSCT patients after lung transplantation was comparable to other transplant recipient populations.[284]

## Approach to Pulmonary Disease in the Immunocompromised Pediatric Host

## Radiographic Testing

In pediatric patients with either oncologic disease or other states of significant immunosuppression, radiographic evaluation including chest radiographs or, in selected cases, CT scans will help define pulmonary abnormalities before proceeding to further treatment such as ablative chemotherapy and HSCT. These preliminary studies will be useful, should post-HSCT pulmonary complications such as pulmonary edema, pulmonary hemorrhage, pneumonia, or BO develop.[133]

The common causes of general radiographic patterns in the immunocompromised patient are shown in Table 64.3, but it must be emphasized that findings on plain chest radiograph are often nonspecific and may underestimate the extent of disease. CT scans may demonstrate other findings such as early cavitation or visceral fungal lesions and, in addition, can better demonstrate pulmonary anatomy, directing other interventions such as bronchoscopy or biopsy.

### Table 64.3

*ARDS,* Acute respiratory distress syndrome; *BOS,* bronchiolitis obliterans syndrome; *DAH,* diffuse alveolar hemorrhage; *PTLD,* posttransplant lymphoproliferative disease; *RSV,* respiratory syncytial virus; *TRALI,* transfusion-related acute lung injury.

Common radiographic findings include air-space consolidation, ground-glass opacities, nodules, and air trapping. Nodular opacities are common, ranging from relatively large and discrete lesions, to smaller nodules that appear to run along bronchovascular bundles (tree-in-bud pattern). Consideration of factors such as medication exposures, the duration of patient symptoms, and the underlying patient immune status can help narrow the differential diagnosis and guide treatment or further diagnostic testing.

## Noninvasive Diagnostic Studies

PFT can be a useful adjunct to other noninvasive studies when evaluating a patient with acute pulmonary complications. PFTs alone will rarely provide strong evidence of a specific diagnosis, but there are important exceptions to this. The first is the chronic and progressive decrease in diffusing capacity, coupled with a decrease in TLC, which is commonly seen secondary to interstitial disease from radiation pneumonitis. The second is the progressive development of airflow obstruction and air trapping, as is seen with BO. PFTs otherwise, however, must be viewed in the context of other factors, including the patient's degree of immunodeficiency, the type of pulmonary symptoms and signs, and the timing of symptoms relative to previous therapy. More important is the utility of following PFTs longitudinally in patients with acquired immunosuppression, as this may alert the clinician to the development of more chronic complications, especially BO. In addition, tests of small airway dysfunction (e.g., multiple breath washout) may be useful for detection of chronic graft versus host disease.[285]

The majority of the data on post-HSCT pulmonary function is from adults, although several pediatric case series have been described.[196,198,250,255,286,287] Pre-HSCT therapy, including chemotherapy and preparative myeloablative therapy, is an important risk factor for pulmonary sequelae. In addition, patient age is important, as the continuing lung development of pediatric patients may mitigate the risk of pulmonary toxicity from chemotherapeutic or myeloablative regimens, lung irradiation, or immunosuppressive medications posttransplantation. Specific agents that may cause pulmonary injury include busulfan, cyclophosphamide, methotrexate, BCNU, and radiation.[288] See Chapter 59 for a further discussion of these agents.

Analysis of sputum produced by cough induced with inhalation of hypertonic saline aerosols has been useful in older immunocompromised children with suspected PCP. Gastric aspirates can be used in the younger child with suspected atypical infections (e.g., tuberculosis). If the child requires endotracheal intubation for respiratory failure, endotracheal aspirates are easy to obtain.

The ability to detect capsular polysaccharide antigens of bacterial pathogens, even after antimicrobials have been administered, is occasionally helpful in hospitalized patients. A number of tests for direct detection of fungal antigens have been described (e.g., the serum galactomannan assay for *Aspergillus*), although its sensitivity and specificity in children may be lower than in adult patients.[81] Direct immunofluorescence can be used to detect *Legionella* sp. with high sensitivity and specificity.[130] Enzyme-linked immunosorbent assays or direct immunofluorescence tests of blood or BAL are now available for the rapid diagnosis of RSV, influenza A virus, parainfluenza viruses, *Chlamydia,* and mycobacterial infections.[289] Viral cultures are generally available, and the shell vial technique for rapid identification of CMV is very useful.

Genetic probes for detecting respiratory viruses, *P. jirovecii, Legionella, Mycobacterium,* and *Mycoplasma pneumoniae,* are now commercially available, and the ability of the PCR to amplify specific regions of genomic DNA or RNA should allow a broader application of these sensitive diagnostic approaches in the immunocompromised patient, particularly when combined with BAL to obtain specimens. Diagnostic tests for the rapid detection of potential respiratory pathogens is an area of expanding importance, and a recent review summarized several technologies, including nucleic acid amplification tests (NAATs).[290]

## Invasive Diagnostic Studies

Unfortunately, radiography and other noninvasive diagnostic studies rarely result in a specific diagnosis in the immunocompromised child with pulmonary disease. The clinician is often faced with either continuing empiric antimicrobial therapy or performing a more invasive diagnostic study to make a specific diagnosis. Fortunately, the safety and availability of these studies have improved significantly over the last decade.

### Flexible Bronchoscopy and Bronchoalveolar Lavage

Flexible bronchoscopy is safe in experienced hands and provides excellent diagnostic material in the immunocompromised child with pneumonia (see Chapter 9 for a detailed discussion).[291–293] Indications for bronchoscopy in children with pneumonia generally include (1) failure of pneumonia or fever to improve with empiric antimicrobial therapy, (2) suspicion of endobronchial obstruction by infection or tumor, (3) recurrent pneumonia in a lobe or segment, and (4) suspicion of unusual organisms. Although the yield of gastric aspiration or BAL is probably superior to bronchoscopy for suspected tuberculosis,[294] bronchoscopy has the added value of allowing evaluation for endobronchial disease or bronchial compression.[295] Simple cytology brushing obtained through the pediatric bronchoscope can be used for cytological examination and viral cultures, but the yield is usually low. The bronchoscope suction channel may become contaminated by upper airway organisms during the procedure, and simple washings obtained through the bronchoscope channel are generally less useful than quantitative cultures of BAL. Nonetheless, BAL is the most useful bronchoscopic technique in the immunocompromised host, and a variety of infectious and noninfectious diagnoses can be made this way.[296] Further, BAL is generally safe, even in patients with thrombocytopenia.[297]

Although bronchoscopy with BAL may provide useful diagnostic information and is generally well tolerated, its limitations should also be appreciated. In immunocompromised patients who have received empiric broad-spectrum antimicrobial therapy for some period of time, the yield of BAL in isolating a new bacterial pathogen is likely to be low.[298] In oncology patients and other non-AIDS immunocompromised patients, the number of *P. jirovecii* organisms is usually low compared with AIDS patients, and BAL may be falsely negative.[299] In populations receiving prophylaxis for this infection, the yield for PCP will also probably be low. CMV can also be diagnosed rapidly by assays on BAL, but CMV may be a commensal rather than an infecting organism. In addition, patients may have copathogens that are the predominating organism, rather than CMV. *Aspergillus* and other fungi are often difficult to diagnose by bronchoscopy, particularly early in the infection when therapy is most likely to be effective. In pediatric HSCT recipients, fungal infections were the most common infection diagnosed by BAL, but the yield was only 17% in the early conditioning (pre-HSCT) period (where broad-spectrum antimicrobial coverage was common), compared with 82% following transplant.[300]

Transbronchial biopsies can also be taken via the flexible bronchoscope. Though safe in older patients, transbronchial lung biopsies may yield an unacceptable number of false-negative results in immunosuppressed patients and are most useful when organisms such as *P. jirovecii* or granulomatous lesions are probable. The standard pediatric bronchoscopes, 2.8 or 3.6 mm in diameter, have suction/biopsy channels of only 1.2 mm diameter, accommodating biopsy forceps of only 1 mm diameter. The resultant biopsies from such forceps are quite small, leading to the risk of false-negative results in infants. Older children are more likely to tolerate larger bronchoscopes with 2 mm (or larger) channels, allowing for the passage of 1.8-mm forceps and larger biopsy samples. Reported experience with transbronchial biopsies in pediatric patients is limited,[300] but transbronchial biopsy has a significant role in monitoring acute rejection and infections in the pediatric lung transplant patient and in skilled hands can be done with conscious sedation and a transnasal approach in the older child.[301] Transbronchial biopsy for the diagnosis of BO complicating HSCT is not recommended, as it is difficult to obtain adequate specimens using this technique.

## Transthoracic Needle Aspiration Biopsy

Needle aspiration of the lung has been used for the diagnosis of PCP in pediatric cancer patients and for the diagnosis of localized infections in other immunosuppressed patients. Pneumothorax has been reported as a relatively frequent complication of needle aspirates done for PCP,[302] and this risk must be considered even with more modern “thin”-needle techniques. The use of CT guidance greatly improves the yield and safety of transthoracic needle aspiration biopsy, particularly in the presence of peripheral nodular disease. As a result, it is the procedure of choice for children with peripheral lesions that are difficult to reach with a flexible bronchoscope, as they can safely be sampled, avoiding an open biopsy.[303]

## Open-Lung Biopsy

Open-lung biopsy (OLB) is the gold standard by which other pulmonary diagnostic modalities are judged. Its advantages include the larger amount of lung tissue sampled and the ability to sample different lobes. Using current surgical techniques, OLB is generally a procedure with a low morbidity[304] that can be done rapidly and allows the surgeon to select optimal tissue for culture and microscopic examination. “Mini-thoracotomy” for lingular biopsy may provide sufficient tissue for the diagnosis of diffuse pulmonary processes, significantly reducing the morbidity of the procedure.

Biopsy using video-assisted thoracoscopy (VATS) is now supplanting OLB in many centers, as it can be performed safely in very small infants[305] and does not require chest tube placement following biopsy.[306] Mechanical ventilation is no longer considered a contraindication to VATS.[307] Complications such as respiratory failure, thrombocytopenia, or coagulopathies, and prior antimicrobial/antifungal therapy, increase the risk of VATS as well as OLB and may also reduce the diagnostic yield.

Some studies have questioned how often lung biopsy results will lead to a change in therapy, if one excludes patients with organisms covered by empiric therapy such as *P. jirovecii* and nonspecific histologic findings without specific therapies such as fibrosis or nonspecific lung injury. Published results on OLB and VATS in immunocompromised pediatric patients have indicated yields that range from 36% to 94% for a specific diagnosis and generally support the utility of either procedure.[264,304,308–310]

Although OLB or VATS are considered the procedures most likely to yield definitive diagnostic information in immunosuppressed patients with pulmonary infiltrates, other invasive procedures (e.g., bronchoscopy with BAL as well as CT-guided needle biopsy) may be useful. In addition, choice and timing of procedures in immunocompromised patients requires consideration of the patient's history and response to therapy. If the patient is improving with empiric therapy, any invasive procedure may not be warranted. On the other hand, if a patient is deteriorating despite therapy, then moving expeditiously to a more definitive diagnostic procedure is advised. Early bronchoscopy is relatively safe and may provide a diagnosis without the need for a more invasive procedure. Limitations of bronchoscopy with BAL, however, must be acknowledged. For example, CT-guided needle biopsy has a higher diagnostic yield for isolated peripheral nodular disease. If a more extensive biopsy is deemed necessary, the choice of OLB or VATS will depend on the condition of the patient and the available surgical and anesthetic expertise. In most centers with experienced surgical and anesthetic staff, either procedure is relatively safe, especially when performed before respiratory failure ensues. Even in this situation, OLB or VATS may be indicated in order to establish a specific diagnosis.

# Prevention Strategies

Prevention of infections in immunocompromised patients starts with good hand hygiene and avoidance of exposure to sick contacts (including use of contact precautions, where appropriate).

Antiviral medications (ganciclovir, valganciclovir) may be used to prevent reactivation of CMV. Palivizumab may be used to prevent severe lower respiratory tract infection from RSV in profoundly immunocompromised children less than 2 years of age.[311] Antifungal agents (voriconazole, posaconazole) are often used to prevent infection with *Aspergillus* species. Prophylaxis for *Pneumocystis* in neutropenic patients is usually accomplished with thrice weekly TMP-SMX, pentamidine (inhaled or intravenously), or dapsone. One should consider isoniazid prophylaxis for patients who are immune suppressed in endemic areas of *M. tuberculosis*. This must be balanced, however, with the potential hepatotoxicity of isoniazid; especially in liver transplant recipients.

Ideally, patients should be fully immunized prior to undergoing immunosuppression, as once immunosuppressed they cannot receive live attenuated vaccines. Patients should receive annual inactivated influenza vaccination, although the antibody response may be attenuated[312] with standard dosing. Patients with increased risk for pneumococcal infection (those undergoing splenectomy or stem cell transplant) should receive pneumococcal vaccination at least 2 weeks prior to therapy.[313]

*Alan Paul Knutsen MD, James Temprano MD, Deepika Bhatla MD, Raymond G Slavin MD*

## Hypersensitivity Pneumonitis

### Epidemiology

Hypersensitivity pneumonitis (HP), also known as extrinsic allergic alveolitis, is an immune mediated lung disease occurring in response to repeated inhalation of an antigen.[1–6] It appears to be an underdiagnosed condition, often masquerading as a recurrent pneumonia, idiopathic pulmonary fibrosis, Hamman-Rich disease, or interstitial pneumonia. Extrinsic allergic alveolitis seems particularly appropriate as terminology, because it describes the disease in graphic terms: "extrinsic," meaning it comes from an outside source; "allergic," denoting a hypersensitivity basis; and "alveolitis," referring to that part of the lung most affected by the disease. Whatever term is used, HP is a hypersensitivity reaction of the lung in response to inhalation of an antigen—most often an organic dust. The prevalence and incidence of HP is difficult to estimate. Among individuals exposed to a known antigen(s), the prevalence of pigeon breeder's disease HP is 6%–20% and the prevalence of farmer's lung is 0.5%–19% among farmers.[1,2] The incidence rate of HP at a Danish referral center was 2 cases per year over a 12-year period during a national cohort study on interstitial lung disease.[7]

## Etiology

There are more than 200 antigens known to cause HP (Table 65.1). The etiology of HP differs between adults and children and is due to differences in exposure. The majority of adult cases of HP are due to various occupational exposures. In children, most cases are due to household exposures, with avian antigens being the most common etiology, followed by molds.[6,8] There are multiple categories of antigenic sources, including fungal, bacterial and amoebal proteins, animal proteins, and chemicals and medications (see Table 65.1). In addition, there are a number of factors that determine how one will respond to inhalation of an organic dust. First, what is the basic immunologic reactivity of the host? An atopic individual will characteristically respond with production of IgE antibody. A nonatopic person will more likely produce IgG. Second, what is the nature and source of the antigen? Is it small enough to reach the distal part of the lung? Is it temperature-required such that it will grow in the respiratory tract, such as *Aspergillus?* Finally, consider the nature and circumstances of the exposure: Is it intense and intermittent or is it low-grade and chronic? An intermittent short-term intensive exposure such as that experienced by a pigeon breeder while cleaning out the coops will manifest acute reversible disease. A pet-store employee who has intermittent, lower grade but long-term exposure will develop a subacute form that is usually reversible. Finally, a long-term low-grade exposure experienced by a parakeet owner may result in chronic irreversible disease.[3]

---

**Table 65.1**

## Common Etiologic Antigens and Sources in Hypersensitivity Pneumonitis

| **Disease** | **Source** | **Antigen** |
|---|---|---|
| **BACTERIA** | | |
| Farmer's lung | Moldy hay, moldy plant materials | *Faeni rectivirgula*<br>*Saccharopolyspora rectivirgula,*<br>*Thermoactinomyces vulgaris*<br>*Thermoactinomyces actinomycetes*<br>*Thermoactinomyces sacchari*<br>*Aspergillus* spp |
| Bagassosis | Moldy sugar cane | *Thermoactinomyces sacchari*<br>*Thermoactinomyces vulgaris* |
| Ventilation pneumonitis | Contaminated air conditioners | *Thermoactinomyces candidus*<br>*Thermoactinomyces actinomycetes*<br>*Thermoactinomyces sacchari*<br>*Naegleria gruberi*<br>*Acanthamoeba polyphagia*<br>*Acanthamoeba castellano* |
| Humidifier lung | Ultrasonic cool mist humidifiers | *Bacillus subtilis*<br>*Klebsiella oxytoca* |
| Mushroom worker's lung | Moldy compost and mushrooms | *Thermoactinomyces sacchari* |
| Machine operator's lung | Contaminated/aerosolized metal working fluid | Nontuberculous mycobacteria<br>*Aspergillus fumigatus*<br>*Mycobacterium immunogenum* |
| Floor finisher's lung | Moldy wood | *Cephalosporium acremonium* |
| Hot tub lung | Hot tub mists, tub water, mold on ceiling | *Mycobacterium avium* complex |
| Swimming pool lung | Mist from pool water, sprays, fountains | *Mycobacterium avium* complex |
| **FUNGI** | | |
| Enoki mushroom worker's lung (Japan) | Moldy mushroom compost | *Penicillium citrinum* |
| Composter's lung | Compost | *Aspergillus* spp<br>*Thermoactinomyces vulgaris* |
| Peat moss HP | Contaminated peat moss | *Monocillium* spp<br>*Penicillium citreonigum* |
| Suberosis | Moldy cork | *Thermoactinomyces viridis*<br>*Aspergillus fumigatus*<br>*Penicillium* spp |
| Malt worker's lung disease | Moldy or contaminated barley | *Aspergillus clavatus*<br>*Aspergillus fumigatus* |
| Sequoiosis | Mold redwood dust | *Aureobasidium pullulans*<br>*Pullularia* spp<br>*Graphium* spp<br>*Trichoderma* spp |
| Maple bark stripper's lung | Contaminated maple logs | *Cryptostroma corticale* |
| Winemaker's lung | Mold on grapes | *Botrytis cinerea* |
| Tobacco grower's lung | Mold on tobacco, tobacco plants | *Aspergillus* spp |
| Woodman's disease | Mold on oak and maple trees | *Penicillium* spp |

|  |  |  |
|---|---|---|
| Potato riddler's lung | Moldy hay around potatoes | *Thermoactinomyces actinomycetes*<br>*Faeni rectivirgula*<br>*Thermoactinomyces vulgaris*<br>*Aspergillus* spp |
| Cheese washer's lung | Moldy cheese casing | *Penicillium casei*<br>*Aspergillus clavatus* |
| Thatched roof lung | Dead/dried grasses and leaves | *Saccharomonospora viridis*<br>*Thermoactinomyces vulgaris*<br>*Aspergillus* spp |
| Wood worker's lung | Contaminated wood pulp or dust | *Alternaria* spp<br>Wood dust |
| Hardwood worker's lung | Kiln-dried wood | *Paecilomyces* |
| Wood trimmer's lung | Contaminated wood trimmings | *Rhizous* spp<br>*Mucor* spp |
| Dry rot lung | Rotten wood | *Merulius lacrimans* |
| Familial HP | Contaminated wood dust in walls | *Bacillus subtilis* |
| Paprika slicer's lung | Moldy paprika | *Mucor stolonifer* |
| Stipatosis | Esparto dust | *Thermoactinomyces actinomycetes*<br>*Aspergillus fumigatus*<br>*Pseudomonas* spp |
| Basement shower HP | Mold or unventilated shower | *Epicoccum nigrum* |
| Basement lung | Contaminated basement | *Cephalosporium* spp<br>*Penicillium* spp |
| Wind instrument lung | Contaminated saxophones, trombones | Mold<br>Bacteria |
| Steam iron HP | Contaminated water reservoir | Sphingobacterium spiritivorum |
| Summer-type HP | Japanese house dust | *Trichosporon cutaneum* |
| Lycoperdonosis | Lycoperdon puffballs | Puffball spores |
| Chiropodist's lung | Foot skin and nail dust | Fungi |
| **ANIMAL PROTEINS** |  |  |
| Pigeon-breeder's disease<br>Bird fancier's lung | Pigeons, parakeets, parrots, doves, cockatiels | Avian proteins from bird excreta, feathers or bloom |
| Feather duvet lung | Feather beds, pillows, duvets | *Avian proteins* |
| Laboratory worker's lung<br>Animal handler's lung | Rat or gerbil urine | Rodent urinary, serum, pelt protein |
| Furrier's lung | Animal pelts | *Animal fur dust* |
| Miller's lung<br>Wheat weevil disease | Infested wheat flour | *Sitophilus granaries* |
| Pearl oyster shellfish HP | Oyster/mollusk shell protein | Pearl oyster proteins. shell dust |
| Mollusk shellfish HP | Sea snail shell dust | Sea snail shell proteins |
| Silk producer HP | Dust from silkworm larvae and cocoons | Silkworm proteins |
| Pituitary snuff taker's lung | Bovine and porcine pituitary powder | Pituitary proteins, snuff |
| Fish meal worker's lung | Fish meal dust | Fish meal |
| Bat lung | Bat droppings | Bat serum proteins |
| **CHEMICAL AND DRUGS** |  |  |
| Chemical worker's lung | Polyurethane foams, paints, elastomers, glues | Diisocyanates<br>Isocyanate |

| | | |
|---|---|---|
| | | Trimellitic anhydride |
| Epoxy resin lung | Heated epoxy resin | Phthalic anhydride |
| Dental technician's lung | Polishing and grinding prostheses | Methyl methacrylate |

*HP,* Hypersensitivity pneumonitis.

Modified from Selman M, and Buendía-Roldán I. Immunopathology, diagnosis, and management of hypersensitivity pneumonitis. *Semin Respir Crit Care Med.* 2012;33(5):543-554 and Costabel U, Bonella F, Guzman J. Chronic hypersensitivity pneumonitis. *Clin Chest Med*. 2012; 33(1):151-163.

The first example of HP described was farmer's lung due to a thermophilic organism. These are unicellular branching organisms that resemble true bacteria. A previously common occupational form of HP was bagassosis or Louisiana sugarcane workers' disease.[4] Mold can also be a cause of HP, with two examples being maple bark strippers disease, developing in loggers who strip the bark and are exposed to *Cryptostroma corticale* underneath the bark and malt workers lung, developing in brewery workers exposed to *Aspergillus clavatus* present in the moldy barley on brewery floors.[4] Probably the most common cause of HP today is avian antigen. Birds are becoming an increasingly popular pet and serve as a potent source of antigens responsible for HP.[5] Finally, an example of a chemical source is toluene diisocyanate, which may cause disease in bathtub refinishers.[6]

## Bird Fancier's Lung

Avian antigens are the most commonly reported cause of HP in children.[9,10] Proteins derived from the bloom, serum, or excrement of several avian species have been demonstrated to cause HP. Bloom, a dust coating the feathers composed of keratin covered with IgA, is produced in large quantities by flying birds. While pigeons are the principal source of avian antigen in HP, several other birds have been implicated, such as parakeets, parrots, doves, and cockatiels.[11–17] Although bird fancier's lung is the commonest form of HP seen in children, it is still a rare disease.[10] Most pediatric reports note that children were initially treated for pulmonary infections or had multiple health care encounters before a diagnosis was made.[10,17–19] The diagnosis should be considered in any child with persistent, unexplained respiratory symptoms. The mainstay of therapy is bird avoidance, and therapy with corticosteroids is frequently required. Importantly, bird antigens have been found to persist at high levels as long as 18 months after bird elimination from the home.[20,21] As is the case with other forms of HP, patients with acute forms of the disease have the best prognosis, while those with chronic disease have higher morbidity.[22]

## Other Environmental Exposures

HP may also result from exposure to various fungal or bacterial antigens. *Thermophilic actinomycetes, Neurospora,* and *Candida albicans* have been reported as causes of HP in patients that used covered swimming pools.[23,24] Residential mold contamination with *Aureobasidium pullulans* has been reported to cause HP in an adult and in child siblings.[25–28] This same species has been implicated as the etiologic agent causing HP in a child exposed to indoor hydroponics.[27] Household exposure to a fungus, *Trichosporon cutaneum,* causes summer-type HP, a common form of HP in Japan.[29] Contamination of the home with the fungus *Bjerkandera adusta* was found to cause HP in an elderly male.[29] A report of two children with HP secondary to exposure from an unventilated basement shower identified *Epicoccum nigrum* as the causative mold.[30] *Fusarium napiforme* was also found to be the etiologic agent in a 17-year-old with HP due to residential mold exposure.[31] Exposure to mold or various bacteria through ultrasonic humidifiers and saunas has also been demonstrated to cause HP.[32–34] *Aspergillus fumigatus* was found to be the causative agent in a child with HP who had repeated exposure to organic compost on a playground.[35] There are also numerous reports of “hot tub lung,” caused by *Mycobacterium avium* complex, a nontuberculous mycobacteria.[36–41] This disease typically occurs after exposure to hot water aerosols from hot tubs, showers, and swimming pools.[39] Most reports note that poor hot tub maintenance or poor personal hygiene practices contribute to the development of the disease. Some controversy does exist on whether this disease is a true representation of HP or has an infectious etiology. Patients with hot tub lung have well-formed, sometimes necrotic, granulomas, obstructive lung disease, and usually lack serum precipitating antibodies to the offending antigen, all supporting an infectious nature of the illness.[38,39] However, the clinical presentation, bronchoalveolar lavage (BAL) lymphocytosis, high-resolution computed tomography (HRCT) findings, and therapeutic response to cessation of exposure and treatment with corticosteroids are consistent with HP.[37–41] *Cladosporium* has also been implicated as a cause of HP in an enclosed hot tub area.[42] Finally, “lifeguard lung,” a granulomatous pneumonitis from indoor swimming pool exposure, was reported in several lifeguards exposed to water spray features at an indoor pool.[43]

## Pathology/Pathogenesis

The pathogenesis of HP is incompletely understood. The initial event involves sensitization to an inhaled antigen in the distal airway, but the level and duration of antigen exposure that is required for sensitization is unknown (Fig. 65.1). After antigen exposure in a sensitized individual, an acute alveolitis develops with an increase in neutrophils.[44–50] This typically peaks at 48 hours and is followed by an increase in the number of macrophages and lymphocytes.[50–54] Typically CD8+ T cells predominate, but CD4+ T cells can also be found distinguishing HP from sarcoidosis.[52] In 2009, Ye et al.[53] identified interleukin (IL) 12, IL-18, and tumor necrosis factor alpha (TNF-$\alpha$) synthesis by BAL macrophages from patients with acute and chronic HP. Spontaneous and lipopolysaccharide stimulated BAL cell culture revealed higher IL-12, IL-18, and TNF-$\alpha$ secretion compared with controls, indicating a

TH1-macrophage axis pathogenesis. Another study by Bellanger et al.[54] revealed significantly higher IL-8, IL-6, TNF$\alpha$, IL-17, and IL-23 levels in BAL fluid samples from HP patients compared with patients with other forms of interstitial lung disease.

**FIG. 65.1** Pathogenesis of hypersensitivity pneumonitis. Small molecular weight antigen that enters the alveoli is engulfed by alveolar macrophages, which become activated and interact with both CD4+ and CD8+ T cells. Other cell types are attracted through chemokines and release a variety of inflammatory mediators typical of T helper cell type 1 (Th1) profile. Many factors, including adjuvants, environmental influences, surfactant composition, and balance of cytokines, influence the inflammatory responses. This response eventually leads to a lymphocytic infiltration and granuloma formation of the interstitial lung spaces and alveoli. (Used with permission from Dr. Jordan Fink and Elsevier Publishing.)

## Type III and Type IV Hypersensitivity Responses

It appears that both type III antigen-antibody complex and type IV cell-mediated responses are involved (see Fig. 65.1). Antigen-specific precipitating antibodies are found in patients with HP in response to the offending antigen supporting a type III reaction[55]; however, precipitating antibodies can also be found in exposed subjects without evidence of clinical disease.[56] In addition, there is no immune complex deposition in the lungs. Inhaled soluble antigens can bind to immunoglobulin and cause complement activation, leading to increased vascular permeability and an influx of neutrophils and macrophages.[57,58] This leads to the production of IL-1, IL-8, TNF-$\alpha$, monocyte chemoattractant protein (MCP)-1, macrophage inflammatory protein (MIP)-1$\alpha$, RANTES (regulated on activation, normal T cell expressed and secreted), and CCL18, with resultant migration of leukocytes into the alveolar interstitium.[59,60] Several studies illustrate the role of T cell mediated immunity in the pathogenesis of HP.[57–61] A variety of factors, such as MIP-1$\alpha$, MCP-1, CCL18, and IL-2, lead to an influx and proliferation of lymphocytes in the lung of patients with HP.[62–65] Secretion of IL-12 and MIP-1$\alpha$ by alveolar macrophages promotes the polarization of CD4+ Th0 lymphocytes to Th1 cells (T helper type 1), which produce interferon (IFN)-$\gamma$ and are essential for granulomatous inflammation and the development of HP.[66,67]

Several other factors may play a role in the pathogenesis of HP. Natural killer (NK) cells are increased in the BAL and lung tissue of patients with HP and appear to provide a protective effect.[61,62] Aberrant regulatory T cell and Th17 cell function may also play a pathologic role.[63–68] As mentioned previously, increased IL-17 levels have been found in the BAL fluid of HP patients compared with patients with other forms of interstitial lung disease. In a murine model of HP, long-term exposure to antigen was associated with increased collagen deposition, IL-17, and IL-1$\alpha$ levels.[54,69] Upregulation of costimulatory molecules on alveolar macrophages and increased expression of L-, E-, and P-selectins may lead to the influx of various leukocytes into the lung.[70–74] MyD88, an adapter protein that interacts with several Toll-like receptors (TLRs), has been found to play an important role in the inflammatory response seen in HP.[74,75] Surfactant protein A stimulates inflammatory cytokine release and is increased in BAL fluid from patients with HP.[76] Increased formation of free radicals, through a variety of mechanisms, also contributes to lung inflammation.[55,77–79] Excessive accumulation of extracellular matrix components through increased levels of fibrinolysis inhibitors, such as thrombin-activatable fibrinolysis inhibitor and protein C inhibitor, or decreased activity of matrix metalloproteinases, contribute to the fibrotic process seen in chronic HP.[80,81]

Multiple susceptibility factors have been implicated in the pathogenesis of HP, such as cigarette smoking, viral infections, endotoxin, and genetic predisposition. Several studies have observed a negative relationship between cigarette smoking and the development of HP in similarly exposed individuals.[82–88] Many patients with HP report a viral type illness or flulike symptoms during the initial stage of disease. An acute viral infection could enhance the antigenic response in HP by increasing the ability of alveolar macrophages to present antigen, decreasing the clearance of antigens and inducing the release of proinflammatory cytokines.[88] Endotoxin coexposure with antigen has been shown to augment lung pathology in a murine model of HP, and may act through TLRs on macrophages, leading to a Th1 T cell response, or play an indirect role in the pathogenesis of HP as an adjuvant.[62,89] Finally, various HLA haplotypes and genetic polymorphisms, such as those of the *TNFA* promoter and *IL6* gene, encoding TNF-$\alpha$ and IL-6, respectively, have been associated with susceptibility to HP.[90–100] Familial cases of HP have also been reported.[25,101]

# Clinical Features

## Symptoms and Physical Findings

Schuyler and Cormier[56] proposed criteria for the diagnosis of HP (Box 65.1). Major criteria included symptoms compatible with HP, evidence of antigen exposure, radiographic abnormalities consistent with HP, lymphocytosis on bronchoalveolar lavage fluid (BALF), lung biopsy demonstrating histologic changes consistent with HP, and reproduction of symptoms of HP upon antigen exposure. Minor criteria included bibasilar rales, decreased diffusion capacity for carbon monoxide (DLCO), and hypoxemia. The clinical manifestations of HP depend on the nature and circumstances of exposure and are divided into three stages: acute, subacute, and chronic.

**Box 65.1**

## Diagnostic Criteria for Hypersensitivity Pneumonitis

### Major Criteria (Four Major Criteria Need to Be Present)

- Symptoms compatible with HP
    - Acute: High level of exposure to antigen over short period of time. Symptoms develop within 4–8 h and include fever, chills, myalgia, fatigue, dyspnea, nonproductive cough. Recovery 2–5 days after removal of exposure.
    - Subacute: Low-level, intermittent, repeated exposure. Low-grade fever, progressive nonproductive cough, dyspnea over weeks-months. Recovery after removal of exposure.
    - Chronic: Low-level, prolonged, and continuous exposure of antigen. Chronic nonproductive cough, dyspnea, malaise, weakness, anorexia, weight loss.
- Evidence of exposure to antigen
    - History
    - IgG antibody to antigen
- Radiographic characteristics consistent with HP
    - Chest radiograph: Reticulonodular infiltrates, linear opacities
    - HRCT:
    - Acute: Ground-glass infiltrates
    - Subacute: Micronodules, air-trapping
    - Chronic: Fibrosis ± honeycombing, emphysema
- BALF lymphocytosis
    - CD8 > CD4 T cells
    - Increased NK cells
- Lung biopsy demonstrates histology consistent with HP
    - Alveolitis, noncaseating granulomas, giant cells, foamy alveolar macrophages or fibrosis

- Positive natural challenge that produces symptoms and objective abnormalities after reexposure to the offending antigen

### Minor Criteria (Two Minor Criteria Need to Be Present)

- Bibasilar rales
- Decreased DLCO
- Hypoxemia, either at rest or with exertion

### Clinical Prediction

- Exposure to known offending antigen
- Positive IgG antibody to offending antigen
- Recurrent episodes of symptoms
- Respiratory crackles
- Symptoms occurring between 4 and 8 h after exposure
- Weight loss

*DLCO,* Diffusing capacity carbon monoxide; *HP,* hypersensitivity pneumonitis; *HRCT,* high-resolution computed tomography.

Modified from Schuyler M, Cormier Y. The diagnosis of hypersensitivity pneumonitis. *Chest*. 1997;111(3):534-536.

## Acute Stage

In the acute form such as seen in pigeon breeders, chills, fever up to 40°C, cough, and shortness of breath are seen within 4–6 hours after exposure. Symptoms may persist for up to 18 hours. Patients usually recover within 2–5 days, with episodes occurring after each subsequent exposure. Physical examination reveals only crackling rales in the lower lung fields. HP is an example of an interstitial pneumonia in which there is a disparity between the symptoms of the patient and the physical findings. Wheezing is uncommon, as most patients exposed to organic dusts do not develop HP and asthma.

## Subacute Stage

This form occurs as a result of an intermittent low grade but continuous long-term exposure, such as seen in a pet-store employee. The symptoms are milder and include malaise, low-grade fever, cough, chills, and progressive dyspnea, often associated with anorexia and weight loss. This form is usually reversible.[102]

## Chronic Stage

A long-term low-grade exposure experienced by a parakeet owner or a contaminated home humidifier may result in chronic irreversible disease. These patients present with dyspnea, chronic cough, fatigue, anorexia, and weight loss.[103]

## Immunologic Studies

Laboratory evaluation generally reveals a marked leukocytosis with prominent neutrophilia during the acute phase of HP.[104] Elevation of markers of inflammation such as erythrocyte sedimentation rate and C-reactive protein may be seen. Elevated rheumatoid factor is found in 50% of patients, along with elevation in serum IgG, IgA, and IgM. Skin testing has limited value in the workup of HP. A high percentage of patients without HP have positive skin tests reactions, and there is a lack of commercially available standardized extracts. A diagnostic hallmark of HP is an IgG precipitating antibody seen on a double gel diffusion plate (Fig. 65.2). However, the presence of a precipitating antibody is only a marker of exposure and sensitization and does not correlate with disease activity. Approximately 40%–50% of asymptomatic exposed individuals will have precipitating antibody to the offending antigen.[105] Reports from commercial laboratories are sometimes inaccurate, and the selection of a laboratory experienced in assays for the diagnosis of HP is important. Methods more sensitive than gel diffusion are available, including counterimmunoelectrophoresis (CIE), enzyme-linked immunosorbent assays (ELISA), and radioimmunoassay (RIA). Lymphocyte proliferation assays to the offending antigen are usually positive in patients with HP.[106] In one study, alveolar macrophages from patients with HP enhanced the lymphoproliferative response, while the response was inhibited in normal patients. This suggests that a defect in the ability of alveolar macrophages to suppress the lymphoproliferative response leads to the development of the observed lymphocytic alveolitis seen in patients with HP.[106] It should be emphasized that these studies are available only in research laboratories.

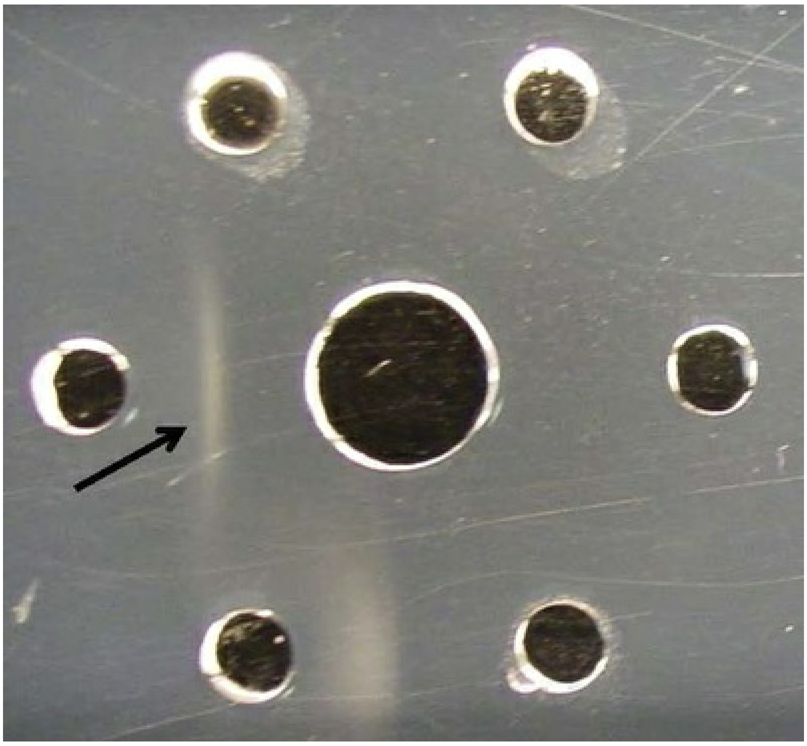

**FIG. 65.2** Ouchterlony double immunodiffusion (agar gel immunodiffusion). The center well contains patient serum and the outer wells contain different antigens. Note the strong line of precipitation between the patient's serum and the antigen *(arrow).*

## Radiologic Findings

Radiologic findings in HP correlate with stage of disease. In acute HP, chest radiography usually demonstrates poorly defined, nodular infiltrates, but patchy ground-glass opacities or diffuse infiltrates may also occur.[62,104,107,108] It is important to note that patients with acute HP may have a normal chest radiograph after cessation of exposure and resolution of the acute episode. HRCT of the chest typically demonstrates ground-glass opacities in acute HP, but the presence of ground-glass opacities is generally a nonspecific finding.[109–111] Ground-glass opacification represents cellular interstitial infiltration, small granulomas within the alveolar septa, or both. These opacities may be found either centrally or peripherally, but are predominantly in the lower lung zones with sparing of the apices in acute HP.[1–3,9,59] In subacute HP, a reticulonodular appearance with fine linear shadows and small nodules is typically present on chest radiograph, although the chest radiograph may also be normal as seen in acute HP.[1–3,9,59] The infiltrates in subacute HP usually predominate in the mid to upper lung zones. HRCT of the chest in subacute HP typically demonstrates centrilobular nodules associated with larger areas of ground-glass opacity, as well as air trapping and mosaic perfusion (Fig. 65.3).[110] Centrilobular nodules correspond to the presence of poorly marginated granulomas and active alveolitis, while mosaic perfusion indicates the redistribution of blood flow, and air trapping denotes obstructive bronchiolitis. The presence of ground-glass opacities, air trapping, mosaic perfusion, and areas of normal lung attenuation on the same film yields an appearance on HRCT known as the headcheese sign.[110] This is characteristic for subacute HP. Chronic HP is characterized by diffuse reticulonodular infiltrates, volume loss, and coarse linear opacities on chest radiography.[1–3,9,110,111] The findings in chronic HP appear to be more severe in the mid to upper zones of the lung. HRCT often demonstrates fibrotic changes that include irregular linear opacities, honeycombing, and traction bronchiectasis. These changes can also be found in several other disorders, such as sarcoidosis, interstitial pulmonary fibrosis, and collagen vascular diseases. Centrilobular nodules are often found in chronic HP when ongoing antigen exposure is occurring. The radiographic findings in chronic HP, unlike acute HP, are unlikely to resolve when antigen exposure ceases. There are several findings that are not characteristically found and may be helpful in differentiating HP from other disorders. Pleural effusions or pleural thickening, as well as cavitation, calcification, or atelectasis, are usually absent in HP. Hilar adenopathy, commonly seen in sarcoidosis, is rarely seen in HP.[104]

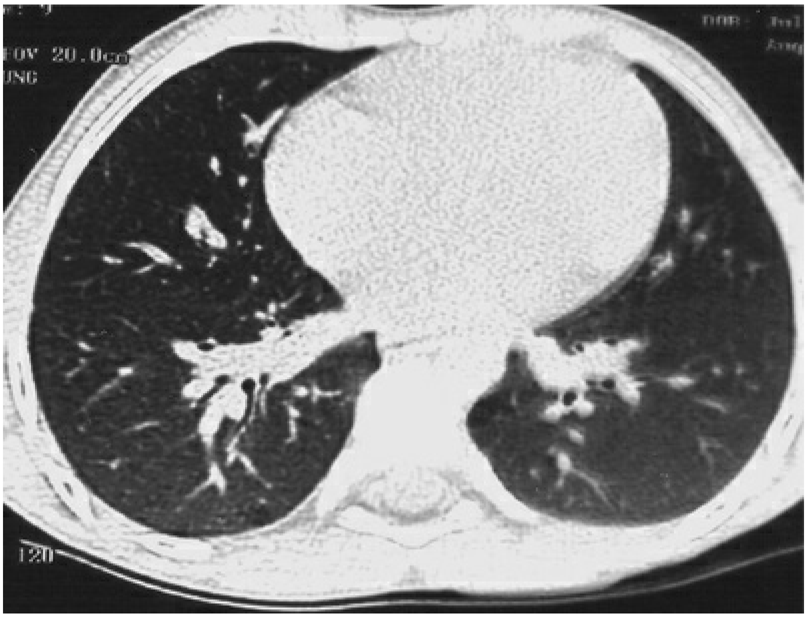

**FIG. 65.3** High-resolution computed tomography scan of the chest in a child with hypersensitivity pneumonitis demonstrating ground glass opacities.

## Pulmonary Function Testing and Bronchial Challenge

Pulmonary function testing typically reveals restriction with a reduction in lung volumes and a decrease in DLCO; however, obstructive, mixed obstructive and restrictive, or normal pulmonary function tests can be seen.[1–3,9,59,104,108,109] A decrease in airway compliance is often seen with a shift in the pressure-volume curve down and to the right. A decrease in arterial oxygen tension ($PaO_2$) on arterial blood gas analysis is most commonly seen in chronic HP, but can be found in both acute and subacute forms of the disease.[55] The hypoxemia and decreased diffusion capacity may be accounted for by filling of the alveolar space with fluid and inflammatory cells. In a cross-sectional longitudinal study of children diagnosed with HP, the forced expiratory volume 1 second (FEV1) was abnormal in only 9.1% of patients, but DLCO and total lung capacity (TLC) were abnormal in 40.9% and 13.6%, respectively. DLCO/alveolar volume (VA) was within the normal range, and peak oxygen uptake was normal in nearly 90% of subjects, suggesting a favorable long-term prognosis.[112]

Oxygen desaturation with exercise or with sleep is not an uncommon finding.[1–3] Twenty percent to 40% display nonspecific airway reactivity, and 5%–10% have asthma.[25,108,113,114] In addition, in patients with farmer's lung, Karjalainen et al.[115] showed an increased risk in developing asthma after their diagnosis of HP. The concomitant or future development of asthma after HP has also been shown in HP caused by diisocyanates, after summer-type HP or after residential mold exposure.[25,29,115–118] Bronchial challenge has been studied in adults but is infrequently used in children.[9,119] These challenges can be performed either through reexposure to the suspected setting or through a controlled challenge in an experienced laboratory. In a review by Fan,[9] 20 of 86 children with HP underwent bronchial challenge, and only 55% of these patients had positive challenges. In a large cohort of patients with bird fancier's lung, Morell and colleagues[55] reported a sensitivity of 92% and specificity of 100% using bronchial challenge to avian extracts. As the authors note in their study, bronchial challenge testing should be performed in a hospital setting with experienced staff and high-quality antigenic extracts.[55] Some difficulties that may be encountered in bronchial provocation are poor standardization of the antigen dose used for the challenge, difficulties in objectively defining a positive test, as well as the difficulty that many young children have in performing routine pulmonary function testing.[119]

## Bronchoalveolar Lavage and Lung Biopsy

The BAL from normal individuals typically reveals a preponderance of alveolar macrophages, with approximately 10% lymphocytes that have a CD4+/CD8+ ratio of 1.8.[1–3,119] Following acute antigen exposure, patients with HP reveal a predominance of neutrophils, which is then followed by a lymphocytic alveolitis and usually comprises 60% or greater of the white blood cell differential in BAL.[1–3,44,46,49,58,103,120] Historically, a low CD4+/CD8+ ratio has been associated with HP, while a CD4+/CD8+ ratio of more than 3.5 : 1 has been associated with sarcoidosis.[58,62,103,120–123] More recent studies, however, have disputed this finding with the demonstration of HP cases with higher CD4+/CD8+ ratios.[58,100,123] A study by Ando and colleagues[124] also suggested that the CD4+/CD8+ ratio may differ by the causative antigen and the smoking status of the patient. The BAL findings in HP may also differ based on the age of the patient. Ratjen et al.[62] evaluated BAL findings in children with HP. Nine subjects, aged 6–15 years, with acute HP were included in this study. The BAL uniformly revealed an increase in the percentage of lymphocytes and foamy macrophages in children with HP. All patients were found to either have an increased expression of human leukocyte antigen (HLA)-DR (7 of 8 children) on BAL lymphocytes or an increase in NK cells (5 of 8 children) in BAL fluid. Importantly, there were no significant differences between normal controls and patients with HP with respect to the CD4+/CD8+ T cell ratio. Histologic findings in HP vary based on the stage of disease.[57,59,125,126] There are few reports on the pathology associated with acute HP, but most note the presence of interstitial mononuclear cell infiltrates.[57,125,126] Granulomas and macrophages with foamy cytoplasm have also been reported.[126] The classic triad of subacute HP includes an interstitial lymphocytic-histiocytic cell infiltrate, bronchiolitis obliterans, and scattered, poorly formed, nonnecrotizing granulomas.[55,57] In a large series of patients with bird fancier's lung, this triad was only seen in 9% of cases that underwent transbronchial lung biopsy, but at least one of the findings was present in 69% of cases.[55] An example of a lung biopsy of an 11-year-old boy with HP due to pigeon sensitivity is shown in Fig. 65.4. There was interstitial pneumonia with inflammation composed of predominantly lymphocytes, macrophages, and plasma cells. Macrophages with foamy cytoplasm surrounded by large numbers of mononuclear cells are unique to HP. Lymphocytes stained for CD3+ T cells and CD56+ NK cells. Typically there is a predominance of CD8+ T cells. CD20+ B cells were also in the center of a lymphoid follicle. Other findings commonly seen in HP include interstitial giant cells, interstitial noncaseating granulomas, or Schaumann bodies.[127] In a pathologic review of 25 cases with chronic HP, giant cells, granulomas, or Schaumann bodies were seen in 88% of cases, and 72% of cases exhibited a usual interstitial pneumonia (UIP)–like pattern.[127] A nonspecific interstitial pneumonia (NSIP)–like pattern or a bronchiolitis obliterans organizing pneumonia-like disease can also be seen in chronic HP.[128–130] Multiple studies have demonstrated decreased survival rates in patients with UIP-like or NSIP-like patterns of fibrosis.[127,131,132] The usefulness of biopsy for the diagnosis of HP has been questioned.[59,132,133] Although the aforementioned findings are commonly seen in various stages of HP, none of the findings are pathognomonic for the disease, as they can be found in other lung disorders. Most patients with HP can be diagnosed based on signs, symptoms, exposure history, radiographic, laboratory, and BAL findings, obviating the need for lung biopsy. When a biopsy is performed, a surgical lung biopsy is the preferred method, as it has greater diagnostic yield.[59] A study in patients with farmer's lung found limited usefulness of transbronchial biopsies as a diagnostic tool in HP.[134] Since the utility of transbronchial biopsies in HP is questioned and the majority of cases can be diagnosed without biopsy, surgical lung biopsy is usually reserved for cases when other studies do not yield a definitive diagnosis.

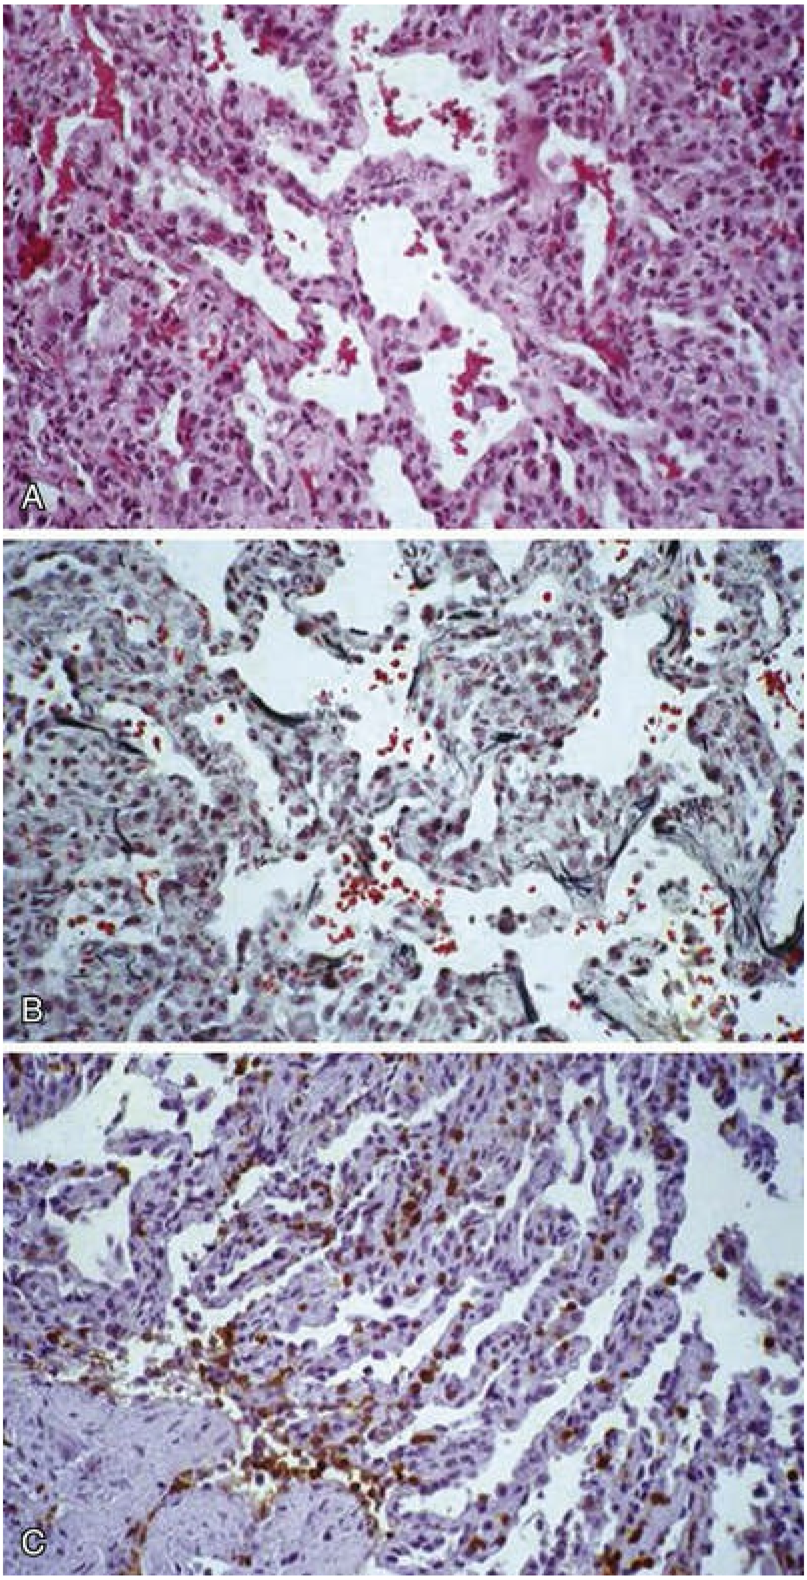

**FIG. 65.4** Transbronchial lung biopsy of an 11-year-old boy at the onset of his illness with hypersensitivity pneumonitis due to sensitivity to pigeon droppings. (A) H&E staining, demonstrates alveolar and interstitial inflammation composed predominantly of lymphocytes, macrophages, and plasma. Macrophages with foamy

cytoplasm surrounded by large numbers of mononuclear cells are unique to hypersensitivity pneumonitis. (B) Anti-CD3 immunoperoxide staining, demonstrates the presence of numerous CD3+ T cells in the interstitium. (C) Anti-CD56 immunoperoxide staining, demonstrates the presence of numerous NK cells in the interstitium.

## Management and Treatment

In the acute form, simple removal from the offending environment generally suffices. If symptoms are severe, the patient should be started on a tapering dose of prednisone, beginning with 60 mg per day. Supportive measures would include oxygen ($O_2$), antitussives, and antipyretics. For repeated, acute, or subacute form, exposures should be decreased as much as possible, with administration of long-term corticosteroids emphasizing alternate day therapy. The chronic form can be treated with long-term corticosteroids, but only if radiographic findings and physiologic changes indicate a response. Clinical follow-up should include spirometry with lung volume and diffusion capacity and chest radiograph. It is vital that the antigen responsible for HP be determined so that appropriate environmental control measures can be carried out. Several initiatives can decrease the antigenic burden. Chemicals can be used to prevent the growth of organisms. A good example is propionic acid, which, when added to sugarcane, eliminates the growth of the thermophilic organism responsible for bagassosis. Water should be changed frequently in humidification or air conditioning units. Storage dryers will decrease the growth of mold and thermophilic organism in hay and straw. Finally, crops should be harvested when the moisture content is low. There are many ways to decrease exposure to organic dust. Dusty materials within closed spaces should be mechanically handled. Effective ventilation will remove dust from the ambient air. In some instances, personal respirators or masks may be used. Finally, when the previous measures have failed, the worker should be removed from the disease-producing environment.

## Prevention

The incidence of HP may be reduced by decreasing exposure to responsible antigens. This may be accomplished by decreasing contact with potential agents, reducing microbial contamination, or using protective equipment.

## Prognosis

The prognosis for patients with HP is generally good if the offending antigen is detected and avoidance measures are enforced during the acute and subacute stages. In a review of HP in children by Fan (9), 97% of reported pediatric cases of HP had a favorable outcome when exposure was eliminated. A study in patients with farmer's lung demonstrated a recovery in DLCO up to 2 years from initial diagnosis.[135] In chronic HP, the prognosis is not as good, especially in patients with continued antigen exposure.[22] The presence of fibrosis seems to be the most important factor in prognosis, as antigen class, symptom duration, and pulmonary function did not appear to be significant predictors for survival in patient with HP.[136] Fortunately, with early identification and treatment, progression to the chronic stage of HP can be avoided.

# Eosinophilic Pulmonary Diseases

## Etiology

The eosinophilic lung diseases include a group of disorders that are characterized by increased peripheral blood and/or pulmonary eosinophilia.[137–140] As seen in Box 65.2, there are diverse causes of eosinophilic pulmonary diseases, including allergic bronchopulmonary aspergillosis (ABPA) and mycosis, drug and toxin induced eosinophilic disease, helminth associated eosinophilic lung disease, acute eosinophilic pneumonia, chronic eosinophilic pneumonia (CEP), eosinophilic granuloma, Churg-Strauss syndrome (CSS; eosinophilic granulomatosis with polyangiitis), and hypereosinophilic syndrome (HES). The clinical presentation of pulmonary eosinophilia consists of pulmonary symptoms, abnormal chest radiographs, and blood and sputum eosinophilia.

**Box 65.2**

### Pulmonary Diseases With Eosinophilia

1. Allergy bronchopulmonary aspergillosis and mycosis
2. Drug and toxin induced eosinophilic disease
3. Acute eosinophilic pneumonia
4. Chronic eosinophilic pneumonia
5. Eosinophilic granuloma (formerly Histiocytosis X)
6. Helminth associated eosinophilic lung disease
7. Churg-Strauss syndrome (allergic angiitis and granulomatosis)
8. Hypereosinophilic syndrome

# Allergic Bronchopulmonary Aspergillosis

## Etiology

Hinson et al.[141] first described ABPA in adults in 1952 in England, and Slavin et al.[142] described the first case in a child in 1970 in the United States. ABPA is a Th2 hypersensitivity lung disease caused by bronchial colonization with *Aspergillus fumigatus* that affects asthmatic and cystic fibrosis (CF) subjects.[143–147] As seen in Box 65.3, ABPA is characterized by exacerbations of asthma, recurrent transient chest radiographic infiltrates, peripheral and sputum eosinophilia, IgE and IgG sensitization to *A. fumigatus*, and elevated total serum IgE level. *A. fumigatus* hyphae are generally found in the sputum at the time of acute exacerbations of ABPA. ABPA may lead to corticosteroid-dependent asthma, bronchiectasis, and/or pulmonary fibrosis. ABPA is most commonly caused by *A. fumigatus;* however, other fungi species such as *Candida, Penicillium,* and *Curvularia* have been identified as causing symptoms similar to ABPA.[148,149] Those patients who have symptoms of ABPA with identification of a fungus other than *Aspergillus fumigatus* are classified with allergic bronchopulmonary mycoses or ABPM.[148–150] Chowdhary et al.[151] reviewed 143 cases worldwide of ABPM and found that *Candida albicans* is the most common fungi causing ABPM seen in 60% of cases. Of note, 70% of the cases from the review of ABPM did not have asthma, which is a clear distinction from ABPA. ABPA is relatively uncommon in childhood, although it has been reported in children with CF from England and the United States. *A. fumigatus* is a ubiquitous mold that is commonly encountered around farm buildings, barns, stables, silos, and compost heaps. Human disease has been reported from most countries of the world. ABPA should be distinguished from other lung diseases caused by *A. fumigatus,* such as invasive aspergillosis, aspergilloma, IgE-mediated asthma from *A. fumigatus* sensitivity, and HP due to *A. fumigatus* or *A. clavus* (malt worker's disease).

**Box 65.3**

## Diagnostic Criteria of Allergic Bronchopulmonary Aspergillosis in Asthma and Cystic Fibrosis[a]

### Minimum Criteria

Patients with asthma or cystic fibrosis
Worsening lung function not attributable to another etiology
Positive skin prick test with *Aspergillus* species
Total serum IgE ≥1000 ng/mL (416 IU/mL)
[b]In CF, total serum IgE levels:

- ≥1000 IU/mL, classic
- ≥500 IU/mL, minimum
- 200–500 IU/mL. If ABPA is suspected, repeat in 1–3 months. If patient is taking steroids, repeat when steroid treatment is discontinued.

Increased *Aspergillus* species-specific IgE and IgG antibodies
New or recent abnormalities on chest radiography or chest CT that have not cleared with antibiotics and standard physiotherapy

### Additional Criteria

Increase in blood eosinophilia ≥400 eosinophils/μL when patient is not on corticosteroids
*Aspergillus* species-specific precipitating antibodies
Central bronchiectasis
*Aspergillus* species-specific containing mucus plugs

## Epidemiology

The prevalence of ABPA is estimated to be 1%–2% in asthmatic patients and 7%–9% (up to 15%) of patients with CF.[143–147] Denning et al.[152] estimated that the global prevalence of ABPA may be 0.7%–3.5% of patients with asthma.

## Pathology/Pathogenesis

The pathology of ABPA demonstrates cylindrical bronchiectasis of the central airways, particularly the upper lobes.[143–147] These airways may be occluded by “mucoid impaction,” a condition in which large airways are occluded by impacted mucus and hyphae. Airway occlusion may lead to atelectasis of a segment or lobe, and if the atelectasis is long-standing, saccular bronchiectasis may result. Typically, ABPA is worse in the upper lobes than in the lower lobes. Microscopic examination of the airways shows infiltration of the airway wall with eosinophils, lymphocytes, and plasma cells. The airway lumen may be occluded by mucus containing hyphal elements and inflammatory cells, especially eosinophils. Squamous metaplasia of the bronchial mucosa develops commonly, and sometimes granulomas form. Rarely, bronchiolitis obliterans or bronchocentric granulomatosis develops.

## Biology of Eosinophils

In ABPA and the other eosinophilic pulmonary diseases discussed later in this chapter, eosinophilic inflammation is prominent. In the pathogenesis of ABPA, there is extensive eosinophilic infiltration and inflammation in the bronchial airways and in the lung parenchyma (Fig. 65.5). Furthermore, there is extensive degranulation of eosinophil mediators, such as major basic protein (MBP) in the lung interstitium.[153] Eosinophils are inflammatory granulocytes important in host defense principally against helminth parasites.[141] They also play an important inflammatory role in a variety of diseases, including asthma, allergic diseases, eosinophilic esophagitis, and HESs. Eosinophils are bone-marrow derived granulocytes.[141] The key cytokines that are critical for bone production of eosinophils are IL-3, IL-5, and granulocyte-monocyte-colony stimulating factor (GM-CSF), produced by CD4+ T cells. The activation of eosinophils is principally by IL-5 stimulation, which also increases tissue eosinophil survival. Tissue recruitment of eosinophils from the vascular system is stimulated by the chemokines platelet activating factor (PAF), leukotriene (LT)-D4, C5a, CCL11/eotaxin, and CCL5/RANTES (regulated on activation normal T cells expressed and secreted). Stimulation by eotaxin is selective for only eosinophils.

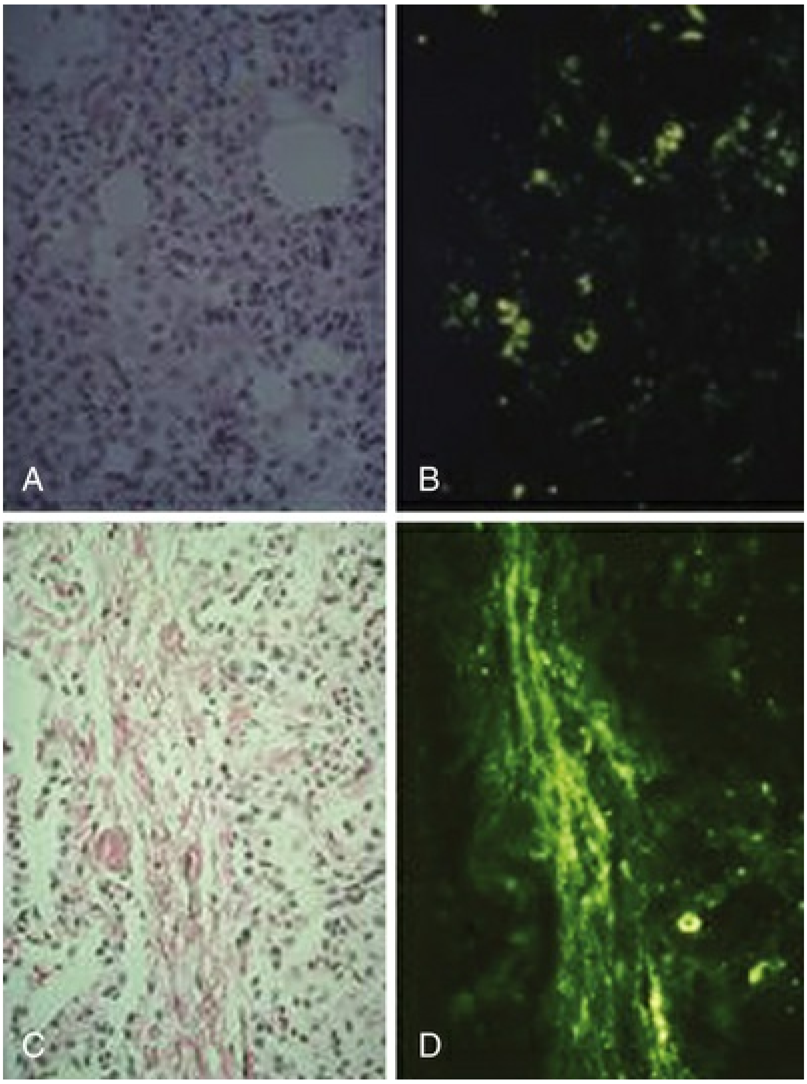

**FIG. 65.5** Lung biopsy of a CF patient with ABPA. (A) H&E stain and (B) major basic protein (MBP) of intact eosinophils in same section as (A); (C) H&E stain and (D) MBP fluorescent staining demonstrating extensive deposits of MBP in the interlobar septum. (Used with permission from Slavin RG, Bedrossian CW, Hutcheson PS, Pittman S, Salinas-Madrigal L, Tsai CC, Gleich GJ. A pathologic study of allergic bronchopulmonary aspergillosis. *J Allergy Clin Immunol.* 1988;81(4):718-725.)

Eosinophils possess a number of preformed granule-derived proteins (MBP, eosinophil peroxidase, eosinophil cationic protein, eosinophil-derived neurotoxin, and Charcot-Leyden crystal protein), de novo synthesized lipid mediators (LTC4, PGE1, PGE2, TXB2, 15-HETE, and PAF), and reactive oxygen species that are released upon stimulation and result in inflammation. Eosinophils synthesize a number of Th2 cytokines (IL-4 and IL-5), Th1 cytokines (IFN-$\gamma$), and chemokines (eotaxin, RANTES). Eosinophils also have

Fc receptors for principally IgA, which may regulate antibody-dependent cellular cytotoxicity (ADCC) eosinophil degranulation. Thus eosinophils are principally Th2-driven granulocytes that have potent inflammatory and tissue destructive properties.

In the pathogenesis of ABPA, *A. fumigatus* spores 3–5 µm in size are inhaled and germinate into hyphae deep within the bronchi (Fig. 65.6).[143–147] In addition, fragments of the hyphae can be identified within the interstitium of the pulmonary parenchyma (see Fig. 65.6). The implication is that there is the potential for high concentrations of *A. fumigatus* allergens to be exposed to the respiratory epithelium and immune system. *A. fumigatus* releases a variety of proteins, including superoxide dismutases, catalases, proteases, ribotoxin, phospholipases, hemolysin, gliotoxin, phthioic acid, and other toxins. The first line of defense against *Aspergillus* colonization in the lungs is macrophage and neutrophil killing of the conidia and the hyphae. In the development of ABPA, Kauffman's group proposed that *Aspergillus* proteins have a direct effect on the pulmonary epithelia and macrophage inflammation.[154–157] They demonstrated that *Aspergillus* proteases induce epithelial cell detachment. In addition, protease-containing culture filtrates of *Aspergillus* induce human bronchial cell lines to produce proinflammatory chemokines and cytokines, such as IL-8, IL-6, and MCP-1. Thus various *Aspergillus* proteins have significant biologic activity that disrupts the epithelial integrity and induces a monokine inflammatory response. This protease activity allows for enhanced allergen exposure to the bronchoalveolar lymphoid tissue immune system. This is evident by the bronchoalveolar lymphoid tissue synthesis of *Aspergillus*-specific IgE and IgA antibodies.

Genetic susceptibility factors have been proposed in the development of ABPA (Box 65.4). Chauhan and colleagues[158–160] observed that asthmatic and CF patients who expressed HLA-DR2 and/or DR5 and lacked HLA-DQ2 were at increased risk to develop ABPA after exposure to *A. fumigatus*. Furthermore, within *HLA-DR2* and *HLA-DR5*, there are restricted genotypes. In particular, *HLA-DRB1*1501* and *HLA-DRB1*1503* were reported to produce high relative risk. On the other hand, 40%–44% of non-ABPA atopic *Aspergillus*-sensitive individuals have the *HLA-DR2* and/or *HLA-DR5* genotype. Additional studies indicated that the presence of *HLA-DQ2* (especially *HLA-DQB1*0201*) provided protection from the development of ABPA. Recently, increased sensitivity to *in vitro* IL-4 stimulation, as measured by enhanced expression of the low-affinity IgE receptor (CD23) on B cells, was observed in ABPA patients. This was associated with single-nucleotide polymorphisms of the IL-4 receptor alpha chain *(IL4RA)* in 92% of ABPA subjects, principally the IL-4-binding single-nucleotide polymorphism ile75val.[143,145,147]

**Box 65.4**

## Genetic Risk Factors in the Development of Allergic Bronchopulmonary Aspergillosis

HLA-DR restriction and HLA-DQ protection
    HLA-DR2: HLA-DRB1*1501 and *HLA-DRB1*1503
    HLA-DR5: HLA-DRB1*1101 and HLA-DRGB1*1104
    HLA-DQ2 protective, decreased in ABPA
        DQB1*0201
*IL-4RA* polymorphisms

- *IL-4RA* ile75val
- *IL-10* polymorphisms
    - Promoter *-1082 GG* genotype
- Surfactant protein A2 (SP-A2) polymorphisms
    - *SP-A2* ala91pro
- Cystic fibrosis transmembrane conductance regulator (CFTR) mutations
    - Heterozygous *CFTR* mutations in asthmatic patients with ABPA
- Toll-like receptor (TLR) polymorphisms
    - *TLR9* T-1237C

*HLA,* Human leukocyte antigen; *IL,* interleukin.

This increased sensitivity to IL-4 is demonstrated by increased expression of CD23 and CD86 on B cells of ABPA subjects and increased CD23 expression during flares of ABPA.[143,147] CD23 is expressed on a variety of cells, including B cells, NK cells, subpopulations of T cells, and a subpopulation of dendritic cells. T-cell CD23 and B-cell CD21 form a costimulatory pathway. T-cell CD28 and B-cells CD80 and CD86 costimulatory pathways activate both T and B cells, and CD28:CD86 is important in IgE synthesis. CD86 is also found on dendritic cells that have the histamine receptor 2, which skews antigen-specific T cells to a Th2 response. In a murine model of ABPA, Kurup and colleagues have found that CD86 expression is upregulated in the lung tissue (V.P. Kurup, Medical College of Wisconsin, personal communication). Recently, we have also observed increased CD86 expression on monocyte-derived dendritic cells of ABPA subjects. Thus antigen-presenting cells such as monocytes and dendritic cells bearing HLA-DR2 and/or HLA-DR5 and increased sensitivity to IL-4 stimulation probably play a critical role in skewing *A. fumigatus*-specific Th2 responses in ABPA.

Brouard and coworkers[161] recently reported a third genetic risk, the association of the *-1082GG* genotype of the IL-10 promoter with colonization with *A. fumigatus* and the development of ABPA in CF. The *-1082GG* polymorphism has been associated with increased IL-10 synthesis, whereas the *-1082A* allele has lower IL-10 synthesis.

Thus dendritic cells expressing HLA-DR2/DR5 that have an HR2 phenotype, increased IL-10 synthesis, and increased sensitivity to IL-4 stimulation due to *IL-4RA* polymorphisms may be responsible for skewing *Aspergillus*-specific Th2 responses in ABPA.

Studies in asthma have implicated the role of bronchial epithelia and mesenchymal cells forming the epithelial-mesenchymal trophic unit (EMTU) with a profibrotic response when stimulated with proteases such as Der p1 and with IL-4 and IL-13.[162] In ABPA subjects, *Aspergillus* proteases and allergen stimulation of the EMTU in conjunction with increased sensitivity to IL-4 due *IL-4RA* SNPs may result in increased bronchial epithelial secretion of IL-8, GM-CSF, and transforming growth factor (TGF-$\alpha$), the ligand for epidermal growth factor leading to bronchial destruction and fibrosis.

# Clinical Features

## Symptoms and Physical Findings

Clinical symptoms of ABPA include increased coughing, episodes of wheezing, anorexia, malaise, fever, and expectoration of brown plugs (see Box 65.3). ABPA can present acutely with acute symptoms and signs associated with transient pulmonary infiltrates and eosinophilia or with mucoid impaction; it may also present an exacerbation of a chronic disease characterized by proximal bronchiectasis. It is thought that the chronic form of the disease develops following the acute process and that it can be prevented by effective therapy. In chronic ABPA, the acute episodes are superimposed on a background of chronic cough and sputum production. In adults, ABPA usually affects the younger age group of adult asthmatics, and most cases occur before 40 years of age. In pediatrics, ABPA rarely affects children with asthma, and it is usually seen in children with CF, who may simply appear to have a worsening of their pulmonary status or an acute pulmonary exacerbation of CF. ABPA does sometimes affect children with asthma, and there is a report of three children who developed it before 2 years of age. Physical examination shows the signs of chronic lung disease from CF or asthma, such as hyperaeration of the lungs, expiratory wheezing, a chronic productive cough, and crackles or wheezes. The chronically ill patient with bronchiectasis may have coarse crackles, weight loss, and digital clubbing.

The criteria for the diagnosis of ABPA are shown in Box 65.5.[144,163] The minimal criteria are worsening of lung function not attributed to another cause in asthmatic or CF patients, new pulmonary infiltrates and/or high-attenuation mucus (HAM) impaction, IgE to *A. fumigatus* demonstrated by either allergy prick skin test or *in vitro* specific IgE to *A. fumigatus,* elevated IgG to *A. fumigatus* demonstrated either by *Aspergillus* specific precipitins or *in vitro* IgG to *A. fumigatus,* elevated serum IgE ≥1000 ng/ml (≥416 IU/ml), and blood eosinophilia ≥400/mL. When central bronchiectasis is also present, ABPA is classified as ABPA central bronchiectasis (ABPA-CB) and when absent classified as ABPA serologic (ABPA-S). In CF, the Cystic Fibrosis Foundation Consensus Conference recommended different criteria for total serum IgE levels.[144] In the diagnosis of ABPA in CF, elevated serum IgE was defined as a level ≥1000 IU/ml. Minimum IgE level was defined as ≥500 IU/mL. If ABPA is suspected and the total level is 200–500 IU/mL, it is recommended to repeat testing in 1–3 months. A problem with applying the criteria in children is that usually ABPA occurs in children with CF in whom many of the criteria could be due to the underlying disease. Some children with CF appear to have a clinical variant of ABPA without having all the typical criteria, and they may respond clinically to corticosteroids. Patients being considered for this diagnosis should have skin testing with *A. fumigatus* antigen.

## Helminth-Associated Eosinophilic Lung Diseases

1. Transpulmonary passage of helminth larvae (Loeffler's syndrome)
   - Ascaris lumbricoides, Ancylostoma duodenale, Necator americanus, Strongyloides stercoralis
2. Hematogenous seeding with helminth larvae

    - Cutaneous larva migrans—nonhuman ascarids and hookworms, *Trichinella spiralis, Schistosoma*
    - Visceral larva migrans—aberrant infection—*Toxocara canis*
    - Disseminated *Strongyloides*
3. Pulmonary parenchymal invasion with helminthes
    - Parogonimus westermani lung flukes
4. Tropical pulmonary eosinophilia—Filaria
    - Wucheria bancrofti, Brugia malayi

## Aspergillosis in Cystic Fibrosis

In 2013, Denning's group proposed a novel immunologic classification of aspergillosis in adult CF patients.[164] Four classification of aspergillosis were identified by examinations of sputum *Aspergillus* colonization using RT-PCR and *Aspergillus* hyphae by galactomannan (GM), total IgE level, and *Aspergillus* specific IgE and IgG level. Class 1 (nondisease) represented ± RT-PCR, negative GM, negative IgE, and IgG *Aspergillus* serology; class 2 (serologic ABPA), positive RT-PCR, positive GM, elevated total IgE, and *Aspergillus* specific IgE/IgG; and class 3 (*Aspergillus* sensitized), ± RT-PCR, negative GM, elevated *Aspergillus* IgE, but not *Aspergillus* IgG; and class 4 (*Aspergillus* bronchitis), positive RT-PCR, positive GM, elevated *Aspergillus* IgG, but not IgE.

In 2016, Mirković et al.[165] reported using *Aspergillus* stimulated basophil activation test (BAT) measuring surface marker CD203c expression to identify ABPA in CF patients. Three groups were identified. In Group 1 (nonsensitized), decreased BAT CD203c, decreased total IgE, and decreased *Aspergillus* specific IgE; Group 2 (*Aspergillus* sensitized), decreased BAT CD203c, decreased total IgE, and decreased *Aspergillus* specific IgE; and Group 3 (ABPA), elevated BAT CD203c, elevated total IgE, and elevated *Aspergillus* specific IgE.

## Clinical Staging

The spectrum of ABPA varies widely, from individuals with mild asthma and occasional episodes of pulmonary eosinophilia (with no long-term sequelae), to patients with fibrosis, honeycomb lung, and respiratory failure. Patterson and colleagues[166] have suggested a clinical classification with five clinical stages, as shown in Table 65.2. Stage I is the acute stage of ABPA, with many of the typical features of the disease. If this stage goes into remission, the infiltrates clear, symptoms reduce, and the serum IgE value will decline by up to 35% within 6 weeks. Stage II is remission. Stage III is an exacerbation associated with the recurrence of the initial symptoms and a twofold increase in serum IgE level. Stage IV is reached when patients need continuous corticosteroids either to control their asthma or to prevent a recurrence of ABPA. Stage V is the fibrotic stage, which is present when there is severe upper lobe fibrosis present on the chest radiograph, and it may be associated with honeycombing. The stage V lesions may not respond to corticosteroids, although steroids are often necessary to maintain a bronchodilator response, and severe wheezing may develop if steroids are discontinued. Pulmonary fibrosis is an advanced complication that can lead to pulmonary hypertension and cor pulmonale.

### Table 65.2

### Staging of Allergic Bronchopulmonary Aspergillosis

| Stage | IgE Level | Precipitins | Eosinophilia | IgE-Af | IgG-Af | Pulmonary Infiltrates |
|---|---|---|---|---|---|---|
| (I) Acute | +++ | + | + | + | + | + |
| (II) Remission | + | ± | — | ± | ± | — |
| (III) Exacerbation | +++ | + | + | + | + | + |
| (IV) Corticosteroid-dependent | ++ | ± | ± | ± | ± | — |
| (V) Fibrotic | + | ± | — | ± | ± | — |

*IgE,* Immunoglobulin E; *IgE-Af,* IgE antibody to *Aspergillus fumigatus; IgG-Af,* IgG antibody to *Aspergillus fumigatus.*

## Radiographic Findings

There are several characteristic radiographic abnormalities associated with ABPA.[144,166–170] The most common lesion is a large, homogeneous shadow in one of the upper lobes with no change in volume. The shadow may be triangular, lobar, or patchy, and it frequently moves to another site. “Tram line” shadows are fine parallel lines radiating from the hila that represent inflammation of airway walls. Mucoid impaction causes toothpaste shadows or gloved-finger shadows. Several adult patients have been reported with normal chest radiographs, so radiographic abnormalities are not invariably present. In these individuals, cylindrical bronchiectasis was demonstrated by high-resolution computerized tomography (HRCT) scan (Fig. 65.7).

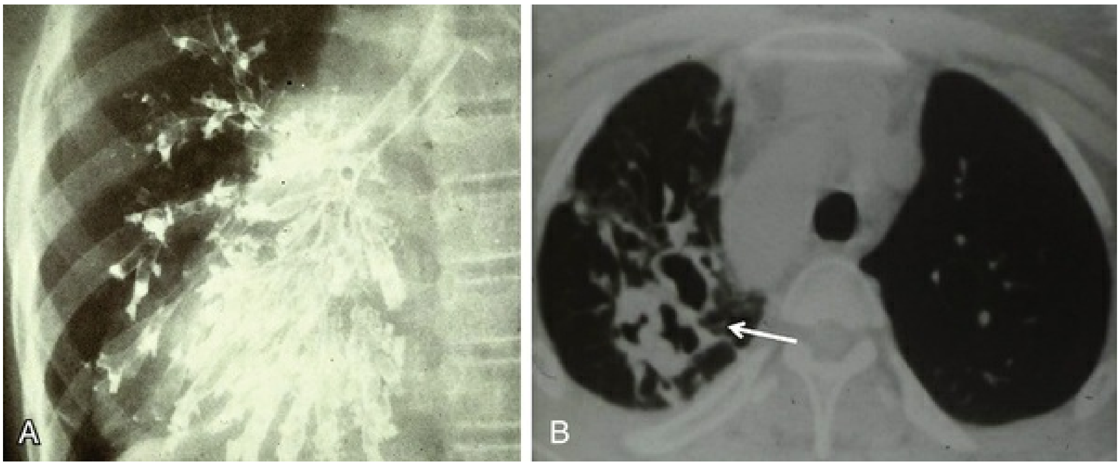

**FIG. 65.7** Central bronchiectasis in allergic bronchopulmonary aspergillosis demonstrated by (A) radiocontrast bronchography and (B) chest scan *(arrow).* (Used with permission from Dr. Raymond G. Slavin.)

HAM has been proposed by Agarwal et al.[167–170] to be evaluated with HRCT. Based on multiple studies, Agarwal et al.[170] found that the presence of HAM is pathognomonic of ABPA. They have also investigated the immunologic severity of these patients with HAM. They, along with International Society for Human and Animal Mycology (ISHAM), have proposed a change in severity and classification based on radiographic studies as follows: mild ABPA-serologic (ABPA-S), moderate ABPA-central bronchiectasis (ABPA-CB), and severe ABPA-CB-HAM.[170] In a study of 234 patients, Agarwal et al. found 25% normal HRCT, 76.5% with CB, 20.9% with HAM, and 11.5% with other radiologic findings.[168] It was noted that patients with CB or HAM had frequent relapses; however, those with HAM had significantly elevated immunologic markers compared with the other groups, which was correlated with more severe cases of ABPA. Of note, failure to achieve remission was associated with CB, not with HAM. HAM has been shown to be 100% specific in the diagnosis of ABPA.[169]

## Laboratory Findings

Laboratory tests that support the diagnosis of ABPA are those that demonstrate allergy to the mold, such as a positive specific IgE test and positive *Aspergillus* precipitins.[143–147] The precipitins are only weakly positive compared with the strong reactions seen in patients with mycetomas. Culture of *A. fumigatus* from the sputum is only a secondary criterion for the diagnosis of ABPA, because a large proportion of individuals with CF without ABPA have *Aspergillus* on sputum cultures. Some normal individuals and many individuals with lung diseases have small numbers of spores in their sputum; these are probably present because of passive inhalation. The presence of hyphae is more specific, and the presence of eosinophils in association with hyphal elements is suggestive of the diagnosis. The presence of eosinophilia in sputum or blood is suggestive of ABPA and is a primary diagnostic criterion. The peripheral blood eosinophil count is usually greater than 1000/mm$^3$, and values greater than 3000/mm$^3$ are common.

An increased serum IgE value is very characteristic of ABPA, and values may reach as high as 30,000 IU/mL. Usually, the value is greater than 1000 IU/mL. Much of the IgE is not specific to *Aspergillus* but is the result of polyclonal B-cell activation. The IgE level is a very useful marker of disease activity, and it can be used to follow outpatients for “flares.” The simple skin-prick test is a useful screening test, as ABPA is very unlikely in patients with a negative reaction. A dual-reaction of intradermal *Aspergillus* skin test with an immediate (10–15 minutes) and a late (4–8 hours) reaction occurs in one-third of patients with ABPA. Alternatively, serum may be measured for the presence of specific IgE and IgG antibodies. Patients with ABPA and *Aspergillus*-sensitive asthma will have *Aspergillus* specific IgE antibody, but patients with ABPA will have quantitatively increased *Aspergillus*-specific IgE levels. Crameri's group[171] has reported that ABPA and *Aspergillus*-sensitive patients have elevated IgE antibodies to recombinant *Aspergillus* Asp f1, Asp f3, Asp f4, and Asp f6 allergens, and that IgE levels to

Asp f4 and Asp f6 are highly specific for ABPA.

The usual pattern of serum precipitins is that immunoelectrophoresis shows one to three precipitin lines, often to only one extract.[153,166] Patients with aspergilloma will have multiple precipitin lines to all antigen extracts. Extracts of *A. fumigatus* contain a complex mixture of proteins that are mainly derived from the hyphae. Antigenic composition varies between batches according to the culture conditions, even within the same laboratory. Thus there is a lack of standardization that makes it difficult to compare results between laboratories. However, there has been some success with purification of the major antigenic components that may lead eventually to improved diagnosis. We find it best to send all our testing to one central laboratory that has well-established methods for the characterization of the serologic responses to *A. fumigatus.*

## Differential Diagnosis

Several diseases cause pulmonary infiltrates in children with asthma or CF. The differential diagnosis of ABPA should include the following: viral or bacterial pneumonia, poorly controlled asthma with mucoid impaction or atelectasis, inhaled foreign body, CF (with or without ABPA), immotile cilia syndrome, tuberculosis with eosinophilia, sarcoidosis, pulmonary infiltrates with eosinophilia, HP, and pulmonary neoplasm.

## Management and Treatment

Treatment is designed first to control the acute episodes and then to limit the development of chronic lung disease.[154,166] Most cases of ABPA require treatment with systemic corticosteroids, and the treatment of choice is prednisone. Steroid therapy rapidly clears the eosinophilic infiltrates and the associated symptoms, although it is less effective at treating mucus impaction. The usual starting dose is 0.5 mg/kg per day, taken each morning, and this dose is maintained for 2–4 weeks while following the patient clinically and checking the chest radiograph for resolution of the acute process. After this induction treatment, the dose of prednisone should be reduced to 0.5 mg/kg given on alternate days. If mucus impaction persists and is associated with atelectasis, bronchoscopy should be performed to confirm the diagnosis and to attempt to remove the mucus plugs.

Following resolution of the acute process, the dose of prednisone should be reduced over 1–3 months. Chronic treatment with corticosteroids is controversial, especially in adults, because a minority of patients with ABPA are at risk of chronic lung disease. The relationship between acute episodes and lung damage is unclear, and the precise dose of prednisone is not certain, since acute exacerbations may continue while the patients are on low doses of steroids. However, children with ABPA usually have CF and may need treatment with long-term corticosteroids to prevent progressive lung damage. Therefore we usually maintain therapy with a dose of 0.5 mg/kg on alternate days for 3 months, and then, after 3 months, the dose of prednisone is tapered over an additional 3 months while checking the chest radiograph and the serum IgE level for evidence of relapse. Initially the serum IgE level should be checked at every visit and, if the level increases by twofold or more, the steroid dose should be increased. We recommend that patients are followed with serum IgE levels and chest radiographs every 6 months for the first 1–2 years, and then, if the patient remains in remission, it should be possible to reduce the frequency of these studies.

The antifungal agent itraconazole has been used to reduce the doses of steroids that are required.[172,173] Initially there were only open nonrandomized studies indicating that itraconazole is a useful adjunct to systemic corticosteroid therapy. Two recent randomized controlled trials have also favored itraconazole use. A double-blind, randomized, placebo-controlled trial of itraconazole 200 mg twice daily dose resulted in decreased IgE levels and an increase in pulmonary function and exercise tolerance. Another randomized, controlled trial showed that treatment of stable ABPA in adults with 400 mg/day itraconazole resulted in a significant reduction in sputum eosinophil count, sputum eosinophilic cationic protein levels, serum IgE concentrations, and *Aspergillus*-specific IgG. There was also a reduction in episodes of exacerbation, requiring treatment with systemic steroids. In the treatment of children with ABPA, we have used a dose of 10 mg/kg per day of itraconazole.

Omalizumab, a humanized monoclonal antibody that binds free

IgE, has been used in patients with refractory ABPA.[174] Current dosing of omalizumab is based on total serum IgE levels. However, patients with ABPA can have IgE levels that far exceed the upper limit of omalizumab dosing, as part of their disease process. Therefore they should be treated with the maximum recommended weight-based dose of omalizumab. Collins et al.[175] performed a retrospective chart review of 21 patients who had received omalizumab for refractory ABPA. This group of patients overall had decrease in steroid use, decrease in levels of total serum IgE, and improved symptoms which were noted with an increase in Asthma Control Test (ACT) scores.[131] In France, Tillie-Leblond et al.[176] evaluated 16 patients with ABPA who received omalizumab for 1 year. This group of patients had decreased exacerbations and the need for oral steroids during this time. In 2016, Voskamp et al.[177] reported a randomized, double-blind, placebo-controlled, crossover trial with 2 treatment phases of 4-month duration. Thirteen patients with asthma and ABPA were identified and underwent the active treatment phase with omalizumab 375 mg every 2 weeks for 4 months with a washout period of 3 months, and crossover arm. ABPA exacerbations occurred less frequently during omalizumab treatment compared with the placebo period, 2 versus 12 events. Mean fractional exhaled nitric oxide (FeNO) decreased from 30.5 to 17.1 ppb during omalizumab treatment. In addition, omalizumab treatment resulted in decreased basophil reactivity to *A. fumigatus* and FcεR1 and surface-bound IgE levels. These recent studies and many case reports show the benefit this additional treatment option offers patients with ABPA.

Recent studies have shown utility in inhaled amphotericin B to provide localized treatment of ABPA and thereby decrease side effects.[178–180] In addition, hypertonic saline has been used to help clear mucus from the airways in patients with bronchiectasis, though patients must be monitored carefully with their first dose, as it can induce bronchoconstriction.[181,182] Macrolide antibiotics have been used for antiinflammatory effects in patients with bronchiectasis, though no studies have been done in patients with ABPA or to compare macrolide versus itraconazole therapy.

There is no place for immunotherapy in children with ABPA, since it is ineffective and potentially dangerous. Inhaled antiinflammatory agents, such as cromoglycate and beclomethasone, are not generally thought to be effective. The role of inhaled spores in the pathogenesis of ABPA is unclear, but there is a seasonal incidence of ABPA that is probably related to seasonal changes in mold spore counts. Therefore it is reasonable to advise patients with ABPA to avoid exposure to places with high spore counts, such as damp basements, barns, and compost heaps.

## Prognosis

The prognosis for children with ABPA is good if the disease is detected early and treatment started promptly.[183] It is important that the diagnosis is made and treatment commenced before there is permanent lung damage from bronchiectasis. In such patients, there should be no progression of the disease, although relapses can occur many years later, and long-term follow-up is recommended. In patients with CF, the relapses seem to be more frequent than in asthma, and careful surveillance is necessary to ensure resolution of the disease process. In some CF patients, it is difficult to wean the steroids without an increase in symptoms, such as dyspnea and wheezing; whether this is due to the underlying CF lung disease or due to patients going from stage II to stage III ABPA on withdrawal of steroids is unclear. Symptoms are not a reliable guide to therapy; therefore it is important to reevaluate the chest radiograph and the serum IgE at regular intervals until a long-term remission is established.

# Drug-Induced Eosinophilia

## Etiology

Many drugs have been associated with the development of pulmonary eosinophilia (Table 65.3).[184–191] In fact, drug reactions are one of the most commonly reported causes of pulmonary infiltrates with blood or pulmonary eosinophilia. Sulfonamides, including sulfasalazine, were the first recognized cause of this reaction, but more recently it has been described with the structurally similar drugs, sulfonylurea and chlorpropamide, and the antituberculous drug *p*-aminosalicyclic acid. The tricyclic compounds imipramine and carbamazepine may also cause pulmonary eosinophilia. Of the hydantoins (nitrofurantoin, dantrolene, and phenytoin), nitrofurantoin is most likely to cause an adverse pulmonary reaction. The reaction may be seen within days of starting treatment.

## Table 65.3

### Drugs That Cause Eosinophilic Lung Disease

| | |
|---|---|
| Ampicillin | L-Tryptophan |
| Aspirin | Mephenesin carbamate |
| Beclomethasone dipropionate (inhaled) | Methotrexate |
| Bleomycin | Minocycline |
| Captopril | Naproxen |
| Carbamazepine | Nickel |
| Chlorpromazine | Nitrofurantoin |
| Clarithromycin | *p*-Aminosalicyclic acid |
| Chlorpropamide | Penicillamine |
| Clofibrate | Penicillin |
| Cocaine (inhaled) | Pentamidine (inhaled) |
| Cromolyn (inhaled) | Phenytoin |
| Desipramine | Pyrimethamine |
| Diclofenac | Rapeseed oil |
| Febarbamate | Sulfadimethoxine |
| Fenbufen | Sulfadoxine |
| Glafenine | Sulfasalazine |
| GM-CSF | Sulindac |
| Gold | Tamoxifen |
| Ibuprofen | Tetracycline |
| Imipramine | Tolazamide |
| IL-2 | Tolfenamic acid |
| IL-3 | Vaginal sulfonamide cream |
| Iodinated contrast dye | |

Other drugs that have been implicated in pulmonary eosinophilia are listed in Table 65.3. In addition, toxins from occupational exposures, such as rubber workers exposed to aluminum silicate and particulate metals, sulfite-exposed grape workers, and Scotchguard® inhalation, should be considered. Loeffler's-like syndrome has been seen in crack cocaine users. Drug reactions may be associated with the simple form of pulmonary eosinophilia-like syndrome, a fulminant acute eosinophilic pneumonia-like syndrome, or may follow a more chronic source. Symptoms normally start within a month of starting the drug and include cough, dyspnea, and fever. Histologically, there is pulmonary interstitial edema with a lymphocytic and eosinophilic infiltrate, and the alveoli contain eosinophils and histiocytes. Peripheral eosinophilia, though common, is not an invariable finding. Chest radiographs show interstitial or alveolar infiltrates and often demonstrate Kerley B lines. High-resolution CT chest scans demonstrate areas of ground-glass attenuation, airspace consolidation, nodules, irregular lines, and sometimes hilar adenopathy or pleural effusion.[192,193]

Drug-induced eosinophilic lung disease resembles other eosinophilic lung diseases, such as Loeffler's syndrome. Thus other causes need to be considered. Confirmation of the adverse reactions may be carried out by challenging the patient with a single dose of the drug. Skin testing with either patch or prick tests is usually negative. In vitro lymphocyte transformation tests have been positive with some drugs, such as nitrofurantoin and carbamazepine. When the offending drug is discontinued, there is usually resolution of the symptoms and the eosinophilia, together with clearing of the chest radiograph. When resolution is slow, corticosteroid drugs may hasten the recover, though not invariably.

# Acute Eosinophilic Pneumonia

## Epidemiology/Etiology

The cause of acute eosinophilic pneumonia is unknown (Table 65.4). It is hypothesized that acute eosinophilic pneumonia is caused by an acute hypersensitivity reaction to an unidentified inhaled antigen.[194,195] However, other causes of eosinophilic lung diseases, such as parasitic, drug-induced, and fungal hypersensitivities, do need to be excluded. It affects predominantly males twice as often as females, and though it may affect individuals at any age, it occurs most often between 20 and 40 years. It has been reported that acute eosinophilic pneumonia developed in individuals who recently started smoking or resumed smoking after a period of cessation.[196] It has also been suggested that home environmental factor exposure may play a role. Provocative home challenges were performed in stable patients who had recovered from acute eosinophilic pneumonia and resulted in the development of acute symptoms of fever, cough, fatigue, and dyspnea.[197] Since leaving the house, the symptoms did not recur.

### Table 65.4

**Characteristics of Acute and Chronic Eosinophilic Pneumonitis**

| Characteristic | Acute | Chronic |
|---|---|---|
| Ages | Children and adults 20–40 years | Adults 40–50 years peak, rare in children |
| Sex | Male preponderance | Female preponderance 2 : 1 |
| Smoking risk | Yes | No |
| Underlying asthma | None | 50% |
| Symptoms | Acute febrile illness 1–5 days<br>Fever, dyspnea, cough, myalgias, pleuritic chest pain, hypoxemia | Insidious over 7.7 months<br>Fever, night sweats, weight loss, cough, wheezing, anorexia |
| PE | High fever, basilar rales, wheezing | Fever, wheezing, lymphadenopathy, hepatomegaly |
| Chest radiograph, HRCT scan | Diffuse bilateral ground glass and/or reticular opacities involving alveolar or mixed interstitial/alveolar infiltrates, pleural effusions | Dense peripheral infiltrates (negative image of pulmonary edema) |
| PFT<br>DLCO | Restrictive pattern<br>Decreased | Restrictive pattern |
| Lung biopsy | Diffuse acute organizing alveolar damage, eosinophilic infiltration of alveoli, interstitium, bronchial epithelium | Eosinophils and lymphocytes in alveoli and interstitium, thickened alveolar walls. Interstitial fibrosis in 50%; BO in 25% |
| BALF | 45 ± 11% eosinophils, 20 ± 11% lymphocytes | >25% eosinophils, lymphocytes |
| Blood eosinophilia | Normal | Elevated |
| IgE level | Elevated in some | Elevated in most |
| Corticosteroids | Prompt response. No relapse of tapered corticosteroids over 8 weeks | Prompt response. Relapse if corticosteroids discontinued within 6 months |
| Omalizumab | ND | Responsive in case report |

Exclusion of drug-induced eosinophilia, helminth infection, fungal associated eosinophilic lung diseases.

*BALF*, Bronchoalveolar lavage fluid; *BO*, bronchiolitis obliterans; *DLCO*, diffusing capacity carbon monoxide; *HRCT*, high-resolution computed tomography; *ND*, not done; *PE*, physical examination; *PFT*, pulmonary function testing.

## Pathology/Pathogenesis

Tazelaar et al.[198] reported on the histopathology from lung biopsies of nine adult patients with acute eosinophilic pneumonia. They reported acute and organizing diffuse alveolar damage (DAD) involving 75% of the surface area of the lung. The main finding was the presence of acute and organizing DAD with marked infiltration of eosinophils in the interstitium and alveoli. Hyaline membranes were seen in seven of the nine patients. There was interstitial widening due to edema, fibroblast proliferation, and in the organizing phase of DAD, eosinophilic inflammation. Type II pneumocyte hyperplasia, interstitial lymphocytes, and organizing intraalveolar fibrinous exudate were also observed. However, granulomata were absent.

# Clinical Features

## Symptoms and Physical Findings

Acute eosinophilic pneumonia is a distinct clinical entity that occurs in both children and adults with a male preponderance (see Table 65.4).[197–204] The clinical manifestations include acute onset of fever, cough, and dyspnea for 1–5 days. There may be associated pleuritic chest pain and myalgias. Patients then develop hypoxemia and respiratory failure, often requiring a mechanical ventilator. Physical examination reveals high fever, respiratory distress, and basilar rales, sometimes with fever. Initial chest radiographs reveal interstitial infiltrates.[199,200] These may progress to diffuse alveolar infiltrates. Chest CT scans demonstrate diffuse alveolar infiltrates, pleural effusions, pronounced septal markings, and normal lymph nodes.

## Laboratory Findings

At the onset of disease, chest radiographs demonstrate reticular and/or ground-glass opacities.[194–196] As the disease progresses, there are bilateral diffuse mixed ground-glass and reticular opacities. Pleural effusions are common, which contain up to 42% eosinophils. Chest HRCT demonstrates bilateral ground-glass and/or reticular opacities. Pulmonary function testing demonstrates a restrictive pattern with decreased diffusing capacity (DLCO). BAL fluid reveals eosinophilia (45% ± 11%) and lymphocytosis (20% ± 11%). There is evidence of eosinophil degranulation in the pleural fluid with an elevated pH. Lung biopsy specimens demonstrate eosinophil infiltration of the interstitium, alveoli, and epithelium. Other findings include type II pneumocyte hyperplasia, interstitial lymphocytes, organizing intraalveolar fibrinous exudate, and perivascular and intramural inflammation without necrosis. Peripheral blood eosinophilia is typically absent; however, serum IgE levels may be elevated in some patients.

## Treatment and Management

Though the etiology of acute eosinophilic pneumonia is unknown, there is a dramatic response to high-dose corticosteroids, typically within 24–48 hours. Steroids are then tapered over an 8-week course.[194,197–201] Relapses or recurrences are unusual.

## Prognosis

Acute eosinophilic pneumonia has a very favorable outcome.[196] After initiation of corticosteroids, there is rapid clinical, radiographic, and pulmonary function testing improvement over a 1–2 months treatment period. Relapse may recur, especially with resumption of cigarette smoking.

# Chronic Eosinophilic Pneumonia

## Epidemiology/Etiology

Idiopathic CEP is a rare disorder, with an incidence of 0.23 cases/100,000 in Iceland,[205] and accounts for 2.5% of interstitial lung disease in Europe.[206] CEP is a disorder that affects primarily middle-age adults (peak 40–50 years), with a 2 : 1 female preponderance (see Table 65.4).[207–212] CEP is rare in childhood. In contrast to acute eosinophilic pneumonia, the majority of patients are nonsmokers. The cause of CEP is unknown, and other conditions that cause eosinophilic lung diseases need to be excluded. A risk factor may be asthma, which occurs in 50% of patients.

## Pathology/Pathogenesis

The inflammatory response is similar to asthma, though the pathogenesis is unknown. Indeed, an underlying risk factor is asthma seen in 50% of the patients with CEP. There is accumulation of eosinophils, which may be the result of a stimulus triggering release of T helper 2 cells and IL-5. Lung biopsy specimens of patients with CEP demonstrate interstitial and alveolar septa infiltration of eosinophils, lymphocytes, histiocytes, and the presence of multinucleated giant cells.[207] In addition, there are alveolar luminal eosinophil and macrophage infiltration. Organizing pneumonia is a common finding, and eosinophilic abscesses may also be seen. There is also prominent intraluminal fibrosis.

## Clinical Features

### Symptoms and Physical Findings

The symptoms of CEP are insidious developing over a 6–8 months period (see Box 65.8).[207–212] They include fever, night sweats, weight loss, cough, and wheezing. The cough is typically nonproductive. Some patients may also experience hemoptysis, lymphadenopathy, and hepatomegaly.

### Laboratory Findings

Chest radiographs reveal extensive, bilateral, peripheral infiltrates, so-called “negative image of pulmonary edema,” which is diagnostic of CEP. Chest HRCT scans show peripheral airspace disease and may show hilar adenopathy. Peripheral blood eosinophilia is prominent. BALF examination reveals increased eosinophils greater than 25% and increased lymphocytes. IgE levels are also frequently elevated.

Lung biopsy specimens display moderate to extensive accumulation of eosinophils and lymphocytes in the alveoli and the interstitium with thickened alveolar walls. Sometimes multinucleated histiocytic giant cells, lymphocytes, and plasma cells are found in the alveoli, a noncaseating granuloma reaction. There is also mild perivascular cuffing of venules with eosinophils and lymphocytes. Interstitial fibrosis has been reported in 50% of patients and bronchiolitis obliterans in 25% of patients.

## Treatment and Management

Response to high-dose corticosteroids is dramatic, with resolution of symptoms within 24–48 hours. Radiographically, pulmonary infiltrates resolve over 10–21 days. Taper of corticosteroids needs to be prolonged typically more than 6 months to prevent relapse. The mean duration of corticosteroid treatment is approximately 19 months. Recurrent attacks have occurred in 34% patients, especially in those with asthma. The outcome for most patients with CEP is excellent despite the risk of recurrences. Some patients have subsequently developed CSS (eosinophilic granulomatosis with polyangiitis), raising the possibility of overlap of the two diseases. Inhaled corticosteroids have been reported to be effective. Nonetheless, long-term prognosis is excellent for most patients. In case reports, omalizumab has been reported to be successful in patients with both atopic asthmatic and CEP who have prolonged dependence on systemic glucocorticoids.[213]

## Prognosis

CEP is responsive to corticosteroid treatment, and the prognosis of CEP is excellent with few relapses.[211] Naughton et al.[212] reported on the long-term follow-up, mean of 10.2 years (range 4–12 years), of 12 patients with CEP. All 12 patients were well on long-term follow-up. Two patients (17%) were tapered off corticosteroids without relapse, 9 patients (58%) had a relapse on corticosteroid withdrawal but responded to increased doses, and 3 patients (25%) have required long-term low-dose corticosteroids. Omalizumab treatment may have a therapeutic role in those patients with corticosteroid dependency.[213] Development of asthma in follow-up of CEP patients is common, and it has been suggested that inhaled corticosteroids may be beneficial.

# Eosinophilic Granuloma (Pulmonary Langerhans Cell Histiocytosis)

## Epidemiology/Etiology

Eosinophilic granuloma, also known as pulmonary Langerhans cell histiocytosis (PLCH), is a rare histiocytic disorder in which the incidence is unknown (Table 65.5).[214,215] PLCH is the nonmalignant form of the three forms of Langerhans cell histiocytosis: Letterer-Siwe disease, Hand-Schuller-Christian disease, and eosinophilic granuloma. The incidence appears to be 3–5 cases per million children. Eosinophilic granuloma affects children from 1 to 3 years old and particularly young adult males 20–40 years.[208] Males and females are equally affected. The etiology and pathogenesis of pulmonary eosinophilic granuloma is unknown. PLCH is strongly associated with cigarette smoking.

### Table 65.5

**Characteristics of Eosinophilic Granuloma (Pulmonary Langerhans Cell Histiocytosis)**

| Characteristic | Eosinophilic Granuloma |
|---|---|
| Ages | Children and adults 20–40 years |
| Sex | Male:Female equal |
| Smoking risk | Yes |
| Pulmonary symptoms | Nonproductive cough, dyspnea, chest pain, hemoptysis, pneumothorax, fatigue, weight loss, fever |
| Extrapulmonary symptoms | Cystic bone lesion 4%–20% of patients. Localized pain, pathologic bone fracture<br>Diabetes insipidus 15% of patients |
| PE | Typically unremarkable. Rales and digital clubbing may be present |
| Chest radiograph<br>HRCT scan | Alveolar pattern, 3–10 mm nodular/reticulonodular pattern affecting apices, fibrosis, honeycombing |
| PFT<br>DLCO | Variable<br>Decreased |
| Lung biopsy | Eosinophils present in lesions |
| BALF | Eosinophils absent |
| Blood eosinophilia | Normal |
| IgE level | Elevated in some |
| Treatment | Smoking cessation<br>Curettage single lesion corticosteroids ± vinblastine, mercaptopurine, etoposide, methotrexate |

*BALF*, Bronchoalveolar lavage fluid; *DLCO*, diffusing capacity carbon monoxide; *HRCT*, high-resolution computed tomography; *PE*, physical examination; *PFT*, pulmonary function testing.

## Pathology/Pathogenesis

The Langerhans cell is a differentiated cell of the monocyte-macrophage lineage and is the pathologic cell in pulmonary eosinophilic granuloma.[214–216] Langerhans cells are identified by pale staining cytoplasm, a large nucleus and nucleoli, and classic pentilaminar cytoplasmic inclusions or Birbeck granules seen on electron microscopy. Langerhans cells also demonstrate positive immunohistochemical staining for S100 protein CD1a on the cell surface. In PLCH, the Langerhans cells are typically found in clusters and are nonmalignant. Cigarette smoking has been linked to pulmonary eosinophilic granuloma, but not to extrapulmonary Langerhans cell histiocytosis.[215–218] It has been hypothesized that cigarette smoke induces bombesin-like peptide synthesis, a neuropeptide produced by neuroendocrine cells.[219–222] Bombesin-like peptides are increased in the lungs of smokers and are chemotactic for monocytes, stimulate epithelial cells and fibroblasts, and stimulate cytokine synthesis. Several abnormalities in immune function have been identified, including increased IgA in BALF, increased immune complexes, and abnormal T cell function.[219,223] Although these factors may be important in the pathophysiology of pulmonary PLCH, they may also represent nonspecific generalized activation of immune effector cells.

## Clinical Features

### Symptoms and Physical Findings

Patients with eosinophilic granuloma present with pulmonary and/or extrapulmonary symptoms (see Table 65.5).[214,215] In PLCH, there is typically only a solitary lesion, but there may be multiple lesions, which may be asymptomatic or may cause pain. The most common presenting symptoms are nonproductive cough, dyspnea, pleuritic chest pain, hemoptysis, pneumothorax, fatigue, weight loss, and fever. Extrapulmonary symptoms include bone lesions and diabetes insipidus. Cystic bone lesions are present in 4%–20% of patients and may produce localized pain and/or a pathologic bone fracture. Any bone may be involved, with the calvarium, ribs, and femur being the most common sites, and the lesions are usually solitary. Histologically, they are composed of foamy vacuolated histiocytes with variable numbers of eosinophils, neutrophils, lymphocytes, and plasma cells. Diabetes insipidus is seen approximately 15% of patients and is due to hypothalamic infiltration. Diabetes insipidus is associated with a worse prognosis.

### Laboratory Findings

Pulmonary interstitial lung disease occurs in approximately 20% of patients with eosinophilic granuloma. Chest radiographs demonstrate an alveolar pattern in an early state. This may be followed by 3–10 mm nodular shadows or a reticulonodular pattern with a predilection for the apices. Fibrosis and honeycombing may also ensue. Chest HRCT reveals multiple nodules and/or cysts. Honeycombing is seen in advanced disease. Histologically, eosinophils are present in the lesions; however, they are not present in BALF specimens. Pulmonary function tests in patients with PLCH are variable, with the most common finding being decreased DLCO. Lung volumes are typically normal or increased and demonstrate a restrictive, obstructive, or mixed pattern.

## Treatment and Management

In the context of Langerhans cell histiocytosis, the intensity of treatment depends on whether the patient has single-system or multisystem disease.[214] In single-system disease, there is unifocal or multifocal involvement of one organ, such as skin, lymph node(s), or bone. The Histiocyte Society has initiated treatment protocols of LCH. Treatment options include single-agent corticosteroids, combination of corticosteroids plus vinblastine, or curettage of bone lesions, and topical therapy such as nitrogen mustard or PUVA for skin lesions. In multisystem disease, ≥2 organs or systems are involved with or without the involvement of “risk organs.” Risk organs include the bone marrow, liver, spleen, and central nervous system, which denote a worse prognosis. Chemotherapy is the treatment of multisystem disease, using chemotherapeutic medications, such as prednisone, vinblastine, mercaptopurine, etoposide, and methotrexate. Other treatments include monoclonal antibodies that target CD1a or CD207, cytokine inhibitors, and 2-chlorodeoxyadenosine. In addition, there are new treatment protocols in clinical trials.

In the treatment of isolated pulmonary eosinophilic granuloma, smoking cessation is recommended. Immunosuppressive treatment with corticosteroids and cytotoxic drugs, such as cladribine (2-chlorodeoxyadenosine), a chemotherapeutic agent cytotoxic for lymphocyte and monocyte cells, are used.

## Prognosis

The overall prognosis for patients with pulmonary eosinophilic granuloma is good, with a 5-year survival greater than 75%.[215,224,225] However, the natural history is variable with some patients progressing to end-stage pulmonary fibrosis. The major causes of death in PLCH are respiratory failure from progressive disease and malignancy.

# Helminth Associated Eosinophilic Lung Disease

Helminth associated eosinophilic lung diseases can be characterized based on their natural life cycle or history of the parasites (see Box 65.5).[226–233] Infection in humans may occur by ingestion of eggs or larvae, penetration of skin by larvae, or inoculation of larvae by biting insects. Eosinophilic inflammation is a host response mechanism to resist these infections. Helminth infections may also lead to elevated serum IgE levels and a dominant Th2 cytokine profile. In developing countries, this Th2 response to parasites may decrease expression of asthma and allergic diseases. The lungs may be affected by transpulmonary passage of helminth larvae, hematogenous seeding with helminth larvae, and pulmonary parenchymal invasion with helminthes. Hematogenous seeding with helminth larvae may be further divided into cutaneous visceral migrans, visceral larva migrans, and disseminated disease.

In transpulmonary passage, the helminth larvae have as part of their life-cycle infecting larvae that pass through the lungs entering via the blood stream. The larvae penetrate into the alveoli and then the ascending airway to transit down the esophagus into the small intestines. In the intestines, the larvae mature and become adult worms. The nematodes that cause Löffler syndrome are *Ascaris* *lumbricoides,* the hookworms *Ancylostoma duodenale* and *Necator americanus,* and *Strongyloide stercoralis.*[227,228] In hematogenous seeding, there is heavy hematogenous infection by helminth larvae or eggs causing eosinophilic pneumonitis. The etiologic helminths include nonhuman *Ascaris* and hookworms, which cause cutaneous larva migrans; *Toxocara canis,* which causes visceral larva migrans; *Trichinella spiralis; Schistosoma;* and disseminated *Strongyloides.*[229,233] In pulmonary parenchymal invasion, human infection is acquired by eating freshwater crab or crawfish. The larvae penetrate the wall of the intestine and migrate through the diaphragm to reach the lungs. Pulmonary infection may be asymptomatic or cause a chronic cough producing blood-streaked sputum. Eosinophilia is common. Pulmonary paragonimiasis is diagnosed by identification of eggs in the stool or sputum specimens. In tropical pulmonary eosinophilia, infection is acquired through insect bites, during which larvae are transmitted. Migration of microfilariae to the lungs causes eosinophilic pneumonitis manifested by wheezing, cough, chest pain, pulmonary infiltrates, and eosinophilia. Diagnosis is established by identification of microfilaria in blood or urine specimens. Tropical pulmonary eosinophilia is caused by *Wucheria bancrofti* and *Brugia malayi.*[227,228] This is described in greater detail in Chapter 33.

# Churg-Strauss Syndrome (Eosinophilic Granulomatosis With Polyangiitis)

## Etiology

CSS is also called eosinophilic granulomatosis with polyangiitis and allergic angiitis and granulomatosis because of its association in patients with asthma, allergic rhinitis and sinusitis, and with its findings of eosinophilic vasculitis and granulomatous lesions (Box 65.6).[234–246] Nearly all patients have allergic rhinitis and pansinusitis. Three phases have been described in CSS. The first phase involves development of asthma with variable severity, typically in adults. Tapering of systemic corticosteroid treatment of asthma may unmask CSS.[238,239] This has been reported as a risk in asthmatic patients treated with omalizumab when prednisone is decreased or discontinued. The second phase is characterized by the development of peripheral blood eosinophilia and eosinophilic tissue infiltrates. The third phase involves eosinophilic vasculitis of extrapulmonary organs, typically skin, gastrointestinal tract, heart, and nervous system.

**Box 65.6**

## Characteristics of Churg-Strauss Syndrome (Eosinophilic Granulomatosis With Polyangiitis)

### Findings

- History of asthma
- Pulmonary
    - Patchy, transient infiltrates
    - Eosinophilic infiltration of alveoli, interstitium, blood vessels
    - Necrotizing and nonnecrotizing granuloma
    - Eosinophilic angiitis
- Systemic vasculitis involving ≥2 extrapulmonary organs
    - Eosinophilic vasculitis of small and medium-size arteries and veins
    - Eosinophilic granulomas
- Nasal symptoms
    - Allergic rhinitis
    - Pansinusitis
- Cutaneous
    - Maculopapular rash
    - Petechiae, purpura, ecchymosis
    - Cutaneous and subcutaneous nodules on scalp and extremities
    - Cardiac

    - Hypertension
    - Pericarditis
    - Heart failure
- Gastrointestinal
    - Abdominal pain
    - Diarrhea
    - Bleeding
    - Obstruction
- Peripheral neuropathy
    - Mononeuritis multiplex
    - Polyneuropathy
- Central nervous system
    - Cerebral infarction
- Hematologic
    - >1500 eosinophils/μL
- Radiologic
    - Chest X-ray: Transient pulmonary infiltrates
    - HRCT: Airspace consolidation or ground-glass appearance, septal lines, bronchial wall thickening

*HRCT,* High-resolution computed tomography.

## Epidemiology

In a population-based study of asthma, the incidence of CSS was 34.6 per million person-years.[247] This was based on identification of 21 cases of CSS from medical records of 184,667 adult asthmatics being treated with ≥3 asthma medications in three managed care organizations.

## Clinical Features

### Symptoms and Physical Findings

CSS may involve multiple organ systems, including pulmonary, cutaneous, cardiac, gastrointestinal, hematologic, and peripheral and central nervous system (see Box 65.6). Pulmonary symptoms are present in nearly all patients.[234–242] This is manifested by worsening of asthma and poorly controlled asthma. Recurrent sinusitis with nasal polyposis is commonly seen. Pulmonary function tests demonstrate primarily an obstructive pattern consistent with the underlying asthma. With lung parenchymal involvement of CSS, a restrictive pattern coincides with airflow obstruction, decreased pulse oximetry, and decreased DLCO. Cutaneous lesions are common, occurring in 70% of patients, variably manifesting as maculopapular rashes, petechiae, purpura and/or ecchymoses, and cutaneous and subcutaneous nodules of the scalp or extremities.[242] Peripheral neuropathies occur in up to 75% of CSS patients, including mononeuritis multiplex and polyneuropathies.[241] Cerebral infarctions may occur and can be a cause of death. Eosinophilic lymphadenopathy has been noted in 30%–40% of patients. Cardiac involvement is a common cause of death and occurs in a third of patients. Gastrointestinal problems include abdominal pain (59%), diarrhea (33%), bleeding (18%), obstruction, and colitis, and may precede or coincide with the vasculitic phase of CSS.[234–238]

## Laboratory Findings

Eosinophilia ≥1500 cells/mm$^3$ is uniformly present.[234–238] Patchy and transient pulmonary infiltrates are seen on chest radiographs.[245] Chest HRCT reveals a variety of findings, which include airspace consolidation or interstitial ground-glass opacities, septal lines, and bronchial wall thickening.[244] Lung biopsy specimens demonstrate extensive eosinophil infiltration present in the interstitium, air spaces, and perivascular spaces.[234,235,244–246] In addition, both necrotizing and nonnecrotizing granulomas may be present, involving blood vessels. The angiitis varies from eosinophilic infiltration of blood vessels to necrotizing vasculitis of small- and medium-sized vessels. Biopsies of the cutaneous nodules reveal eosinophilic infiltration. Antineutrophil cytoplasmic antibodies (ANCA) are found in 40–60% of patients with CSS. The majority of ANCA-positivity is directed against myeloperoxidase (MPO), with a perinuclear staining pattern (MPO-ANCA or P-ANCA). ANCA positivity is associated typically with renal involvement, peripheral neuropathy, and systemic vasculitis.

## Management and Treatment

The treatment of CSS is divided into induction of remission and maintenance of remission.[234–238] Induction of remission is achieved with a combination of high-dose glucocorticoids, prednisone 1 mg/kg per day (maximum 60 mg), and cyclophosphamide 2 mg/kg per day (maximum 200 mg/day) for patients with generalized disease, such as renal or other life-threatening disease. For localized disease, prednisone alone may suffice. For patients with nonlife-threatening systemic involvement from pANC-associated vasculitis, methotrexate may be substituted for cyclophosphamide. Treatment with a combination of low-dose prednisone plus azathioprine or methotrexate for ≥18 months is used to maintain remission. If left untreated, the mortality is significant, as high as 50% in the first 3 months after the onset of vasculitis. In treated patients, the mean survival is 9 years.

In 2010, Kim et al.[248] reported the results of an open-label pilot study treating seven CSS patients with mepolizumab, anti-IL-5 monoclonal antibody. The patients received 4 monthly doses of mepolizumab 750 mg intravenously. Mepolizumab resulted in reduced eosinophilia, and allowed for reduction of corticosteroid dosages. CSS symptoms recurred on cessation of mepolizumab, necessitating corticosteroid bursts. However, as a proof of concept, mepolizumab was safe and effective in the treatment of CSS. Further studies of prolonged use of mepolizumab should be performed.

## Prognosis

Prognosis of CSS depends upon recognition of the disease, initiation of early treatment, and the presence or absence of extrapulmonary organ involvement, such as cardiac failure, myocardial infarction, cerebral hemorrhage, renal failure, or gastrointestinal bleeding. Samson et al.[249] reported on the long-term outcome of 118 patients with CSS. Seventy-four patients had only pulmonary involvement and were treated with corticosteroids alone, while 44 patients had extrapulmonary involvement as well and were treated with corticosteroids plus cyclophosphamide. Overall survival was 90% at 7 years, regardless of extrapulmonary involvement. In the future, mepolizumab treatment may improve on the prognosis.

# Hypereosinophilic Syndrome

## Epidemiology

The term *hypereosinophilic syndrome (HES)* encompasses a group of rare disorders characterized by increased eosinophil count in peripheral blood and end-organ damage caused by eosinophilic inflammation. The incidence and prevalence are not well characterized. The Surveillance, Epidemiology, and End Results (SEER) database estimated the age-adjusted incidence from 2001 to 2005 to be approximately 0.036 per 100,000.[250]

## Etiology

HES was first defined by Chusid et al.[251] in 1975 and specified the following three criteria for diagnosis: (1) absolute eosinophil count ≥1500/mm$^3$ in peripheral blood for greater than 6 months; (2) lack of evidence for parasitic, allergic, and other recognized causes of eosinophilia; and (3) end-organ dysfunction due to eosinophilic infiltration. Tissue hypereosinophilia is defined as greater than 20% eosinophils of all nucleated cells on bone marrow examination or eosinophil tissue infiltration that is extensive, or marked deposition of eosinophil granule proteins in tissue. It is now recognized that HES represents a spectrum of disorders that includes not only the previously described idiopathic HES (IHES) but also disorders characterized by eosinophilic organ infiltration that may or may not be accompanied by peripheral blood eosinophilia, such as eosinophilic pneumonia, eosinophil-associated gastrointestinal disorders (EGID), CSS, and eosinophilic dermatitis (Wells syndrome).[252–254] A revised classification of HES was presented in 2006 by Klion et al.[255] This classification system was the culmination of a workshop conducted by the Hypereosinophilic Diseases Working Group of the International Eosinophil Society, with the intent of allowing accurate identification of the causes of hypereosinophilia, which in turn guides the clinical management of these patients.

In 2011, the Working Conference on Eosinophil Disorders and Syndromes proposed a new terminology for eosinophilic syndrome.[256] The panel recommended the term "hypereosinophilia" (HE) for persistent and marked eosinophilia (absolute eosinophil count >1500/mm$^3$). HE subtypes were further divided into hereditary variant, HE of undetermined significance (in place of idiopathic hypereosinophilia), primary (clonal/neoplastic) HE produced by clonal/neoplastic eosinophils, and secondary or reactive HE. Any HE associated with organ damage is referred to as HES with specific subscripts in each category.

The classification of eosinophilic diseases was revised in the 2008 World Health Organization scheme of myeloid neoplasms (Box 65.7).[257] In recognition of the growing list of recurrent, molecularly defined primary eosinophilia disorders, a new major category was created: myeloid and lymphoid neoplasms with eosinophilia and abnormalities of platelet-derived growth factor receptor alpha (PDGFRA), platelet-derived growth factor receptor beta (PDGFRB), or fibroblast growth factor receptor 1 (FGFR1). Chronic eosinophilic leukemia—not otherwise specified (CEL-NOS) is one of eight disease entities within the group of myeloproliferative neoplasms (MPN), as classified in the 2008 WHO Classification. CEL-NOS is defined by the absence of the Philadelphia chromosome or a rearrangement involving PDGFRA/B and FGFR1, and the exclusion of other acute or chronic primary marrow neoplasms associated with eosinophilia, such as acute myeloid leukemia (AML), myelodysplastic syndrome (MDS), systemic mastocytosis (SM), the classic MPNs (chronic myeloid leukemia, polycythemia vera, essential thrombocythemia, and primary myelofibrosis), and MDS/MPN overlap disorders (e.g., chronic myelomonocytic leukemia, CMML; Box 65.8). CEL-NOS is characterized histologically by an increase in blasts in the bone marrow or blood (but fewer than 20% to exclude acute leukemia as a diagnosis), and/or evidence for clonality in the eosinophil lineage.[258] A diagnosis of idiopathic HES requires exclusion of all primary and secondary causes of hypereosinophilia, as well as lymphocyte-variant hypereosinophilia, with persistence of elevated absolute eosinophil count (AEC) greater than 1500/mm$^3$ and tissue damage from eosinophil infiltration.[256] For the purposes of clinical management, it remains useful to think of HES in the following clinical categories: myeloproliferative (now classified as chronic eosinophilic leukemia NOS in the 2008 WHO classification), lymphocytic, familial, idiopathic, overlap (blood eosinophilia ≥1500/mm$^3$ with single organ involvement), and associated (blood eosinophilia ≥1500/mm$^3$ in association with a distinct second diagnosis, such as inflammatory bowel disease; Box 65.9).

**Box 65.7**

## World Health Organization Classification of Myeloid Malignancies

**Acute Myeloid Leukemia and Related Disorders**

### Myeloproliferative Neoplasms

- Chronic myelogenous leukemia, BCR-ABL1 positive
- Chronic neutrophilic leukemia
- Polycythemia vera
- Primary myelofibrosis
- Essential thrombocythemia
- Chronic eosinophilic leukemia, not otherwise specified
- Mastocytosis
- Myeloproliferative neoplasms, unclassifiable

### Myelodysplastic Syndromes

- Refractory cytopenia with uni-lineage dysplasia
- Refractory anemia
- Refractory neutropenia
- Refractory thrombocytopenia
- Refractory anemia with ring sideroblasts
- Refractory cytopenia with multilineage dysplasia

- RAEB
- RAEB-1
- RAEB-2
- Myelodysplastic syndrome with isolated del(5q)
- Myelodysplastic syndrome, unclassifiable

## Myelodysplastic Syndromes/Myeloproliferative Neoplasms

- CMML
- CMML-1
- CMML-2
- Atypical chronic myeloid leukemia, BCR-ABL1 negative
- Juvenile myelomonocytic leukemia
- MDS/MPN, unclassifiable
- RARS-T

## Myeloid and Lymphoid Neoplasms Associated With Eosinophilia and Abnormalities of Platelet-Derived Growth Factor Receptor, Alpha Polypeptide, Platelet-Derived Growth Factor Receptor, Beta Polypeptide, or Fibroblast Growth Factor Receptor 1

- Myeloid and lymphoid neoplasms associated with PDGFRA rearrangement
- Myeloid neoplasms associated with PDGFRB rearrangement
- Myeloid and lymphoid neoplasms associated with FGFR1 abnormalities

*CMML,* Chronic myelomonocytic leukemia; *FGFR1,* fibroblast growth factor receptor 1; *MDS,* myelodysplastic syndromes; *MPN,* myeloproliferative neoplasms; *PDGFRA,* platelet-derived growth factor receptor, alpha polypeptide; *PDGFRB,* platelet-derived growth factor receptor, beta polypeptide; *RAEB,* Refractory anemia with excess blasts; *RARS-T,* refractory anemia with ring sideroblasts and thrombocytosis.

**Box 65.8**

## Criteria for Chronic Eosinophilic Leukemia, Not Otherwise Specified

Eosinophilia (eosinophil count >1.5 × $10^9$/L)

No Philadelphia chromosome or BCR-ABL fusion gene or other myeloproliferative neoplasms (PV, ET, PMF, systemic mastocytosis) or MDS/MPN (CMML or atypical CML)

No t(5;12)(q31_q35;p13) or other rearrangement of PDGFRB

No FIP1L1-PDGFRA fusion gene or other rearrangement of PDGFRA

No rearrangement of FGFR1

Blast cell count in the peripheral blood and bone marrow is <20% and there is no inv(16)(p13q22) or t(16;16)(p13;q22) or other feature diagnostic of AML

Clonal cytogenetic or molecular genetic abnormality, or blast cells are >2% in the peripheral blood or >5% in the bone marrow

*AML,* Acute myeloid leukemia; *BCR-ABL fusion gene,* Abelson (Abl) tyrosine kinase gene at chromosome 9 and the break point cluster (Bcr); *CEL-NOS,* chronic eosinophilic leukemia, not otherwise specified; *CML,* chronic myeloid leukemia; *CMML,* chronic myelomonocytic leukemia; *FIP1L1,* factor interacting with PAPOLA and CPSF1.; *PDGFRA,* platelet-derived growth factor receptor, alpha polypeptide; *PDGFRB,* platelet-derived growth factor receptor, beta polypeptide.

**Box 65.9**

## Hypereosinophilic Syndromes

### Myeloproliferative Variants (M-HES)

- Myoproliferative HES, etiology unknown
    - Features of myeloproliferative disease without proof of clonality
    - FIP1L1-PDGFRA fusion negative
    - Dysplastic eosinophils on peripheral smear
    - Serum vitamin B12 >1000 pg/ml
    - Serum tryptase >12
    - Anemia and/or thrombocytopenia
    - Hepatosplenomegaly
    - Bone marrow cellularity >80%
    - Spindle shaped mast cells
    - Myelofibrosis
    - PDGFRA associated HES
    - Deletion on 4q12 leading to FIP1L1-PDGFRA fusion
- Chronic eosinophilic leukemia (CEL) HES
    - CEL with cytogenetic abnormalities and/or blasts on peripheral smear
- Other gene mutations
    - PDGFRA or PDGFRB rearrangements
    - PDGFRB and FGFR1 rearrangements
    - JAK2 point mutation and translocation

## T Lymphocytic Variant (L-HES)

- Usually a benign lymphoproliferative disorder, but may progress to T cell lymphoma
    - Polyclonal hypergammaglobulinemia
    - Prominent skin findings (including plaques, erythroderma, urticaria)
    - Aberrant IL-5 producing T cells
    - Increased serum TARC levels

## Familial HES

- Asymptomatic eosinophilia from birth, autosomal dominant
    - Progression may occur
    - Mapped to chromosome 5q 31-33

## Undefined HES

- Benign
    - Asymptomatic with no evidence of organ involvement
- Complex
    - Organ dysfunction, but does not meet criteria for myeloproliferative or lymphocytic variants
- Episodic (Gleich syndrome)
    - Cyclical angioedema, urticarial, fever, weight gain, oliguria, and eosinophilia
    - Increased serum IgM
    - Increased serum IL-5

## Overlap HES (Organ-Restricted HES)

- Eosinophilia associated with eosinophilic infiltration and associated signs/symptoms in a single organ
    - Eosinophil-associated gastrointestinal disease
    - Eosinophilic pneumonia
    - Eosinophilia myalgia syndrome
    - Other organ restricted eosinophilic disorders

## Associated HES

- Marked eosinophilia in the setting of an underlying disorder associated with eosinophilia:
    - Churg-Strauss syndrome
    - Systemic mastocytosis
    - Inflammatory bowel disease
    - Sarcoidosis
    - HIV
    - Other disorders

*FGFR1,* Fibroblast growth factor receptor 1; *FIP1L1,* Fip1-like1; *HES,* hypereosinophilic syndromes; *IL-5,* interleukin-5; *JAK2,* Janus kinase 2; *L-HES,* lymphocytic variant HES; *PDGFRA,* platelet-derived growth factor receptor alpha; *PDGFRB,* platelet-derived growth factor receptor beta; *TARC*, thymus and activation-regulated chemokine.

Adapted from Simon HU, Rothenberg ME, Bochner BS, Weller PF, Wardlaw AJ, Wechsler ME, Rosenwasser LJ, Roufosse F, Gleich GJ, Klion AD. Refining the definition of hypereosinophilic syndrome. *J Allergy Clin Immunol*. 2010;126(1):45-49.

# Pathology/Pathogenesis

There appear to be two mechanisms that account for the hypereosinophilia seen in HES: (1) clonal eosinophilic proliferation as a result of a primary molecular defect(s) involving hematopoietic stem cells or defects in signal transduction from the receptors that mediate bone marrow eosinophil differentiation, and (2) reactive processes, which often involve overproduction of eosinophil activation cytokines, such as IL-5.[259]

# Clinical Features

## Symptoms and Physical Findings

Overall HES is more common in males, mainly due to the fact that the majority of patients with the FIP1L1-PDGFRA myeloproliferative variant are males. In the SEER database, incidence was noted to increase with age with a peak noted between 65 and 74 years.[259] HES is uncommon but has been reported in the pediatric age group.

The clinical presentation of HES can be variable and is influenced by the underlying pathophysiology. The onset of symptoms of HES is often insidious. Common presenting symptoms include fatigue, cough, dyspnea, myalgia, rash, and retinal lesions. HES may affect and damage many organs, including cardiac, cutaneous, neurologic, pulmonary, splenic, hepatic, ocular, and gastrointestinal. Cardiac involvement is the major cause of mortality in patients with HES. Eosinophilic granules and mediators are deposited on the endocardium, resulting in myocardial degeneration and fibrosis.[260] Cardiac disease is characterized by eosinophilic endocardial myelofibrosis, cardiomyopathy, valvular disease, or mural thrombus formation. Serum tryptase levels are often elevated and splenomegaly present.

Pulmonary disease affects up to 49% of patients with HES, and typical symptoms are a chronic nonproductive cough. Asthma is not usually present. Pulmonary infiltrates may develop and may be focal or diffuse. Pulmonary fibrosis may develop. CSS may also occur as an associated variant of HES.

The myeloproliferative variant or “classic” HES presents with features of myeloproliferative disease (i.e., hepatosplenomegaly, cytopenias, circulating myeloid precursors, as well as increased bone marrow cellularity).[261] Elevated serum vitamin B12 or tryptase levels may be seen. There is a strong adult male preponderance, though children can also be affected. Eosinophilic endomyocardial disease and mucosal ulcers are common. Eosinophilic granules and mediators are deposited on the endocardium, resulting in myocardial degeneration and fibrosis.[262–265] This form of HES is thought to arise from a mutation in the hematopoietic stem cell that results in clonal expansion, predominantly of eosinophils. The majority of these patients have a cryptic interstitial deletion on chromosome 4q12 that results in the formation of a fusion protein FIP1L1-PDGFRA that brings together the FIP1L1 and the gene for the cytoplasmic domains of the PDGFR$\alpha$ receptor. This gene fusion results in the formation of a constitutively active tyrosine kinase that is responsible for clonal expansion of eosinophils.[266–268] Other cytogenetic abnormalities that involve PDGFRB and fibroblast growth factor receptor have been reported in patients presenting with the myeloproliferative form of HES. This category also includes HES with features of myeloproliferative disease without proof of clonality as well as chronic eosinophilic leukemia, as defined in the WHO classification.[258]

The lymphoproliferative subtype of HES is characterized by polyclonal expansion of eosinophils, usually in response to chemokines like IL-5 produced by dysregulated T-cells. These cells have a characteristic immunophenotype (CD4+CD3− or CD3+CD4−CD8−) and may show monoclonal or polyclonal expansion. Cutaneous manifestations are common in this group of patients. Some may progress to an overt T-cell lymphoma. The undefined subtype comprises asymptomatic eosinophilia, necrotizing eosinophilic vasculitis, episodic angioedema with eosinophilia, and other symptomatic forms of eosinophilia that do not have features of the myeloproliferative or lymphocytic forms.[254,255] It is possible that patients with these forms of HES, as well as those with the overlapping or associated HES, have dysregulated IL-5 producing T-lymphocytes as well.

### Laboratory Findings

The evaluation of patients with hypereosinophilia should begin with a meticulous search for triggering factors—drug history, travel history and habitat, history of allergies, and exclusion of underlying malignancy or collagen vascular disease. Careful assessment of organ function to evaluate eosinophil mediated organ damage is critical.[259] In the absence of underlying disease or if features of myeloproliferative disease are present, patients with HES should be referred to hematology/oncology for complete evaluation to exclude malignancies, which includes bone marrow examination, radiological imaging to exclude lymphoma, as well as exclusion of a cytogenetic abnormality by TCR gene rearrangement and RT-PCR or FISH for FIP1L1-PDGFRA. Plasma cytokine levels, especially IL-5, should be measured as should serum tryptase, though these may be elevated in both the myeloproliferative and lymphocytic forms of HES.[269]

## Management and Treatment

Control of the eosinophilia is important to prevent organ damage from deposition of eosinophilic mediators. Corticosteroids have been the mainstay of treatment and remain the first-line treatment for FIP1L1-PDGFRA negative HES. Imatinib mesylate (Gleevec 100–400 mg/day) is a tyrosine kinase inhibitor that targets the fusion protein FIP1L1-PDGFRA[266–268] and now constitutes the treatment of choice for the FIP1L1-PDGFRA positive myeloproliferative variant of HES. Dramatic clinical responses to imatinib are described in FIP1L1-PDGFRA-positive HES, with eosinophilia resolving within a 1 week period and reversal of organ dysfunction as early as 1 month. Other myeloproliferative variants that are negative for the FIP1L1-PDGFRA fusion protein may also respond to imatinib.[268] Other drugs, including azathioprine, cyclosporine A, and hydroxyurea, have been used in conjunction with corticosteroids or as steroid sparing agents, particularly for the lymphocytic variant of HES.[268] These patients need careful monitoring for development of a lymphoid malignancy. Immunomodulatory therapy with IFN-$\alpha$ and monoclonal antibody to IL-5 (mepolizumab) has also been described. In two recent reports, patients with HES were treated with three doses of antibody to IL-5.[269,270] Blood eosinophils declined by 10-fold and were sustained for 12 weeks after the last dose of antibody to IL-5. The anti-CD52 monoclonal antibody alemtuzumab has been used to successfully treat patients with HES, with complete hematologic responses seen in up to 80% of patients.[271–273] Allogeneic stem cell transplant has been used for patients with aggressive disease, with disease-free survival ranging from 8 months to 5 years.[273,274]

## Prognosis

The prognosis of HES or HE depends on the underlying pathophysiology as well as the extent of organ damage. With greater understanding of the cellular and molecular basis of eosinophilia, the treatment of hypereosinophilic disorders is no longer limited to corticosteroids alone. The identification of clonal cytogenetic abnormalities identifies a subset of patients who respond dramatically to imatinib.[266–268] Elucidation of the drivers of eosinophil proliferation may help identify patients who respond to other targeted therapies, including monoclonal antibodies. The overall aim of treatment remains to limit end-organ damage from persistent eosinophilia.

# Respiratory Disorders in Human Immunodeficiency Virus–Infected Children and Adolescents

*Heather J. Zar MBBCh, FCPaeds, FRCP (Edinburgh), PhD, Diane Gray MBChB, FRACP, PhD*

Respiratory disease is the most common complication occurring in human immunodeficiency virus (HIV)-infected children. Prior to widespread use of antiretroviral therapy (ART), acute respiratory infection was a major cause of mortality and morbidity in HIV-infected children with chronic lung disease, a common sequelae.[1] Revised World Health Organization (WHO) guidelines now recommend ART initiation early in all children and adolescents, with a particular focus on infants.[2] The use of ART early after birth or as soon as a child is diagnosed with HIV, improved diagnostics for infant HIV and better preventative and management strategies have reduced HIV-associated mortality substantially. Furthermore, with improved ART formulations for children and strengthened management strategies, pediatric HIV has evolved to become a chronic disease with long-term survival of children through adolescence and adulthood. Nevertheless, respiratory illness remains the commonest cause of morbidity in HIV-infected children and adolescents on ART.

The epidemiology of pediatric HIV has changed as access to mother to child preventative strategies has strengthened and with the increasing availability of ART. Pediatric HIV infection is predominantly a disease of sub-Saharan Africa, with most HIV-infected children currently residing in this geographical area. In 2015, there were approximately 1.8 million children under 15 years old living with HIV, of whom 89% lived in sub-Saharan Africa, and there were 150,000 new infections and 110,000 deaths among HIV-infected children.[3] Since 2000, there has been a 60% decline in new pediatric HIV infections and a 42% decline in HIV-related deaths, but scale-up of ART has been inadequate with only a third of HIV-infected children who need treatment receiving ART.[4] Many children are still diagnosed with HIV late and have limited access to therapy; among these children, acute severe respiratory infection and chronic respiratory disease are common.[5,6] Furthermore, as pediatric HIV infection has become a chronic disease, increased numbers of HIV-infected children are reaching adolescence and adulthood. Adolescent HIV has become a global health priority, with a trebling in HIV related adolescent deaths since 2000, making HIV/acquired immunodeficiency disease (AIDS) the leading cause of death among adolescents in sub-Saharan Africa and the second leading cause of death among adolescents globally. Forty percent of new adolescent infections occurred outside sub-Saharan Africa, highlighting the imperative of HIV preventive efforts.[3] Chronic lung disease in perinatally infected HIV-infected adolescents is also common.[7,8]

In areas with strong prevention of mother-to-child HIV transmission programs, the prevalence of pediatric HIV infection has fallen dramatically; however, HIV-exposed children (who are HIV-negative but born to an HIV-infected mother) have an increased risk of respiratory morbidity compared to unexposed children.[9–12] As prevention and treatment programs in underresourced areas are strengthened and become more available, this group of children will be increasingly important in considering the burden of respiratory disease.

## Spectrum of Respiratory Disease

The spectrum of respiratory disorders ranges from acute infection to chronic disease (Box 66.1). A pulmonary problem may frequently be the presenting manifestation of HIV infection. Among children known to be HIV-infected, including those on ART, acute pulmonary infections are among the most common causes of poor health. Bacterial pneumonia and tuberculosis (TB) are the most common respiratory infections in both ART-naïve and ART-exposed children.

**Box 66.1**

### Pulmonary Complications of Human Immunodeficiency Virus Infection

#### Acute Lung Disease

- Infections
  - Viral
  - Bacterial
  - Mycobacterial
  - Fungal
  - Mixed infections

#### Chronic Lung Disease

- Chronic infection
- Interstitial pneumonia
  - Lymphoid interstitial pneumonia
  - Nonspecific interstitial pneumonitis

    - Desquamative interstitial pneumonia
- Malignancies
    - Kaposi sarcoma
    - Lymphoma
- Immune reconstitution inflammatory syndrome
- Bronchiectasis
- Bronchiolitis obliterans
- Aspiration pneumonitis
- Airway hyperresponsiveness/asthma
- Pulmonary hypertension

# Acute Respiratory Disease

## Lower Respiratory Tract Infection or Pneumonia

HIV-infected children have a much higher risk of developing pneumonia and of severe disease or mortality compared to HIV-uninfected children, with a sixfold higher rate of hospitalization or death.[13] The most common respiratory infections in ART-naïve children are episodes of bacterial pneumonia (which comprise approximately 25% of all opportunistic infections [OIs] in such children) or pulmonary tuberculosis (PTB) comprising around 10% of all OIs.[14] Extrapulmonary TB (EPTB) also occurs commonly in around 7% of OIs; pneumocystis pneumonia (PCP) occurs in 4% of OIs. In children on ART, OIs due to bacterial pneumonia, PTB, EPTB, or PCP were reported to comprise 22%, 4%, 1%, and 2.5%, respectively, of all OIs. The effect of ART in reducing these infections is most marked for EPTB (85% reduction), PTB (60% reduction), and PCP (30% reduction); however, for bacterial pneumonia, the impact is more modest with a 15% reduction.[14]

Furthermore, HIV-exposed infants are at higher risk of developing pneumonia or other respiratory diseases compared to HIV-unexposed children.[10–12,15] Exposure in utero to HIV viral proteins, a maternal proinflammatory and/or immune compromised state, exposure to ART and other drugs both in utero and in breast milk, reduced levels of protective maternal antibodies or increased exposure to infections in a HIV-household may contribute to this susceptibility.[12,16,17] In addition, HIV-exposed or infected children living in sub-Saharan Africa often have exposure to several other risk factors for pneumonia or severe disease such as poor birth outcomes (preterm birth or low birth weight), suboptimal or no breastfeeding, compromised growth and nutrition, maternal ill health or death, and poverty.[12]

The highest incidence of pneumonia occurs in infancy, especially in the first 6 months of life. HIV-infected children are more susceptible to developing pneumonia from a broader spectrum of pathogens, including opportunistic pathogens such as *Pneumocystis jirovecii, Mycobacterium tuberculosis,* or cytomegalovirus (CMV). Coinfections with bacterial, viral, mycobacterial, or fungal pathogens may be common, with increasing numbers of pathogens associated with more severe disease.[18] However, attributing etiology may be especially difficult, as obtaining a representative specimen from the lower respiratory tract can be challenging, and sensitive diagnostic assays may not distinguish colonizing from pathogenic organisms.[19]

## Bacterial Pneumonia

Bacterial pneumonia is the most common lower respiratory tract infection in both ART-naïve and ART-exposed children.[14] Bacterial pneumonia occurs more frequently and with greater severity in HIV-infected than uninfected children because of defects in both cellular and humoral immunity.[18] HIV-exposed or infected children also have a higher risk of developing severe pneumonia, with a poorer outcome than HIV-negative children.

The use of newer conjugate vaccines including pneumococcal conjugate vaccine (PCV) and *Haemophilus influenzae* b (Hib) vaccine has reduced the burden of bacterial pneumonia and bacteremia in HIV-infected and uninfected children. Prior to PCV, *Streptococcus pneumoniae* was the most commonly reported bacterial pathogen causing pneumonia and bacteremic illness, with an incidence of pneumococcal bacteremia or invasive disease that was 9 to 43-fold greater in HIV-infected compared to uninfected children.[20] *Staphylococcus aureus* has also been reported to have a higher incidence in HIV-infected children.[21] Other bacterial pathogens include *Haemophilus influenzae, Escherichia coli,* and *Salmonella* spp. A postmortem study of Zambian children found that bacterial pneumonia was the predominant cause of death in both HIV-infected and uninfected children; TB occurring in 8% had not been diagnosed in 90% prior to death.[22] Pneumonia associated with *Bordetella pertussis* has increasingly been reported in young infants; a study of infants hospitalized with pneumonia or apnea reported that HIV-infected infants had the highest incidence followed by HIV-exposed infants.[23] The risk of pertussis also decreased with each extra dose of vaccine received, with the lowest risk after completion of a primary three-dose schedule.

The high incidence of antimicrobial-resistant bacteria that colonize the nasopharynx may potentially cause pneumonia in HIV-infected children.[24]

The clinical symptoms or signs and radiological features of bacterial pneumonia are similar to those in HIV-negative children. Bacteremic illness occurs in a minority of cases, and induced sputum induction (obtained through nebulization of hypertonic saline) may be useful for diagnosis of *B. pertussis* by polymerase chain reaction (PCR), with a higher yield than nasopharyngeal samples.[10,23]

Treatment of bacterial pneumonia should be with broad-spectrum antimicrobials and supportive therapy including oxygen as required, which is similar to immunocompetent patients.[25] The use of case management guidelines for treatment of pneumonia, as contained in the WHO Integrated Management of Childhood Illness (IMCI) program, are effective for reducing pneumonia and all-cause mortality,[26] but these require adaptation for use in high HIV prevalence areas.[18,27] Modified IMCI guidelines for use in high HIV prevalence settings include ampicillin and gentamicin or ceftriaxone as first-line therapy for pneumonia, while cotrimoxazole (CTX) should be added for infants (Table 66.1).[25]

**Table 66.1**

**Antibiotic Treatment of Pneumonia in Human Immunodeficiency Virus Infected Children**

| Infection | First Line Therapy | Dose | Regimen |
|---|---|---|---|

| | | | |
|---|---|---|---|
| Bacterial pneumonia | If severe pneumonia, broad spectrum antibiotic β-lactam plus aminoglycoside **or** second or third generation cephalosporin | Amoxicillin 45 mg/kg per dose<br>Ampicillin 50 mg/kg per dose<br>Gentamicin 7.5 mg/kg<br>Ceftriaxone 50–75 mg/kg per dose<br>Cefotaxime 50 mg/kg per dose | Orally, twice daily for 5 days<br>IV, 4 times daily<br>IV, daily, for 5 days<br>IV or IM daily<br>IV, 3 times daily |
| | If *S. aureus* suspected: Cloxacillin<br>If methicillin resistant *S. aureus* suspected: vancomycin | Cloxacillin 25 mg/kg per dose or 50 mg/kg per dose<br>Vancomycin 10–15 mg/kg | Orally, 4 times a day<br>IV, 4 times a day<br>IV, 3 times daily |
| Cytomegalovirus | Ganciclovir for CMV | *Induction*<br>5 mg/kg per dose | Daily, 14–21 days |

Immunization with PCV and Hib provides protection against specific bacterial infections, but long-term immune responses may be impaired with a shorter duration of seroprotection in HIV-infected compared to uninfected individuals even with use of ART.[28–30] Generally, children on ART have lower levels of immunity to vaccines given before treatment, but most respond to revaccination.[30] Although the efficacy of PCV for prevention of invasive pneumococcal disease and pneumonia is lower in HIV-infected children compared to uninfected children, the overall burden of disease prevented is much greater among HIV-infected children because of the higher burden of pneumococcal disease.[28] Thus, the overall vaccine-attributable reduction in invasive pneumococcal disease was almost 60 times higher in HIV-infected children compared to uninfected children, while the reduction in pneumonia was 15-fold greater following PCV.[31] As most pneumococcal serotypes associated with antimicrobial resistance are included in PCV, vaccination has also been associated with a reduction in infections with antimicrobial-resistant pneumococci.[28] Pneumococcal vaccination is indicated for HIV-infected children according to the regular immunization schedule.[32] The long-term efficacy of PCV wanes in HIV-infected children who are not on ART; vaccine efficacy against invasive disease declined from 65% by 2 years post vaccination to 39% by 6 years in HIV-infected children in the absence of a booster dose, while efficacy was maintained in HIV-uninfected individuals. Reimmunization after 3–5 years is therefore recommended in children not on ART.[33] Quantitative and qualitative antibody responses to PCV in HIV-infected infants are enhanced when vaccination occurs on ART and if vaccination occurs when the CD4+ cell percentage is ≥25% and if the nadir CD4+ is greater than 15%.[34]

The Hib conjugate vaccine also has reduced efficacy in HIV-infected ART-naïve children compared to uninfected children.[29,35] However, similar to PCV, a substantial proportion of immunized children will be protected from Hib-related pneumonia or invasive disease because of the increased disease burden in HIV-infected children, with an almost sixfold higher risk of invasive disease.[29] HIV-infected children should therefore be immunized with Hib vaccine according to the routine childhood immunization schedule.

Continuing CTX prophylaxis in older children after at least 2 years on ART has been shown to reduce hospitalization in African children due to pneumonia, malaria, sepsis, or meningitis.[36] This occurred in children of all ages irrespective of CD4 count. Long-term CTX prophylaxis is therefore recommended as a strategy to prevent infections in settings with a high burden of infectious diseases. Strategies for the prevention of lower respiratory tract infections in HIV infected children are summarized in Box 66.2.

**Box 66.2**

### Strategies for Prevention of Pneumonia in Human Immunodeficiency Virus Infected Children

Early antiretroviral therapy
Immunization
    Pneumococcal conjugate vaccine[a]
    *Haemophilus influenzae* type b vaccine
    Pertussis
    Measles
    Influenza
Antibiotic prophylaxis
    Cotrimoxazole prophylaxis
    Isoniazid prophylaxis
Optimizing nutrition
Decreasing indoor air pollution

---

[a] Consider reimmunization after 3–5 years in children not on antiretroviral therapy.

## Tuberculosis

The incidence of TB has increased in parallel with the HIV epidemic. Epidemiologically, both TB and HIV have the highest prevalence in sub-Saharan Africa; HIV predisposes to TB disease, while infection with *M. tuberculosis* worsens immunosuppression and hastens progression to AIDS. Children living in a household with an HIV-infected adult are more likely to be exposed to TB.[37,38] Moreover, HIV-infected children progress more rapidly to disease or disseminated illness following infection. Mortality from TB is also higher in HIV-infected children than uninfected children, with coinfected children having a poorer clinical and radiologic response to treatment.[39,40] The use of ART has reduced the incidence of EPTB and PTB by around 85% and 60%, respectively.[14] However, HIV-infected children on ART still have a higher risk of TB disease than immunocompetent children.[41] Because of the association of TB and HIV, children presenting with TB disease should be tested for HIV infection. Conversely, screening for TB should be done in HIV-infected children with respiratory symptoms or weight loss.

The clinical manifestations of TB in HIV-infected children are similar to those in uninfected children. However, disease in HIV-infected children may be more severe, and extrapulmonary disease (e.g., miliary disease or TB meningitis) may occur more commonly.[42] The clinical presentation of PTB includes chronic cough and failure to thrive, but may also frequently present as acute pneumonia.[43] The use of clinical scoring systems for diagnosis of PTB performs poorly with wide interobserver variability especially in HIV-infected children.[44] Chest radiographic changes may be nonspecific, and interpretation, particularly of hilar lymphadenopathy, is subject to wide interobserver variation; a cavity, pleural effusion, expansile pneumonia with airway compression or a miliary pattern may suggest PTB in the appropriate epidemiological context (Fig. 66.1).[45]

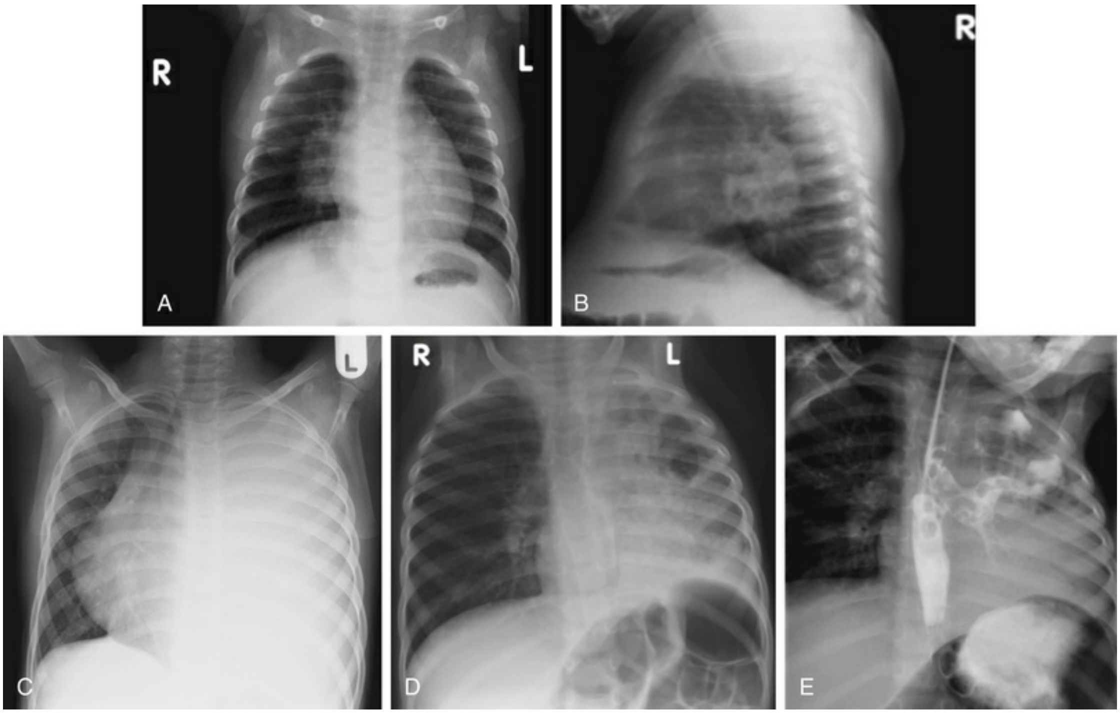

**FIG. 66.1** Chest radiographs of tuberculosis (TB) in human immunodeficiency virus (HIV) infected children. (A) Chest radiograph of an HIV-infected child with culture confirmed TB. Note the right parahilar nodal mass, marked right and left bronchial compression by lymphadenopathy and, on the lateral view (B), the classical parahilar nodal mass. (C) Chest radiograph of an HIV-infected child with large left sided TB pleural effusion with mediastinal shift towards the right. (D–E) Bronchogenic TB in an HIV infected child with complication of a bronchoesophageal fistula secondary to lymph node erosion. (D) Chest radiographic showing parahilar adenopathy, extensive left sided bronchogenic TB with dense left lower lobe consolidation. (E) Contrast swallow outlining the bronchoesophageal fistula.

Annual screening of HIV-infected children for *M. tuberculosis* infection is recommended using the tuberculin skin test in children who have a negative test. A reaction greater than 5 mm is considered positive. However, the sensitivity of skin testing is reduced in HIV-infected children compared to uninfected children because of anergy; a blood interferon (IFN) gamma assay has a higher sensitivity and specificity for diagnosis of *M. tuberculosis* infection in HIV-infected children.[46] However, discordance between skin test and IFN gamma results occurs, and neither can distinguish infection from disease.[47]

If PTB is suspected, respiratory specimens for microbiologic confirmation, using molecular methods and liquid culture, should be obtained. The availability of rapid PCR-based molecular methods (Xpert *mycobacterium tuberculosis* [MTB]/Rifampicin [RIF] [Xpert]) enables rapid diagnosis of TB and detection of Rifampicin resistance. Bacteriologic confirmation of PTB in infants and children is underutilized, especially in hospitalized children. Expectorated sputum is the recommended initial specimen for testing to diagnose TB in the older child who can produce sputum. In children who cannot expectorate, sputum induction using 3%–5% hypertonic saline is effective and safe, even in infants, with a yield that is higher than gastric lavage for culture confirmation.[48] In addition, use of induced sputum has been shown to be useful and effective for microbiologic confirmation of TB in young children in community-based studies.[49] At least two specimens should be obtained, as a second specimen increases the yield from Xpert by 25%–30% and from culture by approximately 20%.[48] Xpert has a reported sensitivity of approximately 66% in children, with a specificity of approximately 99%.[50] The WHO has endorsed Xpert as the first-line investigation to replace smear microscopy as the initial diagnostic test for suspected HIV-associated TB or multidrug-resistant (MDR) PTB in children and adults (http://www.who.int) on respiratory specimens. The potential to rapidly make a microbiologic diagnosis at the point of care including rapid identification of Rifampicin resistance makes use of sputum induction in children even more important. The organism can also be identified from bronchoalveolar lavage (BAL), from fine needle aspirate of an enlarged node, from fluid from a discharging ear, or from lung tissue obtained by biopsy.

Empiric therapy for PTB in HIV-infected children should include four drugs (isoniazid, rifampicin, pyrazinamide, ethambutol) daily for a 2-month induction period followed by 4 months of daily isoniazid and rifampin.[51] Modification of therapy should be made based on susceptibility testing. The minimum duration of treatment is 6 months, with some recommending up to 9 months, especially in severely immunocompromised children who are at increased risk of relapse.[32,52] Adjunctive corticosteroids are recommended for endobronchial disease with bronchial obstruction at 1–2 mg/kg per day tapered over 6–8 weeks.

For children on ART, the antiretroviral regimen should provide optimal TB and HIV therapy and minimize potential toxicity and drug interactions.[51] Rifampicin is compatible with all nucleoside reverse transcriptase inhibitors (NRTIs); therefore two NRTIs should be used as the backbone of ART. However, rifampicin induces hepatic Cytochrome P450 enzymes and reduces the levels of some antiretroviral agents, particularly the protease inhibitors (PIs) and, to a lesser extent, the nonnucleoside reverse transcriptase inhibitors (NNRTIs). Therefore rifampicin should preferably be used with an NRTI-based regimen rather than with a PI-based regimen. For children older than 3 years, two NRTIs with the NNRTI efavirenz are recommended. For children younger than 3 years, two NRTIs with the NNRTI nevirapine may be used. Alternatively, if a PI is used, a boosted regimen (additional ritonavir boosting with lopinavir/ritonavir) is recommended.[53] Adding ritonavir to lopinavir/ritonavir sufficient to achieve milligram-for-milligram parity may achieve adequate lopinavir levels, but doubling the dose of lopinavir/ritonavir is ineffective.[53,54] Rifabutin is a less potent inducer of the P450 enzymes and is therefore a suitable alternative to rifampicin, but there is limited pediatric experience with its use. For a child who is not yet on ART, the decision when to initiate ART depends on the child's age and clinical and/or immunologic condition. ART should be started in all children less than 5 years within 8 weeks. In children with CD4 less than 750 cells/mm$^3$ or less than 25% or with WHO clinical stage 3 or 4 disease, ART must be started within 2 weeks of starting TB treatment. In children older than 5 years, ART should be started for all children and as a priority if CD4 is less than 350 cells/mm$^3$ or there is clinical stage 3 or 4 disease.[2] ART may be deferred for 2 weeks in children with mild immunosuppression, which reduces the risk of immune reconstitution inflammatory syndrome (IRIS).

For MDR TB, a minimum of three drugs to which the organism is susceptible should be given. Streptomycin, cycloserine, or ethionamide may be substituted for ethambutol (see Chapter 29); regimens should be individualized based on the resistance pattern of the organism from the child or source case. Daily therapy should be given for at least 12 months, and second-line drugs include clarithromycin, azithromycin, and ciprofloxacin. Directly observed therapy should be used when possible to ensure adherence.[55]

Primary isoniazid (INH) prophylaxis for HIV-infected children living in a high TB prevalence area has been reported to reduce mortality by approximately 50% and to reduce TB incidence by approximately 70% in the setting of limited access to ART.[56] However, in a study of infants who were initiated on ART early and who were carefully followed with initiation of prophylaxis on exposure to a TB contact, no effect of primary INH prophylaxis was shown.[41] The impact in older children established on ART is less clear, but further study suggests that INH prophylaxis may reduce TB incidence in such children, even when they are taking ART.[57] The WHO revised policy for primary INH prophylaxis in HIV-infected children advises use in high TB prevalence areas in children who are older than 1 year. The optimal duration of prophylaxis is unknown, but extended use appears safe and effective; WHO policy now recommends prophylaxis for up to 3 years in high TB prevalence areas.[58,59]

Secondary prophylaxis should be given to all HIV-infected children (irrespective of the tuberculin skin test or IFN gamma test) for 6–9 months following exposure to a close contact with TB once TB disease has been excluded in the child. If the source case has an INH-resistant strain, rifampicin should be used. If the strain is MDR, then two drugs to which the strain is susceptible should be used.[32,44]

Bacillus Calmette–Guérin (BCG) vaccine is contraindicated in HIV-infected children because of the high risk of developing disseminated disease and of death.[60] However, BCG is given at birth as part of the routine immunization program in many high incidence TB areas; thus HIV-infected children may receive immunization before they are diagnosed with HIV. The key to TB control is adequate public health measures with good contact and source tracing and adherence to medication regimens. In addition, integrating TB and HIV services and the use of ART are essential to reducing the TB caseload.

## Nontuberculosis Mycobacteria

*Nontuberculosis mycobacteria (NTM), of which Mycobacterium avium* complex (MAC) is the most common, are ubiquitous in the environment. MAC was a common OI in HIV-infected children in the pre-ART era, but ART has substantially reduced the risk of disease.[14] Disease may manifest as a localized infection or disseminated disease, and localized disease includes cervical adenitis, pneumonitis, hepatic dysfunction, or abscess. Respiratory symptoms are not a prominent feature, but tachypnea and chronic lung infiltrates may be present. The importance of the organism in the bronchial secretions is unclear, but it most likely reflects disseminated disease rather than localized pulmonary infection. Symptoms caused by disseminated MAC infection are nonspecific, including fever, weight loss, night sweats, cachexia, and diarrhea.[61]

Patients with disseminated MAC have a poor prognosis[62]; for example, of children who died in one report, 42% had disseminated MAC, and it was the underlying cause of death in 24%.[63]

Recommendations for prophylaxis and therapy for disseminated MAC in patients with HIV[32] are to use a minimum of two agents to minimize the development of resistant strains. Treatment should include either azithromycin or clarithromycin with ethambutol as a second drug. For disseminated disease, a third or fourth drug (clofazimine, rifabutin, rifampin, ciprofloxacin, or amikacin) may be added. Improved immunologic status is essential to controlling MAC infection; ART should be initiated in children who are not on therapy. The optimal timing of ART is unclear; at least 2 weeks of antimycobacterial therapy is recommended prior to starting ART to minimize the potential for IRIS.[32,44]

Primary prophylaxis with clarithromycin or azithromycin is recommended for severely immunosuppressed children with CD4+ cell counts less than 50/μL if older than 6 years of age, less than 75/μL if 2–6 years of age, less than 500/μL if 1–2 years of age, and less than 750/μL if younger than 1 year of age.[32] Prophylaxis may be discontinued in children older than 2 years of age who are stable on ART for 6 months or longer and who have sustained immune recovery.

## Viral Infection

Viruses are increasingly reported as a cause of pneumonia in the context of high immunization coverage with PCV and Hib.[64,65] Among viral pathogens, respiratory syncytial virus (RSV) predominates; other common viruses include influenza, parainfluenza, human metapneumovirus, and adenovirus.[10,66] Multiple infections may occur including viral-viral, viral-bacterial, viral-mycobacterial, or viral-fungal pathogens. HIV-infected children with viral lower respiratory tract infection have more severe disease compared to uninfected children and are likely to develop pneumonia rather than bronchiolitis.[21,64] Prolonged RSV antigen shedding for up to 90 days may occur in HIV–infected children.

In HIV-infected children, measles virus and varicella-zoster virus may cause severe pulmonary disease (Fig. 66.2).[67] Acyclovir or valacyclovir are the agents of choice for varicella infection. HIV-infected children with influenza should be treated with a neuraminidase inhibitor such as oseltamivir for 5 days (ideally within 72 hours) of symptom onset, as this may reduce severity of disease and complications. High-dose vitamin A should be given to children with measles.

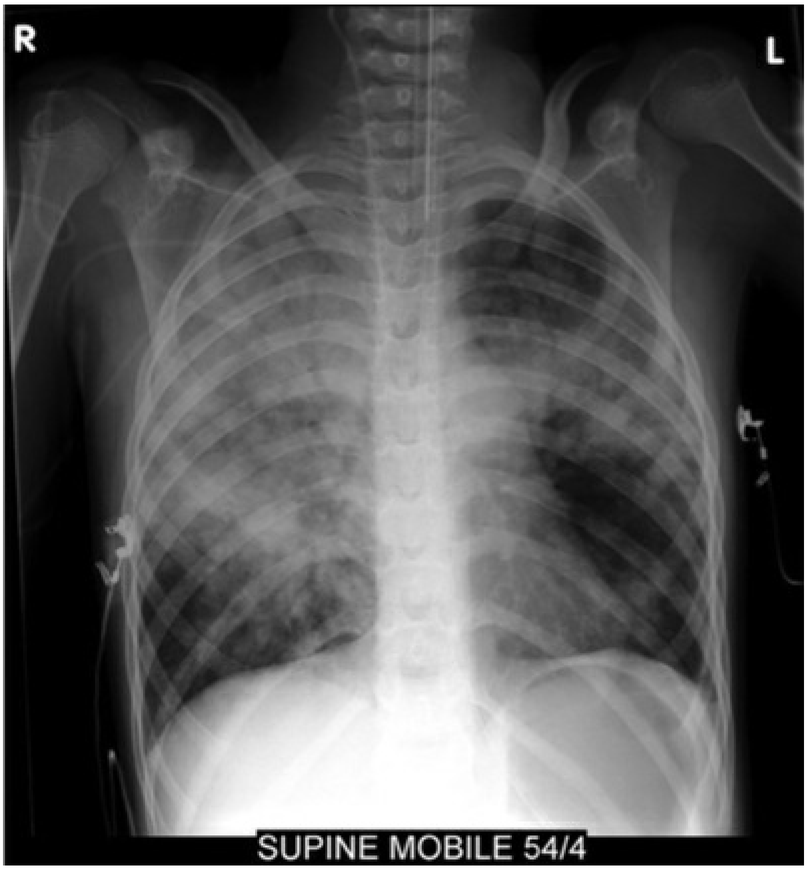

**FIG. 66.2** Chest radiograph of varicella zoster pneumonia in a human immunodeficiency virus-infected child showing bilateral diffuse infiltrates and consolidation.

CMV has been reported to commonly cause pneumonia in HIV-infected children who are ART-naïve. In postmortem studies, CMV has been reported to be a common pathogen, since it has been found in around 9% of HIV-infected children dying from pneumonia, similar to that in HIV-uninfected children.[22] However, CMV may coexist with other pathogens such as pneumocystis, so defining the contribution of CMV to severity of disease may be difficult. Antemortem diagnosis of CMV pneumonitis is difficult, as isolation of CMV from respiratory secretions may represent infection but not disease; consequently, definitive diagnosis requires a lung biopsy. A study of HIV-infected South African infants hospitalized with severe pneumonia reported that approximately 70% of children had CMV viremia as detected by PCR, while 36% also had CMV identified in BAL fluid or induced sputum, which was more common than PCP.[68] Children with CMV-associated pneumonia had a 2.5-fold higher mortality than those without CMV pneumonia despite treatment with ganciclovir in most. However, this association was not evident when adjusting for severe immunosuppression, indicating that CMV pneumonia may be a marker of severe immunosuppression.

Histologically, alveolar macrophages, type II pneumocytes, bronchial and bronchiolar epithelial cells, and capillary endothelial cells may manifest cytomegaly and nuclear and cytoplasmic inclusions. Infection with CMV stimulates HIV replication, leading to more rapid HIV disease progression. ART has substantially reduced the incidence of CMV disease reflected in a reduction in the prevalence of CMV retinitis.[14,69–71]

Ganciclovir should be used for treatment of CMV pneumonia, switching to oral valganciclovir once clinical improvement has occurred, for a total of 6–8 weeks of therapy. To prevent recurrence, prophylactic valganciclovir should be given to children with severe immunosuppression. Initiation of ART is crucial to contain CMV infection and prevent recurrence of disease, and prophylaxis may be discontinued once sustained immune reconstitution has been achieved with ART.

Strategies to prevent other viral infections are available; for example, yearly inactivated influenza vaccine is recommended for children 6 months of age and older. However, a randomized controlled study of two doses of inactivated influenza vaccination in HIV-infected children (median age 2 years; 92% on ART) reported an efficacy of only 18%, possibly due to poor immunogenicity or mismatch between circulating strains and vaccine strains.[72] Immunization of pregnant women has an efficacy of around 50% in HIV-infected women, but a much lower efficacy in their HIV-exposed infants.[73] HIV-infected children mount antibody responses to influenza vaccination, but antibody titers are lower than in HIV-negative controls. Varicella and measles vaccines are recommended for children who are not severely immunocompromised. Passive immunization should be given to children who are exposed to measles with intramuscular immunoglobulin within 6 days of exposure. Postexposure prophylaxis with human varicella immune globulin (VariZIG) or varicella-zoster immune globulin (VZIG) should be given to unvaccinated children or those who are moderate or severely immunosuppressed within 96 hours of a close contact with chickenpox.

## Fungal Infection

### *Pneumocystis jirovecii* Pneumonia

*P. jirovecii* is a fungus that attaches to the alveolar epithelium, leading to a diffuse desquamative alveolitis, and filling of the alveoli with a foamy exudate of alveolar macrophages and cysts containing sporozoites with accompanying interstitial inflammation.

*P. jirovecii* is the most common pathogen identified in HIV-infected infants with pneumonia who are not taking prophylaxis or ART.[74,75] Postmortem studies report *P. jirovecii* to be one of the most common pathogens, occurring in around 33% of children dying from pneumonia, with a 10-fold higher incidence in HIV-infected than uninfected infants.[22,27] The incidence during the first year of life in the pre-ART era was estimated to range from 10% to 42% in antemortem studies[74,76,77] and up to 52% in postmortem studies.[78–80] The incidence is highest in the first year of life, peaking at 3–6 months of age, and use of ART and CTX prophylaxis has substantially reduced the incidence of disease.[14]

Clinical features include acute onset of cough, fever, tachypnea, and hypoxia. Normal, decreased breath sounds or crackles may be present, while hypoxia may be severe. A high plasma HIV RNA load strongly predicts PCP; CD4+ measures may be less useful, especially in young children. Approximately one-quarter of infants had CD4+ counts greater than 1500 cells/mm$^3$ at the time of PCP diagnosis.[81,82] However, a rapid rate of decline in CD4+ is associated with the development of PCP, and low CD4+ counts in older children are associated with PCP.

There is a high rate of respiratory failure and need for mechanical ventilation. Early reports indicated a mortality rate exceeding 40% with the initial episode and the majority surviving less than a year thereafter.[75,83]

Laboratory findings include a normal white blood cell count, elevated lactic dehydrogenase (LDH), and normal immunoglobulin G (IgG). LDH levels greater than 1000 IU/L are associated with PCP but are nonspecific. The most common changes on chest radiographs are hyperinflation, diffuse bilateral opacification, and reticulonodular infiltrates most prominent in the perihilar region and extending peripherally (see Fig. 66.3).[84] Air bronchograms, focal infiltrates, a normal radiograph, pneumothorax, pulmonary interstitial emphysema, or pneumatoceles have also been described.[84]

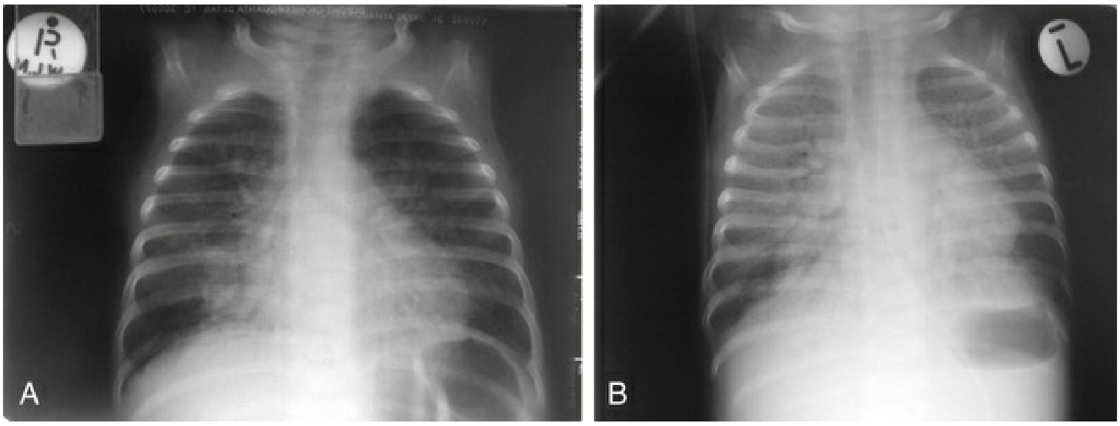

**FIG. 66.3** Chest radiograph of a 3-month-old infant presenting with *Pneumocystis jirovecii* pneumonia. (A) The initial radiograph shows a bilateral infiltrate most prominent in the perihilar region. (B) A chest radiograph taken 72 hours later shows progression of disease with opacification of both lung fields.

Microbiologic diagnosis relies on identification of the organism from bronchial washings, sputum, or lung tissue. BAL with fiberoptic bronchoscopy is a reliable method for diagnosis.[85] Sputum induction with 3% saline can be useful for diagnosis,[86,87] but the diagnostic yield is variable and dependent upon expertise for specimen collection and the diagnostic test. Nasopharyngeal aspirates have been used to identify *P. jirovecii;* the yield is lower than with induced sputum using staining methods,[75,86] but it is similar to lower respiratory secretions (BAL or induced sputum) when PCR based diagnosis is used.[88]

Methenamine silver, toluidine blue O, and fluorescein-conjugated monoclonal antibody are stains that identify the thick-walled cysts of *P. jirovecii.* Fluorescein staining is more sensitive than other staining methods. Trophozoite forms are identified with Giemsa stain or modified Wright-Giemsa stain. However, much higher sensitivity is reported for PCR-based diagnosis compared to immunofluorescence.[88,89]

High-dose intravenous CTX (trimethoprim-sulfamethoxazole [TMP-SMX]) is the treatment of choice for PCP. The conventional dose is 6–12 mg/kg per day TMP and 30–60 mg/kg per day SMX for 21 days. In addition, oral treatment can be given to complete the 21-day course when there is clinical improvement or if the disease is mild. Revised WHO management guidelines recommend empiric therapy with TMP-SMX in HIV-infected or exposed infants with pneumonia (Table 66.2).[90]

**Table 66.2**

**Recommended Cotrimoxazole Prophylaxis in Human Immunodeficiency Virus Infected Children**

| Age | Prophylaxis |
|---|---|
| Birth to 4–6 weeks | No |
| 4–6 weeks to 12 months | Yes, all |
| 1–5 years | CD4+ count < 500 cells/µL or CD4% < 15% |
| ≥5 years | CD4+ count < 200 cell/µL or CD4% < 15% |

A clinical response is usually observed in 5–7 days, although deterioration may occur in the first days of therapy; and side effects to TMP-SMX include a rash and thrombocytopenia. An alternative treatment is pentamidine administered intravenously or intramuscularly (4 mg/kg per dose once daily) if TMP-SMX is poorly tolerated or no response occurs after 1 week of treatment. The intramuscular route is painful and can cause sterile abscesses, so it should be avoided if possible. Side effects from pentamidine include pancreatitis, renal dysfunction, and both hyperglycemia and hypoglycemia. Other alternatives include atovaquone, dapsone with trimethoprim, trimetrexate glucuronate with leucovorin, and clindamycin with primaquine.[32]

A National Institutes of Health consensus panel recommended that corticosteroids be used as adjunctive therapy in hypoxic adults with PCP based on studies showing improved survival and decreased incidence of respiratory failure.[91] Moderate to severe infection has been defined for this purpose as partial pressure of oxygen in arterial blood ($PaO_2$) less than 70 mm Hg in room air or an alveolar-arterial oxygen gradient more than 35 mm Hg. Controlled clinical trials using corticosteroids in children with PCP have not been conducted, but uncontrolled data suggest that corticosteroids are beneficial[92] at a dose of 1 mg/kg per dose twice daily 1 mg/kg per dose twice daily for 5 days; 0.5 mg/kg, twice daily, day 6–10; 0.5 mg/kg, once daily, for day 11 through 21.[93]

Because of the high mortality and morbidity associated with PCP, prevention should be the primary objective. Guidelines for prophylaxis for PCP prophylaxis for children infected with HIV are shown in Table 66.2, and prophylaxis for PCP is recommended in all infants born to HIV-infected mothers beginning at 4–6 weeks of age. Prophylaxis can be stopped once HIV-infection in the infant has been excluded and infants are no longer breastfeeding. For HIV-infected children, prophylaxis should continue throughout the first year of life. Discontinuation of PCP prophylaxis should be considered for HIV-infected children when, after receiving ART for at least 6 months, the CD4+ percentage is ≥15% or the CD4+ count is ≥200 cells/μL for those older than 6 years of age and the CD4+ percentage is ≥15% or the CD4+ percentage is ≥500 cells/μL for children 1–5 years of age for more than 3 consecutive months.[94] However, an African randomized controlled trial of stopping or continuing CTX prophylaxis in older children on ART for at least 2 years demonstrated benefit in children continuing CTX prophylaxis irrespective of CD4 count, with a substantial reduction in hospitalization.[36]

CTX is the drug of choice for prophylaxis. The recommended regimen is 150 mg TMP/$m^2$ per day with 750 mg SMX/$m^2$ per day administered orally once or divided twice daily dose, three times a week on consecutive or alternate days. Alternatively, prophylaxis can be given 7 days a week. TMP-SMX prophylaxis may also be effective for reducing bacterial infections, and daily therapy is associated with a lower incidence of bacteremia than thrice-weekly therapy.[95] If TMP-SMX is not tolerated, alternative prophylactic regimens include dapsone 4 mg/kg (not to exceed 200 mg), orally, once a week; or atovaquone 30 mg/kg once daily for children 1–3 months of age and older than 24 months of age and 45 mg/kg for infants 4–24 months of age. In children older than 5 years of age who cannot take TMP-SMX, dapsone, or atovaquone, aerosolized pentamidine 300 mg administered via inhaler once monthly is recommended.

## Other Fungal Infections

Opportunistic fungal infections can cause severe pulmonary disease, but the number of reported cases is small. The most common infections are with *Candida* spp., *Cryptococcus neoformans, Histoplasma capsulatum, Coccidioides immitis, Aspergillus.* Dissemination of infection is common, and treatment is difficult. Constitutional symptoms (e.g., weight loss and fever) may reflect extrapulmonary involvement.

*Cryptococcus* usually presents as meningitis, but this can involve the lungs and cause interstitial pneumonia.[96] *Histoplasma capsulatum* most commonly affects the lungs and is likely to become disseminated in HIV-infected patients.[97,98] Standard serologic tests can be positive for both coccidioidomycosis and histoplasmosis, but false-negative results occur in the most profoundly immunocompromised patients.[99] In addition, skin testing is not useful because of problems with anergy and lack of standardization of most fungal skin test preparations. Cultures of bone marrow, cerebrospinal fluid, and lymph node or lung biopsy can be diagnostic. *Candida* spp. is often found in the oropharynx and esophagus in HIV-infected children, and tracheobronchial candidiasis or pulmonary infection is less common. Isolation of *Candida* from BAL fluid most likely represents an oropharyngeal contaminant, because pulmonary infection is rarely confirmed on lung biopsy. Tissue invasion should be demonstrated on bronchial or lung biopsy to confirm the diagnosis.

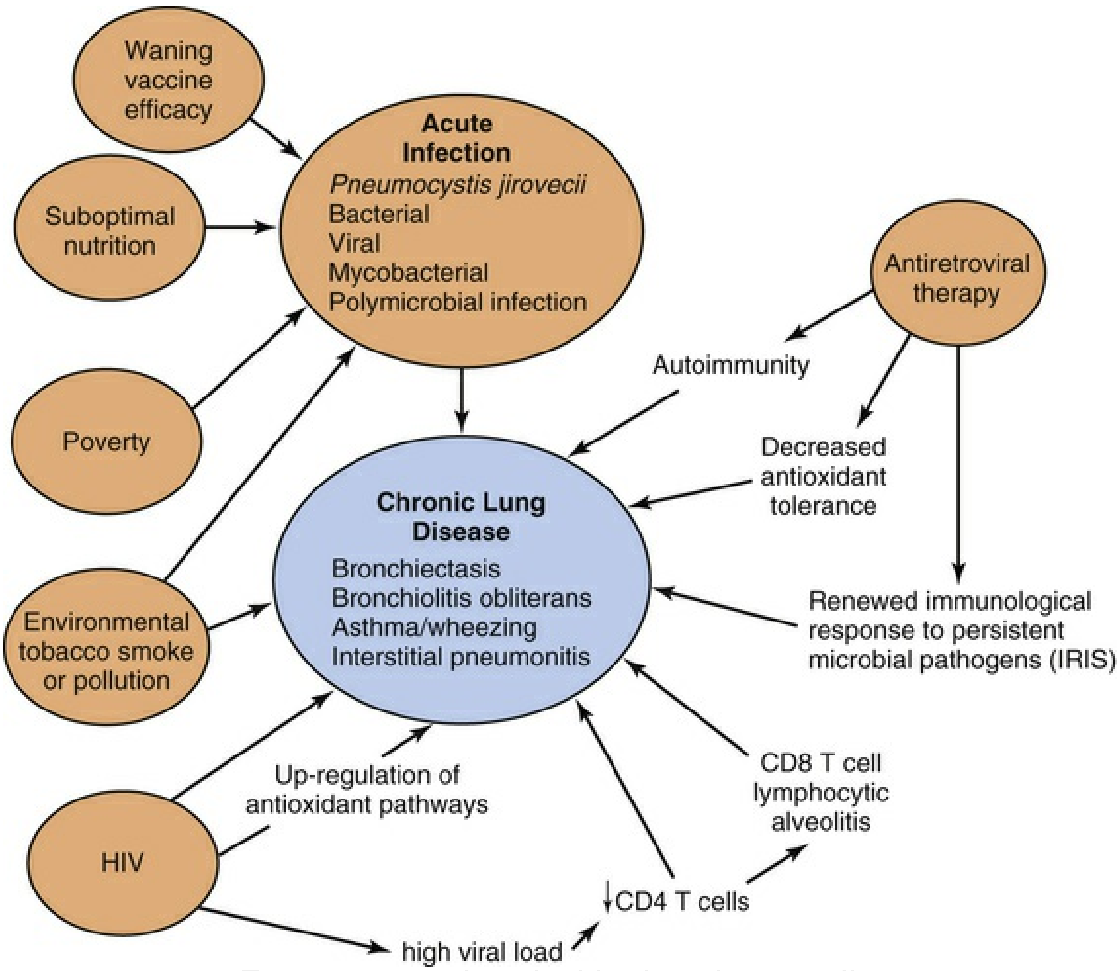
*Aspergillus* infection has been reported in HIV-infected patients, late in the course of disease, or following corticosteroid use or neutropenia.[100] Aspergilloma and invasive cavitary aspergillosis have been described[101,102]; *Aspergillus* infection can cause formation of a fungal pseudomembrane, resulting in severe airway obstruction.[103] Transmural and peribronchial extension of the infection may occur, and the most prominent symptoms are cough, fever, and dyspnea.

Amphotericin-B is the drug of choice for most life-threatening fungal infections (see Chapter 31). Alternative regimens include fluconazole and itraconazole. However, even with treatment, relapse and mortality is high. Chronic suppressive therapy is required following infection.

## Chronic Lung Disease

Chronic lung disease is common in HIV-infected children as they survive longer.[1,7,104,105] The spectrum of chronic lung disease includes lymphocytic interstitial pneumonitis (LIP), chronic infection, IRIS, malignancies bronchiectasis, bronchiolitis obliterans, and asthma (see Box 66.1). In HIV-infected adults, chronic obstructive pulmonary disease, pulmonary hypertension, and lung cancer are increasingly recognized.[106]

Factors contributing to chronic lung disease in perinatally infected children and adolescents are multifactorial and include direct influences of HIV, immune dysregulation with increased inflammation, recurrent or severe infections, ART and is compounded by environmental exposures such as microorganisms, diet, poverty, tobacco smoke, or environmental pollution (Fig. 66.4). Delayed access to ART, pneumonia, particularly TB, and extent of preexisting immunosuppression impact the severity or extent of chronic lung disease. Although ART may halt progression of lung damage, it will not reverse established chronic disease. Improvement of lung disease on ART is suggested by radiological improvement[105]; a study of lung function in perinatally infected adolescents on ART showed relatively mild lung function impairments despite children only being started on ART at 5 years.[8]



Waning vaccine efficacy
Suboptimal nutrition
Poverty
Environmental tobacco smoke or pollution
HIV
Acute Infection
Pneumocystis jirovecii
Bacterial
Viral
Mycobacterial
Polymicrobial infection
Antiretroviral therapy
Autoimmunity
Decreased antioxidant tolerance
Renewed immunological response to persistent microbial pathogens (IRIS)
Chronic Lung Disease
Bronchiectasis
Bronchiolitis obliterans
Asthma/wheezing
Interstitial pneumonitis
CD8 T cell lymphocytic alveolitis
Up-regulation of antioxidant pathways
↓CD4 T cells
high viral load

**FIG. 66.4** Factors associated with chronic lung disease in human immunodeficiency virus (HIV) infected children.

In the absence of ART, chronic lung disease was dominated by LIP, chronic or recurrent infections with bronchiectasis, bronchiolitis obliterans, and decreased lung function.[7,104] Use of early ART prevents lung damage[107] but even when ART is only started in the early childhood years, it may provide substantial protection from development of severe chronic lung disease. For example, among African HIV-infected adolescents started on ART at 5 years of age, only a minority (<10%) had evidence of severe lung function abnormalities at adolescence.[8] Further use of ART can lead to chest radiographic improvement and prevent radiological progression even when started in late childhood.[105]

The Pediatric Pulmonary and Cardiovascular Complications of Vertically Transmitted HIV followed 287 HIV-infected US children (some of whom were receiving one or two antiretroviral therapies [ARVs]), for 4 years.[104] Chronic lung disease was defined as persistent bronchovascular or reticular markings for 6 months or longer, or consolidation or nodules present for 3 months or longer. The cumulative prevalence of chronic radiographic changes was 29%, of which 23% were severe radiological abnormalities, either persistent consolidation or nodules. Chronic changes were associated with lower CD4 counts and higher viral loads. Radiographic changes were associated with an increased frequency of clubbing, crackles, tachypnea, and decreased oxygen saturation. LIP was diagnosed in 19%, chronic PCP in 6% and TB in 2%. Among those with no defined cause for the chronic chest x-ray (CXR) abnormality, an increase in bronchovascular markings was the most common finding, followed by focal consolidation and pulmonary nodules.[104] Mortality in HIV-infected children with chronic radiographic changes was not different from that in HIV-infected children without these changes.

In a South African study of 330 HIV-infected children (median age 24 months), mostly with advanced clinical disease and moderate or severe immunosuppression, almost 85% had an abnormal chest x-ray.[108] Only 23% of children were on ART, as the study predated the availability of ART. In addition, bronchial wall thickening occurring in 70% and was the most common radiographic abnormality. A third had increased bronchovascular markings, while around 50% of x-rays had extensive diffuse or multifocal changes either opacification, reticulonodular infiltrates, or a combination of these.[108] Atelectasis (12%), bronchiectasis (4%), or isolated thin-walled pulmonary cysts (2%) were also reported in association with diffuse changes. More extensive radiological disease was associated with advanced clinical disease, CD4 count less than 20%, and age greater than 2 years. Children were followed for a median of 24 months, with chest radiology performed every 6 months; during this time, almost 80% of participants went onto ART (median ART duration was 16 months). In the first 6 months, the proportion with severe radiological abnormality increased slightly from 50% to 54% remaining mostly unchanged at 12 months.[105] Subsequently, slow but sustained radiological improvement occurred, with 40%, 28%, 19%, and 16% showing severe abnormality at 24, 36, 48, and 54 months, respectively. The cumulative prevalence of persistent, severe abnormality was 60%

(almost 3 times that in American children) and lasted a median of 18 months. LIP (45%) and pulmonary TB (31%) were the leading causes of persistent, severe abnormality, accounting for over three-quarters of cases. The use of ART was associated with an improvement in radiological findings and less deterioration, within 6 months of use including for LIP and TB.[105]

## Lymphoid Interstitial Pneumonitis

Prior to availability of ART, LIP was common, with chronic nodular densities observed in 8% of patients by 5 years of age in a North American study.[104] In 25 studies of 128 children with biopsy proven LIP, almost all reported chest x-ray findings as diffuse, bilateral, nodular, or reticulonodular (Fig. 66.5A).[109] In HIV-infected children under 5 years of age who died at home in Zimbabwe, 9% had LIP on autopsy.[110] However, the prevalence of LIP has reduced dramatically with use of ART.

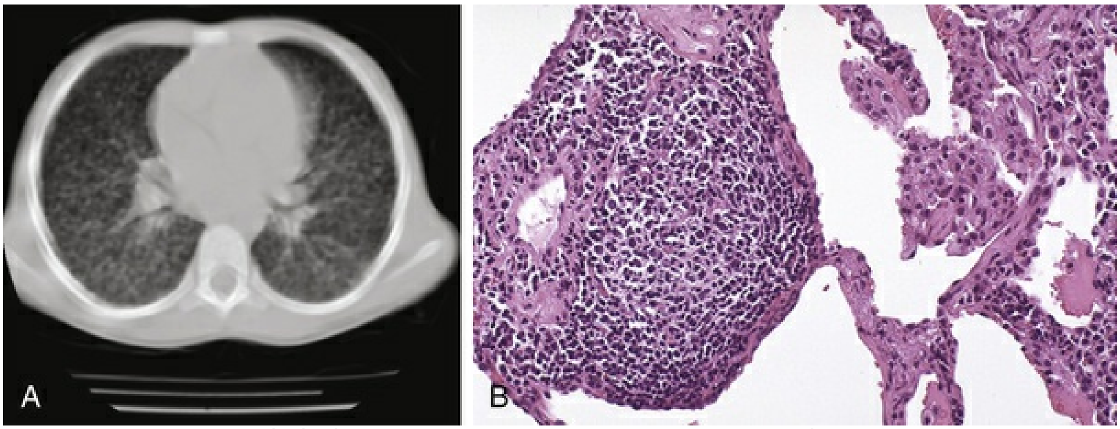


**FIG. 66.5** (A) Computed tomography scan of a child with lymphocytic interstitial pneumonitis (LIP). Diffuse nodular infiltrates are present bilaterally with perihilar prominence. (B) Lung biopsy from a child with LIP. Note the interstitial and peribronchiolar lymphoid infiltration.

LIP is characterized by diffuse infiltration of lymphocytes into the interstitium and scattered nodules of mononuclear cells; the etiology of the abnormal lymphoproliferative response is unclear. The principal hypotheses are that lymphoproliferation is a response to the HIV (Fig. 66.5B) alone or coinfection with another virus. Epstein-Barr viral DNA has been found in lung biopsies of children with LIP, and HIV RNA has been identified in the lungs of infants with LIP.[111]

The onset of LIP is insidious and the course slowly progressive. The median age of onset is 2.5–3 years of age. However, reticulonodular changes on x-ray may be observed before 12 months of age.[104] Cough or tachypnea may be present. Auscultation of the chest may be normal or reveal crackles and wheezes. Generalized lymphadenopathy, hepatosplenomegaly, clubbing, and parotid gland enlargement are commonly associated physical findings. The chest radiograph typically shows a bilateral diffuse interstitial reticulonodular pattern with or without hilar adenopathy.[104,109] Elevated serum immunoglobulin levels are associated with LIP and IgG levels greater than 2500 mg/dL are strongly associated with LIP. Lung biopsy establishes the diagnosis. However, a presumptive diagnosis of LIP can be made based on the clinical findings and the typical reticulonodular radiographic pattern lasting more than 2 months without another cause. In a longitudinal study of African children, LIP was the leading causes of persistent, severe abnormality on chest x-rays, accounting for 45% of cases.[105] Chest x-ray findings may resolve with steroid treatment or with ART.[112]

Treatment of LIP is nonspecific. Inhaled bronchodilators may provide symptomatic relief, and oxygen is administered for hypoxemia. Although treatment of LIP with corticosteroids has been reported to improve hypoxemia in a small number of patients, there are no controlled clinical trials.[112]

Some cases of LIP may progress to a lymphoproliferative disorder characterized by polyclonal, polymorphic B-cell content with extranodal systemic and prominent pulmonary involvement, or to malignant lymphoma.

## Chronic Infection

Chronic lung disease may result from recurrent or persistent infection from bacterial, mycobacterial, viral, fungal, or mixed infections. Although ameliorated by ART, susceptibility to recurrent and severe bacterial or viral infection persists even with use of ART. TB is one of the most common causes of chronic lung disease and of chronic chest radiological abnormalities in African children.[1,105,113]

Localized or disseminated disease from *Mycobacterium bovis* or the NTM (particularly *M. avium-intracellulare* complex) may also result in chronic disease. Chest x-ray features include mediastinal adenopathy, diffuse pulmonary nodules, cavitation, or bronchiectasis.

Case reports of chronic PCP in children have been described with focal opacification, cysts, pneumothorax, pneumatoceles, or diffuse interstitial disease.[114–116]

## Pulmonary Tumors

Children with HIV have an increased risk of malignancy, occurring in 2.5% of children with AIDS in the United States.[117] Non-Hodgkin lymphoma (NHL) is most common, followed by Kaposi sarcoma (KS), leiomyosarcoma, and Hodgkin lymphoma.[117] Although the ART reduces the risk of AIDS-defining malignancies, HIV-infected children remain at increased risk of malignancies compared to HIV-uninfected children.[118] Primary NHL may arise in a lymph node or be extranodal. AIDS-related NHL may occur in almost any extranodal site including the lungs. In addition, pulmonary disease may result from dissemination from a primary focus. In African HIV-infected children, KS is the most common AIDS-defining malignancy probably due to the prevalence of Kaposi sarcoma-associated herpes virus (KSHV).[118–120] In high-income settings, most cases of KS in the pediatric age group have occurred in adolescents, and KS lesions may produce upper airway obstruction. Pulmonary dissemination may result in chronic progressive dyspnea, cough, and fever; hemoptysis may occur with endobronchial lesions.[122] Chest radiograph abnormalities include multifocal homogeneous opacification, a diffuse reticular or nodular pattern, pleural effusion, mediastinal adenopathy, or a combination of these.[114]

A single case of a child with a tumor of the trachea (leiomyoma) and of the left main bronchus (leiomyosarcoma), presenting as tracheal narrowing and left lower lobe collapse respectively has been described.[123] Pseudolymphomas and lymphomas have also been reported.

## Aspiration Pneumonitis

Esophagitis, related to candida, herpes simplex virus (HSV), and CMV infections may occur in HIV infected children, particularly those with severe immunosuppression, and can be associated with swallowing difficulties and risk of pulmonary aspiration.[124,125] Neurological impairment secondary to HIV encephalopathy can also increase risk of pulmonary aspiration and recurrent lower respiratory tract infections or aspiration pneumonitis. Pulmonary aspiration should be considered in HIV infected children with clinical or radiological concerns of aspiration and recurrent lower respiratory tract infection (LRTI).

## Bronchiectasis

Bronchiectasis is an important cause of chronic infiltrates and atelectasis on chest radiographs and may be focal or bilateral. Bronchiectasis may be associated with LIP or lower respiratory tract infection. Development of bronchiectasis is associated with the severity of immunosuppression. A retrospective review of 749 HIV-infected children (mostly before the availability of ART) found that all 19 who developed bronchiectasis were Centers for Disease Control and Prevention (CDC) immunological category stage 3.[126] In Zimbabwean adolescents with vertically transmitted HIV and delayed access to ART, 43% had bronchiectasis on chest computed tomography (CT) scans and 66% had a chronic productive cough.[7] Diagnosis may be suspected in a child with a recurrent productive cough and chest radiographs that show persistent abnormalities for more than 6 months. Diagnosis is confirmed with a CT scan of the chest. Therapy includes optimizing ART, physiotherapy to improve lung clearance, and aggressive treatment of intercurrent infections. The efficacy and safety of long-term azithromycin has not been evaluated in HIV-infected children with bronchiectasis.

## Bronchiolitis Obliterans

In vertically infected Zimbabwean adolescents, chronic respiratory symptoms, hypoxia, reduced lung function, and high resolution CT scan findings suggestive of postinfective bronchiolitis obliterans (BO) have been described.[7] Over half (55%) had areas of decreased attenuation on chest CT scan in keeping with small airway disease. Coexisting bronchiectasis was common as is typical of postinfectious BO, and BO may be a sequel of acute lower respiratory tract infection or of repeated infections (Fig. 66.6).[127,128] The extent of mosaic attenuation on CT scan was inversely correlated with lung function as measured by forced expiratory volume in 1 second (FEV1). Management includes lung protective strategies (optimizing ART therapy, vaccinations against respiratory pathogens, nutritional support, regular screening, and prophylaxis for TB in endemic areas) and pulmonary rehabilitation as appropriate. Bronchodilators may be used for those who are bronchodilator responsive. The role of inhaled corticosteroids or azithromycin has not been evaluated in HIV infected children with BO.

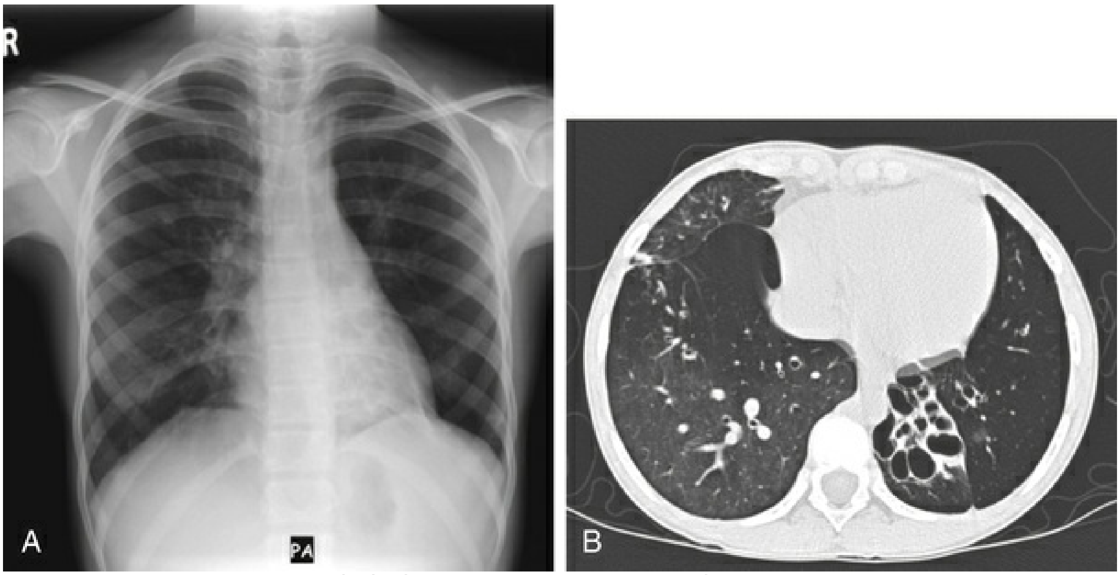

**FIG. 66.6** (A) Chest radiograph of a human immunodeficiency virus infected adolescent showing hyperinflation and left lower lobe bronchiectasis. (B) Computed tomography scan, note the mosaic perfusion and bronchiectasis.

## Immune Reconstitution Inflammatory Syndrome

With increasing use of ART, an IRIS associated with mycobacterial infection or with other OIs (e.g., CMV) has been reported.[129] TB IRIS may occur weeks to months after initiation of ART therapy and may result either from unrecognized mycobacterial infection or from a florid immune response directed against a mycobacterial antigen in those already on therapy.[130] IRIS has been described with different mycobacterial species including *M. tuberculosis, M. bovis,* or MAC infection.[131–134] Clinically, IRIS is characterized by a paradoxical worsening in signs with increasing lymphadenopathy and new clinical and radiological respiratory signs.[131,132,134] The tuberculin skin test may become positive, and chest radiographs may show development of lymphadenopathy or new infiltrates. IRIS must be distinguished from other infections, drug resistant TB, or nonresponse to TB therapy caused by nonadherence. To minimize the risk of IRIS, HIV-infected children with confirmed or probable TB should be treated with anti-TB drugs when possible for 2 weeks before commencing ART.[51,131] When IRIS develops in a child who was unknown to have TB, therapy for TB should be initiated without stopping the ART. If lymphadenopathy or respiratory signs are severe, oral corticosteroids may be beneficial, although there are no controlled trials in children.

## Airway Hyperreactivity/Asthma

The prevalence of asthma has been reported to be higher in cohorts of HIV infected children on ART compared to uninfected children, but the data are limited.[135–137] A study comparing use of asthma medications in HIV infected children on ART with HIV infected children not on ART, suggested that immune reconstitution may increase asthma risk.[135] However, asthma diagnosis was based on use of asthma medication and confounding factors associated with ART usage, such as severe immune suppression, were not accounted for. Some studies have reported HIV infected children to have a higher incidence of asthma and atopic dermatitis compared to uninfected children, although only use of asthma medication was significantly different.[137] A recent study investigating clinical asthma and lung function in HIV-infected and HEU youth found that, compared to HEU youth, HIV-infected youth had decreased bronchodilator reversibility of obstructive lung disease. This suggests that much of the clinically diagnosed asthma may indeed reflect early chronic obstructive lung disease rather than airway hyperresponsiveness.

## Lung Function as a Measurement of Chronic Lung Disease

Lung function may be useful to describe the functional impairment of respiratory disease, understand the underlying mechanisms of disease, and track progression or regression. In HIV-infected children and adolescents, there is a paucity of lung function data. Most data are from small cross-sectional studies, with heterogeneous patient groups and minimal longitudinal data. It is likely that lung involvement begins in early life or in utero. In a birth cohort study investigating respiratory and cardiovascular disease in infants born to HIV infected mothers,[139] HIV infected children had higher respiratory rates and more respiratory symptoms compared to HIV exposed but uninfected infants.[140] To assess if early potentially serious pulmonary disease could be detected before onset of clinical symptoms, infants born to HIV infected mothers were screened with technetium 99m diethyltriaminepentacetic acid ($^{99m}$Tc DTPA) radioaerosol inhalation-clearance scintigraphy from 3 months onwards and repeated every 6 months.[141] HIV infected infants had a higher $^{99m}$Tc DTPA radioaerosol clearance compared to HIV exposed but uninfected infants, suggesting early alveolar interstitial inflammation. Another infant study measuring airflow resistance using the interrupter technique found HIV-infected children (aged 9–113 months) to have higher airway resistance compared to age matched HIV uninfected infants. Airway resistance was similar between symptomatic and asymptomatic HIV-infected infants.[142] Resistance measured after 1 year was significantly higher than initial measurement in HIV infected children, in contrast to the growth associated decline in airway resistance that was seen in healthy HIV uninfected children.[142] These studies suggest that lung involvement occurs early, that clinical symptoms are insensitive measures of early lung damage, and that in the absence of ART these changes are progressive.

In older HIV-infected children and adolescents, abnormal spirometry is common, with restrictive, obstructive, or mixed spirometric patterns described. Reduced FEV1 has been reported in small African[7,143,144] and Italian[142] cross-sectional studies of HIV-infected children. In a Zimbabwean study of 116 children (70% on ART but diagnosed with HIV late at a median of 12 years), 45% had a reduced FEV1.[7] The group had a 71% incidence of physician diagnosed chronic lung disease with exercise intolerance in 21%, dyspnea and/or hypoxia at rest in 35%, and desaturation following a walk test in 29%. Despite the limitations of these studies, they suggest that delayed treatment with ART in HIV infected children results in severe debilitating lung disease with low lung function in those who survive infancy. However, a South African study in which children were started on ART at around 5 years of age found that, although mildly reduced lung function was common 7 years after ART initiation, severe lung function abnormalities were rare.[8]

Impairment of diffusion capacity and airway hyperreactivity has been described in HIV-infected adults, but HIV-infected children or adolescents have not been tested. Obstructive lung disease in HIV-infected adults on ART has been reported, but whether this is mediated by direct viral factors, ART related immune preservation or restoration, lifestyle issues (most notably tobacco smoking), or inflammation related to recurrent OIs is unclear.[145,146] The impact of early ART and immune reconstitution or preservation on lung function has not been assessed in HIV infected children.

## Human Immunodeficiency Virus-Associated Cardiomyopathy and Pulmonary Hypertension

Ventricular dysfunction and cardiomyopathy may occur frequently in HIV-infected children in the absence of ART.[147] In the pre-ART era, up to 25% of HIV-infected children manifested significant cardiac abnormalities, such as dilated cardiomyopathy, left ventricular hypertrophy, or pericardial disease.[148] However, the prevalence of severe cardiovascular impairment has decreased substantially with ART. The Pediatric Pulmonary and Cardiovascular Complications of Vertically Transmitted HIV study showed that inadequate or reduced left ventricular wall thickness was an independent predictor of morbidity and mortality, while even small decreases in fractional shortening were associated with marked increases in 5-year mortality.[149] It is therefore important to consider cardiac disease with congestive heart failure in HIV-infected children presenting with respiratory symptoms.

Pulmonary hypertension was reported in 7% of Zimbabwean HIV-infected adolescents, who were only diagnosed with HIV at 12 years.[7] Primary pulmonary hypertension has been increasingly reported in HIV-infected adults, but there are very limited data in children.[106]

## Upper Airway Disease

Recurrent upper airways infections including otitis media or sinusitis may occur. Lymphoid proliferation with tonsillar and adenoidal hypertrophy, and pharyngeal infiltration may lead to upper airway obstruction.[150] Lymphoid infiltration of the epiglottis has also been described with gradual onset of drooling and dysphagia.[151] *Candida* epiglottitis has been described in HIV-infected children and highlights the importance of considering uncommon pathogens in immune-compromised children presenting with supraglottic inflammation.[152] Airway obstruction requiring tracheostomy was most commonly due to severe laryngotracheobronchitis in HIV-infected children in a South African cohort. The majority of children in this study were not on ART at time of tracheostomy and subsequently did well after treatment initiation.[153]

## Summary

Respiratory diseases cause major morbidity and mortality in HIV-infected children, particularly in sub-Saharan Africa. The spectrum of illness encompasses acute and chronic disease. HIV-exposed, uninfected children have a higher risk of respiratory infections early in life compared to unexposed children. General and specific preventive strategies are effective for reducing respiratory morbidity and mortality, while early use of ART is highly effective for reducing the incidence of OIs, pulmonary morbidity, and mortality. Preventive interventions including immunization and use of long-term CTX prophylaxis reduce the incidence of specific respiratory infections and improve survival. With long-term survival, chronic lung disease in perinatally HIV-infected adolescents is an important cause of morbidity that may be ameliorated by the use of ART.

# Pediatric Lung Transplantation

*Joshua A. Blatter MD, Blakeslee Noyes MD, Stuart Charles Sweet MD, PhD*

## Introduction

With reports of successful heart-lung and lung transplantation in adults in the early 1980s,[1,2] the application of lung transplantation to the pediatric population became an appealing prospect. Early reports of success in children undergoing lung transplantation[3–5] led to a marked increase in such procedures beginning in the early 1990s. Between January 1986 and June 2014, more than 2000 lung and almost 700 heart-lung transplantations in patients less than 18 years old have been reported to the Registry for the International Society for Heart and Lung Transplantation (ISHLT).[6] The number of lung transplant procedures performed annually from 2006 to 2015 has varied between approximately 95 and 140. Historically, heart-lung transplant was considered for patients with end-stage lung disease, with the relatively healthy native recipient heart considered for use in a "domino" transplant. Heart-lung transplant was also considered in patients with right ventricular failure associated with severe pulmonary hypertension. However, in the current era, heart-lung transplant is typically reserved for cases associated with left ventricular failure or congenital heart disease not amenable to surgical repair. Thus the number of heart-lung transplants performed has dropped to approximately 10 per year worldwide.

Typically, 40–45 centers report pediatric lung transplants, yielding a statistical average of 2–3 transplants per center annually. In reality, a few centers perform the majority of these procedures, and most centers perform very few.[6] The number of lung transplants performed yearly is far below the number of other solid-organ transplants such as heart, liver, and kidney transplantation. This relative paucity is likely due to multiple factors, including lower prevalence of end-stage pulmonary diseases in children, improved therapies for cystic fibrosis (CF) and pulmonary hypertension, the significantly lower procurement rate of donor lungs compared with other organs, and the small number of pediatric lung transplant centers in the United States and worldwide.[7] Notwithstanding changes in the allocation of lung allografts (discussed later), the mortality rate for pediatric candidates aged 1–11 years awaiting lung transplantation remains higher than that in adults, underscoring the need to expand the potential donor pool and perhaps the number of centers performing this procedure.[8]

## Indications and Timing

Indications for lung transplantation in children have undergone considerable change in the past three decades as experience with this procedure has grown. Lung transplantation has been performed successfully even in young infants with distinctly uncommon problems such as surfactant protein B deficiency and alveolar capillary dysplasia.[9,10] The most common diagnoses for which children are transplanted are listed in Fig. 67.1 according to the age in years at time of transplantation. In children younger than 1 year, the most common indications are pulmonary hypertension, usually associated with congenital heart disease, other pulmonary vascular diseases, primarily pulmonary vein stenosis, and rarely alveolar capillary dysplasia; disorders of surfactant metabolism, including surfactant protein B and C deficiencies and ABCA3 transporter mutations; and a spectrum of “fibrotic” lung diseases. Less common indications include interstitial lung disease, bronchopulmonary dysplasia,[4] and pulmonary hypoplasia. In patients 6–17 years of age, CF is the most common indication, and in the 12- to 17-year group, nearly 70% of pediatric lung transplants are performed in CF patients. In the 1- to 5-year age group, disorders leading to pulmonary hypertension remain a common indication. The relative percentage of children with primary pulmonary hypertension coming to lung transplant has diminished significantly during the past two decades, largely because of the introduction of effective medical therapies, including prostaglandins (epoprostenol), phosphodiesterase (PDE) inhibitors (bosentan), and sildenafil (see Chapter 35).[6] Surprisingly, despite a steady increase in the median survival for CF, the relative percentage of children with CF receiving lung transplants has not changed appreciably in recent years. Historically, timing of referral for lung transplant has been predicated on matching predictions of mortality with the anticipated waiting time for donor lungs. For example, studies in CF led to recommendations for referral for lung transplantation once the forced expiratory volume in 1 second ($FEV_1$) declined below 30% predicted.[11] Although more recent studies have attempted to add to these criteria,[12,13] none have improved significantly on the ability to predict waiting list mortality. Even in the best model, the positive predictive value is less than 50%.[12] In other diseases leading to lung transplant, criteria are less clear. Given absent or imperfect disease-specific criteria, before committing a child to lung transplant, most pediatric centers carefully consider multiple factors beyond lung function, including growth and nutritional status, frequency of hospitalizations, and potential for improvement in overall quality of life.

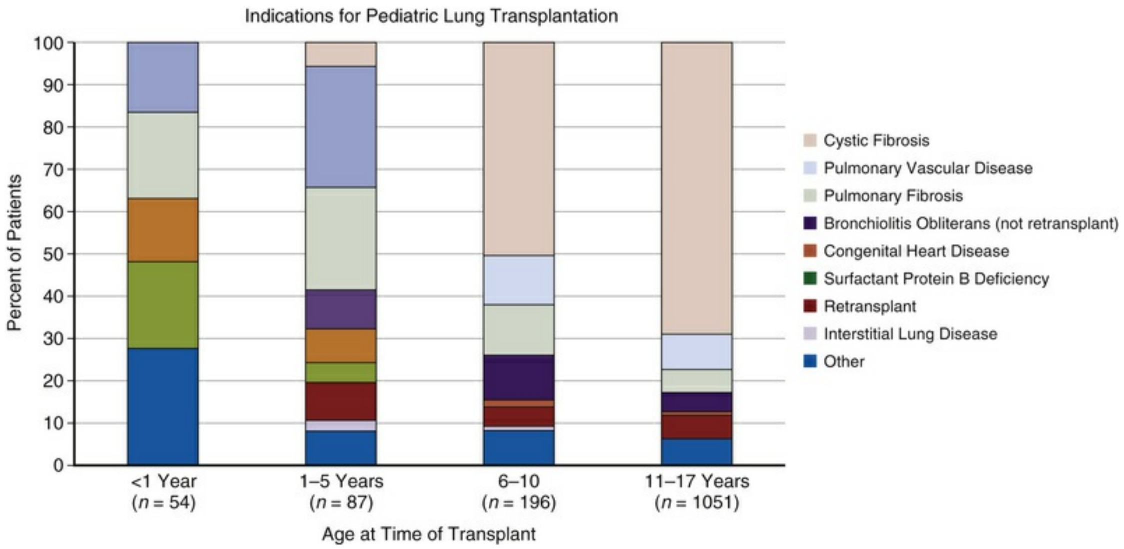

**FIG. 67.1** Indications for pediatric lung transplant, January 2000–June 2014. (Data modified from Goldfarb SB, Benden C, Edwards LB, et al. The Registry of the International Society for Heart and Lung Transplantation: Eighteenth Official Pediatric Lung and Heart-Lung Transplantation Report—2015; Focus Theme: Early Graft Failure. *J Heart Lung Transplant*. 2015;34(10):1255-1263.)

During the past 10 years, listing practices for children >12 years of age and adults have been affected by the adoption in 2005 of the “Lung Allocation System” (LAS) in the United States by the Organ Procurement and Transplantation Network (OPTN).[14] Based on models of waiting list mortality and posttransplant survival, this new system attempts to allocate donor lungs to maximize the 1-year transplant survival benefit. The survival models are based on diagnosis and other factors including age, height and weight, need for supplemental oxygen, pulmonary artery pressures, 6-minute walk distance, and lung function. Since adoption of the LAS, waiting time and waiting list mortality have decreased in the United States.[8] Nevertheless, an increased number of sicker patients are undergoing transplant—and a significant proportion of those patients (primarily those requiring mechanical ventilation) have had poorer overall survival than historical lung transplant cohorts—because the contribution of the waiting list mortality to the LAS is twice that of posttransplant survival[15]:

$$\text{LAS} = \text{posttransplant survival} - 2 \times \text{waiting list survival, normalized to a } 0-100 \text{ scale.}$$

An important aspect of the LAS is the potential for serially collected data from patients listed for lung transplant to be used for refinement of the underlying models that generate the priority score. For children younger than 12 years of age, in an effort to reduce waiting list mortality for these candidates, lung allocation was modified in the fall of 2010 to create two urgency tiers, similar to the status 1 and 2 in heart transplant allocation. Current changes in allocation involve the broader geographic sharing of pediatric donor lungs with pediatric recipients, which has been predicted to improve access for pediatric patients without adversely affecting adult ones.[16] It is difficult to predict the long-term benefits of these policy modifications.

There are numerous unsolved challenges in pediatric lung allocation, and a root problem is the relative scarcity of organs. Some usable organs are probably not being transplanted: among children whose families have agreed to donate at least one organ, less than 5% of 11-year-old-and-younger donors are providing lungs.[17] Extending pretransplant survival with lung bypass technologies, as well as salvaging suboptimal lung allografts (e.g., with *ex vivo* lung perfusion, [EVLP] discussed later in this chapter), have the potential to marginally increase the numbers of available donor lungs at a given time.[18]

## Contraindications

As experience with pediatric lung transplant has grown, the number of absolute contraindications has declined, with most considered *relative* contraindications based on each transplant center's experience and expertise (Table 67.1).[19] Common absolute contraindications to pediatric lung transplantation include systemic disease affecting other organ systems, such as malignancy, HIV, hepatitis B or C, tuberculosis, and liver, renal, or left ventricular failure. However, in some transplant centers, multiorgan transplantation (e.g., liver-lung transplantation) may be an option in selected patients with failure of an organ other than the lung. In CF patients, *Burkholderia cepacia* complex (BCC) organisms are often a concern. Initially, all BCC organisms were thought to lead to poor outcome after lung transplantation, but more recent analyses have suggested that only colonization with *B. cenocepacia* (formerly BCC, Genomovar III), and a related organism, *B. gladioli*, carries significant risk.[20–22] *B. cenocepacia* colonization remains an absolute contraindication to lung transplant at a significant percentage of pediatric centers. Infection or colonization with Aspergillus, atypical mycobacteria (particularly *Mycobacterium abscessus*), or multiresistant organisms is a relative but not absolute contraindication in patients with CF.[23–26] It is not uncommon for lung transplant candidates to present unique and complex challenges to the transplant center, including malnutrition, diabetes, osteoporosis or osteopenia, vertebral compression fractures, and the use of systemic corticosteroids. These are considered relative, but not absolute, contraindications. Prior pleurodesis, either chemical or surgical, although not a contraindication to transplant, may prolong the ischemic time because of excessive bleeding from the parietal pleura, particularly when cardiopulmonary bypass and attendant heparinization are used, and is associated with higher mortality.[27]

## Table 67.1

**Contraindications to Pediatric Lung Transplantation**

| Absolute | Relative |
|---|---|
| Active malignancy within 2 years[a] | Pleurodesis |
| Sepsis | Renal insufficiency |
| Active tuberculosis | Markedly abnormal body mass index |
| Severe neuromuscular disease | Mechanical ventilation |
| Documented, refractory nonadherence | Scoliosis |
| Multiple organ dysfunction[b] | Poorly controlled diabetes mellitus |
| Acquired Immunodeficiency Syndrome | Osteoporosis |
| Hepatitis C with histologic liver disease | Chronic airway infection with multiply resistant organisms[c] |
| — | Fungal infection/colonization |
| — | Hepatitis B surface antigen positive |

[a] Some centers prefer a disease-free interval of 5 years.

[b] Consider heart-lung transplant with concomitant left ventricular insufficiency or irreparable congenital heart disease, liver-lung transplant with concomitant hepatic failure.

[c] For some transplant centers, infection with *Burkholderia cepacia* complex organisms, particularly genomovar III *(B. cenocepacia),* is an absolute

contraindication.

Modified from Faro A, Mallory GB, Visner GA, et al. American Society of Transplantation executive summary on pediatric lung transplantation. *Am J Transplant*. 2007;7(2):285-292.

Finally, psychosocial concerns for children, particularly nonadherence, can be particularly challenging, especially when the responsibility for adherence is shared between separated parents. Decisions about how to handle such cases—without creating the perception that the parent's misbehavior led to the child being denied the opportunity for transplant—must be an individualized, shared responsibility of both the referring and transplant centers. In families where nonadherence to a recommended treatment regimen is recognized, some centers recommend formulation of a contract between the referring physician and family that outlines the need for strict adherence to a treatment program over a 3- to 6-month period prior to evaluation/listing for lung transplant. In general, adherence concerns become an absolute contraindication only in combination with other medical risk factors or after persistent failure on the part of the child and family to meet a set of agreed upon expectations for care and follow-up. In contrast, a significant psychiatric or mental health disorder in either the primary caregiver or the patient is considered an absolute contraindication to transplant.

# Surgical Technique

Potential donor lungs are evaluated using arterial blood gases, chest radiographs, airway cultures, and airway examination by bronchoscopy. The donor history is reviewed for signs/symptoms of acute viral infection. In addition, the donor is routinely screened for hepatitis A, B, and C, HIV, varicella-zoster, cytomegalovirus (CMV), Epstein-Barr virus (EBV), and herpes virus.[28]

One response to organ scarcity has been to explore the feasibility of longer-term lung bypass technologies. Extracorporeal membrane oxygenation (ECMO) is now being used as a “bridge to transplant” in some patients with end-stage disease. Patients who undergo short pretransplant ECMO runs may spend a longer intraoperative period on cardiopulmonary bypass, but they do not have worse survival.[29] This approach to bridging is now being extended to include “ambulatory ECMO,” which allows for intensive physical rehabilitation for patients on the waiting list. Most pediatric patients undergoing ambulatory ECMO have had only short ECMO courses,[30] but an evaluation of outcomes in these cases will help to determine whether extended courses of ECMO could be used to augment the quality and quantity of pretransplant survival. Paracorporeal lung assist devices, which remove and oxygenate blood from the pulmonary artery, subsequently returning it to the left atrium, have been used as a longer-term bridge (e.g., greater than 2 months).[31] Nevertheless, these bypass technologies put patients at elevated risk of bleeding or infectious complications.

Another promising perioperative approach to organ scarcity is EVLP, which entails organ procurement followed by *ex vivo* diagnostics and organ reconditioning. Antibiotics can be used to perfuse the organ, thereby reducing bacterial load,[32] and clots can be washed from the pulmonary circulation.[33] Outcomes to date with EVLP lungs have been similar to non-EVLP lungs, and there is hope that this technology could be used to capture “marginal donor lungs” that would otherwise go unused.[34]

In most pediatric transplant procedures, cardiopulmonary bypass with heparinization has traditionally been used for the implantation procedure, but ECMO has become an increasingly common alternative.[35] The surgical approach is via a bilateral anterolateral transsternal incision (the “clamshell” incision), which optimizes visualization and access to both pleural spaces. The clear majority of children undergo bilateral sequential lung transplantation with telescoped bronchial-to-bronchial anastomoses. Pericardial or peribronchial lymphatic tissue from the donor and recipient is used to cover the anastomosis. This improves the blood supply to the anastomosis and may reduce the exposure of adjacent vascular structures to infection, in the event of airway infection and subsequent dehiscence.[36] In patients with CF, careful attention to maintaining sterility of the donor allograft requires vigorous washing of the recipient trachea and bronchial stumps with an antibiotic solution prior to implantation.

Heart-lung transplantation is rarely used in children in the United States at this time.[6] Even in the presence of marked right ventricular hypertrophy associated with pulmonary hypertension, successful bilateral lung transplantation is generally associated with resolution of right ventricular dysfunction.[37,38] In patients with pulmonary hypertension caused by a congenital heart defect, intracardiac repair of the anatomic defect may take place at the time of bilateral lung transplant, obviating the need for heart-lung transplantation.[39] Single lung transplantation is used infrequently among children, and much less than in adults.[6]

Success with living donor lobar lung transplantation was first reported by Starnes in 1994.[40] In this procedure, a right lower lobe from one healthy donor and a left lower lobe from another (generally family members) are implanted in the recipient. Typically, this technique has been used in both adults and children in the setting of rapidly progressive respiratory failure where cadaveric lung allografts were judged unlikely to be available or where further deterioration in clinical status would make the patient ineligible for deceased donor transplantation. Although living donor lung transplant has virtually disappeared in the United States since the introduction of the LAS, it is still used in Japan, where access to donor organs suitable for children has been restricted. Other strategies for increased availability of organs for children and other smaller recipients include donor downsizing using linear stapling devices or lobectomy and lobar transplant.[41]

# Posttransplant Management

## Immunosuppressive Regimen

In the immediate preoperative period, triple drug immunosuppression and directed antimicrobial therapy is begun. In virtually all circumstances, immunosuppression consists of a calcineurin inhibitor (CNI; either tacrolimus or cyclosporine A [CSA]), a cell cycle inhibitor (azathioprine or mycophenolate mofetil [MMF]), and corticosteroids. Based on studies suggesting marginally better efficacy, there has been a trend in recent years toward the use of tacrolimus and MMF over CSA and azathioprine.[42,43] Nearly all pediatric lung transplant recipients are on tacrolimus and more than 80% are on MMF at the end of the first year.[6] Because lung transplant recipients have a higher risk for rejection episodes than other solid organ transplant recipients, more intense immunosuppression regimens have been developed.[44] For example, the initial targets for trough levels for tacrolimus and CSA are typically maintained in a range of 10–20 mg/mL and 300–500 mg/mL, respectively. Initial dosing for prednisone is typically 0.5–1.0 mg/kg per day with the goal of 0.25–0.5 mg/kg per day by 3–4 months after transplant, depending on the clinical course. Nearly all patients remain on prednisone at 1 and 5 years posttransplant.[6] In addition, the use of induction immunotherapy at the time of transplant remains widely used in pediatric lung transplantation; recent data indicate that almost 70% of patients receive either a polyclonal agent (antilymphocyte or antithrombocyte globulin) or, more commonly, an interleukin-2 (IL-2) receptor antagonist (daclizumab or basiliximab).[6]

## Antimicrobial Regimen

Most patients receive intravenous (IV) antibiotics before and after lung transplantation, based on the most likely potential infecting organisms. Cultures from the donor may allow precise choices of antibiotics. In patients without CF, a single antibiotic with broad gram-positive and gram-negative coverage is typically used for 7–10 days posttransplant. In recipients with CF, their pretransplant sputum cultures help guide therapy; typically, such antimicrobial therapy is directed against gram-negative organisms, commonly *Pseudomonas aeruginosa* and occasionally *Achromobacter* spp. Vancomycin is often included to cover methicillin-resistant *Staphylococcus aureus* (MRSA), which is being found increasingly in children with CF and advanced lung disease. In CF patients in whom *Aspergillus fumigatus* has been found, many transplant centers use voriconazole or anidulofungin postoperatively and, in some circumstances, aerosolized amphotericin, oral itraconazole, or oral voriconazole.[7] Prophylaxis against *Pneumocystis jiroveci* is begun shortly after transplant with trimethoprim/sulfamethoxazole (TMP/SMX) administered three times weekly. In patients unable to tolerate TMP/SMX, nebulized pentamidine, oral atovaquone, or dapsone are alternatives. Oral nystatin is begun in the early posttransplant period to reduce the likelihood of candida infection.

Although the availability of ganciclovir has reduced the significance of CMV in lung transplant recipients, CMV remains a serious potential complication associated with an increased risk of mortality.[45,46] The approach to CMV prophylaxis in the pediatric lung transplant recipient is controversial, varying considerably among transplant centers. In most instances, CMV prophylaxis is not administered when both recipient and donor are CMV seronegative.[47] If either the donor or recipient is seropositive for CMV, ganciclovir or valganciclovir are administered for 4–12 weeks posttransplant. More recent studies have suggested a potential benefit to extending the duration of prophylaxis (with IV ganciclovir or oral valganciclovir) to 6 months or longer.[48,49] Some pediatric centers administer CMV hyperimmune globulin (CMVIg) in conjunction with ganciclovir based on reports of improved outcomes with CMV disease in adult patients.[50] However, the long-term benefit of CMVIg remains unclear.[51]

## Management Issues Unique to Pediatrics

Although guided by the strategies used in adult lung transplant recipients, several significant differences exist in therapy and monitoring for pediatric lung transplant recipients, most importantly related to the ability to diagnose chronic lung allograft dysfunction (CLAD; defined later in this chapter).

Although spirometry is essential for the clinical diagnosis of CLAD, it is generally not reliable until children reach 6 years old. Using thoracoabdominal compression techniques, infant pulmonary function testing (PFT) can identify the presence of airflow obstruction, but this testing requires specialized equipment and experience.[52,53] Moreover, such tests cannot be performed as frequently as conventional spirometry because they require sedation or anesthesia. Infant PFT has not been used in recent chronic allograft dysfunction diagnostic criteria.[54]

An additional limitation for infants and toddlers relates to transbronchial biopsies (TBBx). Although TBBx forceps small enough to fit through the suction channels of endoscopes used for bronchoscopy in young children became available in the 1990s, the smaller forceps typically yield much smaller pieces of tissue. Therefore obtaining tissue for the diagnosis of rejection in infants may be technically challenging.

Therapeutic challenges also exist. Newer immunosuppressant and antiinfective agents often are not available in the liquid forms required for young children. Management of liquid forms can be difficult for patients and families, as they usually must be compounded by local pharmacies and may have a short shelf life. In addition, the use of liquid forms may be problematic for transplant centers because dosing decisions must often be made when appropriate absorption and pharmacokinetic data for infants and children are not available.

## Complications

Complications following lung transplantation occur in predictable timelines: a few weeks after transplant, when the most common complications are related to the condition of the donor organs and the surgical procedure; an early phase, 1–6 months after transplant, when infectious and acute immunologic complications become more prevalent; and a late phase, >6 months after transplantation when chronic immunologic complications such as bronchiolitis obliterans (BO) and malignancies are observed more frequently (Fig. 67.2).

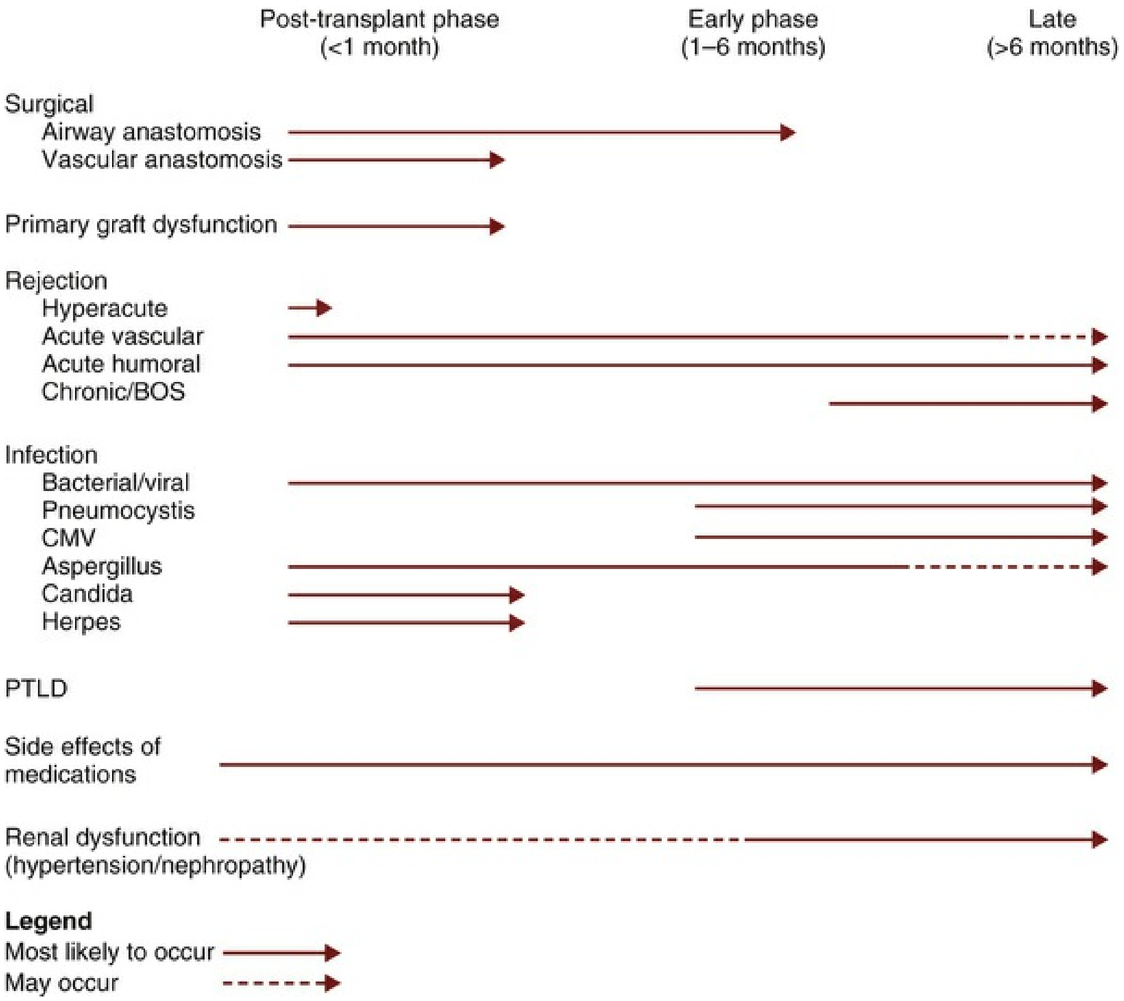

**FIG. 67.2** Timing of complications after lung transplantation. *BOS,* Bronchiolitis obliterans syndrome; *CMV,* cytomegalovirus; *PTLD,* posttransplant lymphoproliferative disease.

## Immediate Posttransplant Phase

Because pediatric lung transplant procedures are performed with cardiopulmonary bypass or ECMO, postoperative bleeding, particularly in the pleural space or at the site of the vascular anastomoses, is a common concern.[4] Other complications of the surgical procedure include injury of the phrenic or recurrent laryngeal nerve, causing diaphragmatic or vocal cord dysfunction. Dehiscence at either the vascular or the bronchial anastomoses may require prompt surgical attention and an early return to the operating room. Most transplant centers perform flexible bronchoscopy within 24–48 hours of transplantation to obtain cultures from the lower airways and to assess the integrity of the airway anastomosis. Fortunately, dehiscence of the airway anastomosis has become rare since the development of techniques to cover the anastomosis with vascularized tissue.[36,55] However, other airway complications occur at a frequency comparable to that seen in adult lung transplant recipients, including fibrotic strictures, excessive granulation tissue, and airway collapse at the site of the anastomosis.[56,57] In the event of the development of stenosis of the airway lumen, balloon dilatation or stent placement by bronchoscopy may be necessary. Mechanisms invoked to explain the development of anastomotic narrowing include donor airway ischemia, impaired airway healing, and barotrauma if prolonged ventilation is needed after transplantation.[56]

## Rejection

Lung allograft rejection remains problematic, representing an important obstacle to long-term success of transplantation, particularly in comparison to other solid organ transplant procedures. A variety of mechanisms have been proposed to explain this discrepancy, including the richness of immune effector cells resident in the pulmonary vasculature and lymphatic system, the ongoing daily exposure of the vast epithelial surface of the lung allograft to potential environmental irritants, toxins, and pathogens, and the fact that the lungs are exposed to the entire cardiac output.[58]

Hyperacute rejection within hours of transplant is a rare, potentially catastrophic complication in the immediate posttransplant period associated with circulating recipient antibodies that bind to donor human leukocyte antigen (HLA) molecules on vascular endothelium, leading to significant graft ischemia.[4] It can be prevented by screening the recipient for anti-HLA antibodies and avoiding donors with related antigens. However, because the logistics of organ allocation often preclude HLA information being available at the time of organ offer, this approach is typically reserved for patients with antibodies to a significant percentage of HLA types. Alternatively, patients with a low percentage of antibodies reactive to the spectrum of HLA antigens undergo cross-matching at the time of transplant. Patients with positive cross-matches are usually treated with plasmapheresis to prevent hyperacute rejection, and even highly sensitized patients can undergo transplant.[59]

The most frequent problem that occurs in the first posttransplant week is primary graft dysfunction (PGD) related to reimplantation lung injury.[60,61] PGD is associated with the procurement procedure and duration of ischemia prior to implantation; the generation of hydroxyl radicals and proinflammatory cytokines during ischemia may be causative factors.[62–64] Complications related to graft dysfunction vary from mild, noncardiogenic pulmonary edema to a picture of acute respiratory distress syndrome histologically characterized as diffuse alveolar damage. Patients generally have marked hypoxemia and diffuse infiltrates. Treatment is supportive with careful fluid management and ventilatory support[65]; ECMO support has also been used in selected cases.[66,67] Although early retransplantation may be considered, outcomes in this setting are generally poor.[68]

Acute rejection is much more common than hyperacute rejection: most patients undergo at least one episode. Acute rejection can occur as early as 1 week after transplantation or as long as 2–3 years later. Most commonly, episodes of acute rejection occur 2–12 weeks after transplantation.[58] Nonspecific signs and symptoms of acute rejection include cough, fever, dyspnea, hypoxemia, and radiographic changes. Lung function studies, if available, tend to show an obstructive pattern. Chest examination may show tachypnea and crackles on auscultation. Since these findings are not specific for rejection and are difficult to differentiate from infection, evaluation by bronchoscopy with bronchoalveolar lavage (BAL) and TBBx is generally indicated, particularly for patients presenting in the first 3 months after transplant. Histologically, biopsy specimens in acute rejection show perivascular lymphocytic infiltrates with or without airway inflammation. They are classified according to a standardized scoring system.[69,70] Because patients with acute rejection may be asymptomatic, many transplant centers advocate surveillance bronchoscopy with TBBx on a scheduled basis (e.g., at 2 weeks, 1, 2, and 3 months after transplant, quarterly intervals for the rest of the first year, and semiannually thereafter).[19] Some transplant centers perform bronchoscopy and biopsies only when symptoms of lower respiratory tract disease become manifest, arguing that long-term outcomes are unaffected with this approach.[71] Performance of screening biopsies during the first posttransplant year has increased following publication of data suggesting that a single episode of minimal acute rejection is an independent risk factor for chronic rejection.[72,73] However, this finding was not confirmed in a multicenter analysis of pediatric lung transplant recipients.[74]

Treatment of acute rejection consists of 10 mg/kg of IV methylprednisolone daily for 3 days. For persistent or recurrent acute rejection, lympholytic therapy with, for example, antithymocyte globulin may be initiated or the daily immunosuppressive regimen may be altered or enhanced. Although episodes of acute rejection are common after lung transplantation (perhaps even expected), there are data suggesting that younger transplant recipients (<3 years of age) have fewer episodes of acute rejection than older children or adults.[75–77]

## Infection

Sources of increased risk of infection in the immediate posttransplant period and beyond are multifactorial. These include organisms present in the donor at the time of procurement, the intensity of immunosuppression, the loss of a normal cough reflex because of postoperative pain and the disruption of afferent and efferent nerves responsible for coordinating the cough response, impairment of mucociliary transport, and alteration in trafficking of immune effector cells to regional lymph nodes.[78] Despite the use of prophylactic antibiotics in the perioperative period, recipient factors (particularly in patients with CF) and donor factors (e.g., active viral infection) may lead to significant infectious complications early in the postoperative period. Younger children appear to be at greatest risk for early viral infections, perhaps because they are less likely to have developed immunity.[9] In CF transplant recipients, the chronically infected lungs may cause seeding of the blood or mediastinum with recipient airway flora during explantation. Furthermore, chronic sinus disease typical of CF is a potential source of infection to the allograft and has led some transplant centers to advocate pretransplant sinus surgery coupled with antibiotic washing of the sinuses.[79,80] However, a recent retrospective analysis of sinus surgery in patients with CF undergoing transplant at a major transplant center showed no survival benefit associated with pretransplant sinus surgery.[81]

## Early Phase (1–6 Months)

### Rejection

In addition to acute rejection, which has peak incidence during this period, it has become clear that the posttransplant development of donor specific anti-HLA antibodies (i.e., *allo*antibody response) can lead to antibody-mediated rejection (AMR).[82] AMR can also develop in response to circulating self-antigens (i.e., *auto*antibody response) such as collagen V and K-alpha 1 tubulin.[83] The clinical manifestations of humoral lung allograft rejection are difficult to differentiate from infection or acute cellular rejection. Patients present with dyspnea, pulmonary infiltrates, and decreased lung function. Although there is no "gold standard" for diagnosis, the presence of circulating donor specific antibodies (identified using solid phase flow cytometry techniques), alveolar capillary complement (C4d) deposition, and capillaritis in the setting of allograft dysfunction is usually considered sufficient evidence.[84,85] Diagnosis is complicated by disagreement regarding the meaning of laboratory testing: many laboratories report a mean fluorescence intensity (MFI) value, which—although it represents some amount of bound antibody to a single antigen bead—cannot be interpreted as a true titer.[86] Treatment of humoral rejection is also controversial. Most centers use some combination of steroids, plasmapheresis, IV immunoglobulin, and B-cell reduction (Cytoxan or rituximab).[87,88] The role of newer agents such as bortezomib, a proteosome inhibitor targeted at plasma cells, or complement inhibitors such as eculizumab remains to be elucidated.[89,90]

### Infection

During this period, the risk of infectious complications is typically highest, especially in patients who have received an induction agent. The initial concern is for organisms carried with the donor organs during implantation or (primarily in the case of CF) harbored in the upper airways of the recipient. Subsequently, community and nosocomial organisms may cause infection, as may opportunistic (pneumocystis, candida) pathogens. Patients who are seropositive for CMV or who are seronegative and receive lungs from a CMV-positive donor are at risk for CMV disease during this early phase because most prophylactic regimens against CMV are completed during this period.

Clinical manifestations of CMV infection vary from a febrile, viral syndrome associated with leukopenia to invasive disease with viremia affecting, most commonly, the lung but also other organs, particularly the gastrointestinal (GI) tract. In CMV pneumonitis, patients may develop a constellation of signs and symptoms, including cough, fever, chills, respiratory distress, crackles, and diffuse interstitial infiltrates. Isolation of CMV by BAL or TBBx in the setting of a typical clinical picture is strongly suggestive of CMV pneumonia, although it is worth noting that asymptomatic shedding of CMV occurs. Treatment for CMV includes IV ganciclovir for 2–6 weeks and, in some centers, adjunctive therapy with CMV hyperimmune globulin. Oral valganciclovir may be administered for 2–3 months after completion of the IV ganciclovir course.

In the preganciclovir era the incidence of CMV disease in mismatched recipients reached 75% or higher in the first 6 months after transplant,[91] and CMV pneumonitis was a risk factor for the subsequent development of BO.[92] With the availability of ganciclovir for prophylaxis and treatment, the frequency of CMV pneumonitis has decreased and the significance of CMV disease in the lung transplant population has been reduced.[93,94]

*P. jiroveci* was a frequent problem in lung transplant recipients in the early phase after transplant before routine administration of TMP/SMX began in the late 1980s. As with other solid organ recipients, TMP/SMX prophylaxis has resulted in a marked decline in disease attributable to this fungus in lung transplant recipients. Patients ill with *Pneumocystis* present with acute onset of fever, respiratory distress, hypoxemia, and interstitial infiltrates. Silver or fluorescent staining of BAL specimens will demonstrate organisms with a typical morphology and is diagnostic of disease. IV TMP/SMX is the treatment of choice.

Viral infections can be particularly problematic during this period. Adenovirus [95] and paramyxoviruses including parainfluenza and respiratory syncytial virus (RSV) can cause significant lung injury or mortality.[96,97] Many centers treat these viruses aggressively with cidofovir and ribavirin, respectively.[97–99] Moreover, fungal infections also pose significant risk.[100]

## Medication Side Effects

Triple drug immunosuppressive therapy has offered a therapeutic approach that allows long-term success in solid organ transplantation. However, the side effects of these medications can be troublesome enough in some patients to ultimately affect functional outcome and quality of life. The degree of immunosuppression is a delicate balance between too much, with risks for the development of opportunistic infections, and too little, with its attendant risks of allograft rejection.

CSA and tacrolimus are both associated with hypertension and nephropathy, although these may be less severe with tacrolimus.[101] The risks of renal dysfunction with CSA or tacrolimus are compounded by the frequent use of other nephrotoxic drugs, such as aminoglycosides, ganciclovir, or amphotericin. One year after lung transplantation, 41% of patients have hypertension and 9% have renal dysfunction; this rises to 68% and 30%, respectively, 5 years after transplant.[6] Hirsutism and gingival hyperplasia appear to occur more frequently in CSA-based immunosuppression.[101] CNIs also cause neurologic toxicity, and seizures, headache, and sleep disturbance are common problems in the first months after transplant.[102] In patients with CF, inconsistent and erratic metabolism and absorption of CNI can occur and underscores the need for close monitoring of blood levels. Routine blood counts are necessary for patients receiving azathioprine or MMF because of their effects on white blood cell counts. Systemic and oral corticosteroids have the potential to cause a host of well-known side effects. For example, daily use of oral corticosteroids may lead to glucose intolerance and diabetes, particularly in patients with CF, with prevalence rates of more than 35% in long-term survivors of lung transplantation.[6] Patients receiving tacrolimus have a higher risk of developing diabetes than those receiving CSA.[42]

## Late Phase (>6 Months)

Ongoing complications in the late phase include those related to infection, drug toxicity, acute cellular and humoral rejection, and airway anastomotic narrowing. Posttransplant lymphoproliferative disease (PTLD) and CLAD, two very serious complications, also become apparent.

### Posttransplant Lymphoproliferative Disease

The incidence of malignancy after lung transplantation in children is 5% 1 year after transplant and rises to 10% at 5 years; PTLD is by far the most common malignancy.[6] PTLD is generally an EBV-driven lymphoma in an immunosuppressed patient[104,105] and appears to occur more commonly in lung transplant recipients (as compared with other solid organ transplant recipients), in patients with CF, and in children as compared with adults.[106] These findings are probably explained by the intensity of immunosuppression in lung transplant recipients and the fact that many pediatric patients are EBV seronegative at the time of transplantation.[105]

Manifestations of PTLD are protean, often vague, and often confusing. A high index of suspicion is required because early diagnosis and treatment improves the likelihood of resolution of disease. In the first posttransplant year, the most common site of PTLD involvement in lung transplant patients is the allograft.[107] Although PTLD can be asymptomatic, symptoms of cough, fever, and dyspnea are typical. The typical radiographic finding is single or multiple round or ovoid pulmonary nodules.[108] Involvement of lymph nodes draining the chest is not uncommon. After the first year, the incidence of extrapulmonary PTLD increases. Other sites of involvement in PTLD include the GI tract, the skin, and other lymphatic tissue including lymph nodes and the nasopharynx.[109,110] Elevated quantitative measurement of EBV by polymerase chain reaction (PCR) has been shown to be a sensitive and somewhat specific marker for PTLD; most centers monitor this test on a regular basis.[111] In addition, positron emission tomography can be a sensitive and specific test that is often performed when EBV PCR or other clinical indicators raise suspicion for PTLD.[112] After a suspicious lesion is identified, histologic diagnosis is important for prognostic purposes. CD20-positive tumors may be more amenable to antibody therapy. A monomorphous histologic pattern has a worse prognosis.[113]

If PTLD is identified early, the mainstay of treatment is reduction in immunosuppression alone. Although some adult centers reduce immunosuppression based only on the presence of elevated EBV PCR,[114] a study suggests caution should be taken with this approach in children.[115] Although reduced immunosuppression can be successful in some patients, in many cases additional therapy is needed. Most centers now use therapy modeled after a Children's Oncology Group protocol that includes rituximab, an anti-CD20 monoclonal antibody shown to be effective in non-Hodgkin's lymphoma, low-dose cyclophosphamide, and prednisone. This approach has been promising in pediatric solid organ transplant recipients with PTLD.[116]

## Chronic Lung Allograft Dysfunction

Chronic allograft dysfunction, most commonly BO, is the greatest obstacle to long-term success of adult and pediatric lung transplantation. By 6 years after lung transplantation in children, only 40% of survivors are free of BO, a worrisome figure because BO is the leading cause of death after the first year posttransplant.[6] Histologic analyses of lesions of BO show progressive and irreversible stenosis of the bronchiolar lumen, eventually resulting in fibrosis and near occlusion of the airway lumen with collagen.[94]

BO is generally equated with chronic lung allograft rejection, although the immunologic basis of BO remains poorly understood. As diagnosis of BO from tissue obtained by TBBx may be difficult because of the patchy and uneven distribution of the disease, a clinical correlate, bronchiolitis obliterans syndrome (BOS) was described. Among the criteria used to establish a diagnosis of BOS is an otherwise unexplained fall in $FEV_1$ of greater than 20% from the best previous baseline studies.[117] BOS was previously considered the clinical manifestation of BO, but it is now known that BOS is not specific for BO[118] and that chronic rejection can occur without evident changes in tissue pathology. Due to the variety of disease presentations of chronic rejection, the term “chronic lung allograft dysfunction” is now used to describe persistent lung function decline in transplant patients. Although BOS is associated with obstructive PFTs (i.e., $FEV_1$ decline), it is now recognized that some patients with chronic rejection develop progressively restrictive PFT changes (i.e., decline in total lung capacity) and have a worse prognosis—a clinical entity that has come to be known as "restrictive allograft syndrome" (RAS).[119]

A variety of risk factors for the development of CLAD have been proposed, most based on single-center studies. A comprehensive review of these reports identified acute rejection as the only consistent risk factor with acute rejection episodes occurring more than 3 months posttransplant carrying the greatest significance.[92] The presence of lymphocytic bronchitis or bronchiolitis ("B-grade" rejection) was also significant, particularly when observed beyond 6 months after transplant. The role of CMV (based on donor or recipient serology, CMV "infection," or CMV pneumonitis) as a risk factor was deemed inconclusive, likely due in part to the use of ganciclovir prophylaxis and treatment.[93,94] More recently the presence of anti-HLA antibodies,[120,121] as well as autoantibodies to structural proteins such as K-alpha 1 tubulin and collagen V, have been identified as risk factors.[122,123] In addition, gastroesophageal reflux has been identified as a risk factor, with some evidence that fundoplication can reduce the incidence of BO.[124,125] An association between community-acquired respiratory viruses (paramyxoviruses, influenza, and adenovirus) has been suggested.[126,127] Finally, nonadherence with the immunosuppressive regimen can also result in BO.[128] In contrast, there are center-specific data showing that younger children[77] and patients receiving living related lobar transplantation[129,130] are at *lower* risk for developing BOS. Currently, the most prevalent hypothesis is that CLAD represents a final common pathway resulting from the immune response to an airway injury induced by one or more of these above risk factors leading to chronic airway epithelial damage and eventually severe airway obstruction.[131] The consistent identification of acute rejection as a risk factor for BO reinforces the importance of routine surveillance bronchoscopy to detect and treat subclinical acute rejection. As noted previously, this issue is further complicated by reports that episodes of minimal acute rejection (grade A1) were a risk factor for early-onset BO.[72,73] Although the consensus approach to grade A1 rejection in *asymptomatic* patients has been observation, to reduce the risk for early development of BO, the possibility of altering or enhancing immunosuppression in this setting has been entertained.

Treatment of CLAD is problematic at best, with augmented immunosuppression the general recommendation. Some transplant centers have endorsed changing the immunosuppressive regimen from CSA to tacrolimus, with anecdotal reports of success (though most pediatric centers no longer use CSA as their primary CNI).[132] The use of azithromycin 3 times weekly as an antiinflammatory agent appears to benefit a subset of patients, typically those with airway neutrophilia, leading to the suggestion that BO has at least one phenotype based on azithromycin responsiveness.[133] Treatment is complicated by the phenotypic variability of what is known as chronic rejection. Antilymphocyte agents such as antithymocyte globulin or OKT3 may be effective adjunctive therapy in some patients.[134] Recently, treatment with photopheresis has shown some benefit,[135,136] although not all CLAD patients will show equal response to therapy.[137] As with PTLD, early identification and treatment is most likely to be effective. However, in many patients, progression of disease is inexorable and often complicated by infection with bacterial or viral pathogens. The goal of therapy is to ameliorate the chronic rejection, reduce the risk of infectious complications, and prevent further deterioration in lung function. Many centers consider retransplantation as an option in patients with progressive decline in lung function.

# Outcomes

## Survival

Survival after pediatric lung transplantation for patients transplanted between January 1990 and June 2013 is depicted in Fig. 67.3.[6] There is no statistical difference in survival rates among the different age groups shown, with a 50% survival rate of 5.3 years collectively. When analyzed by era, median survival has improved significantly, from 3.3 years in the era between 1988 and 1999 to 5.8 years in the recent era (2000–2007). This improvement mostly reflects better early outcomes, not late outcomes[6]—with CLAD providing the primary barrier to longer-term survival. However, there has not been an improvement in survival between the eras 2000–2007 and 2008–2013. In addition, these results do not compare favorably with pediatric patients undergoing heart transplantation, in whom the median survival is more than 14 years.[138] In the most recent ISHLT report,[6] analyses of risk factors for 1-year mortality also demonstrated increased mortality in patients requiring ventilation at the time of transplant (hazard ratio [HR], 2.8) and in retransplant patients (HR, 2.8). Risk factors for 5-year mortality include retransplant (HR, 1.6) again. The hazard of 5-year mortality has a U-shaped distribution, with HR approximately 1 at age 1 that decreases to 0.85 at age 7, then rises to 1.4 by age 17,[6] with this significant rise typically attributed to issues with patient adherence.[139]

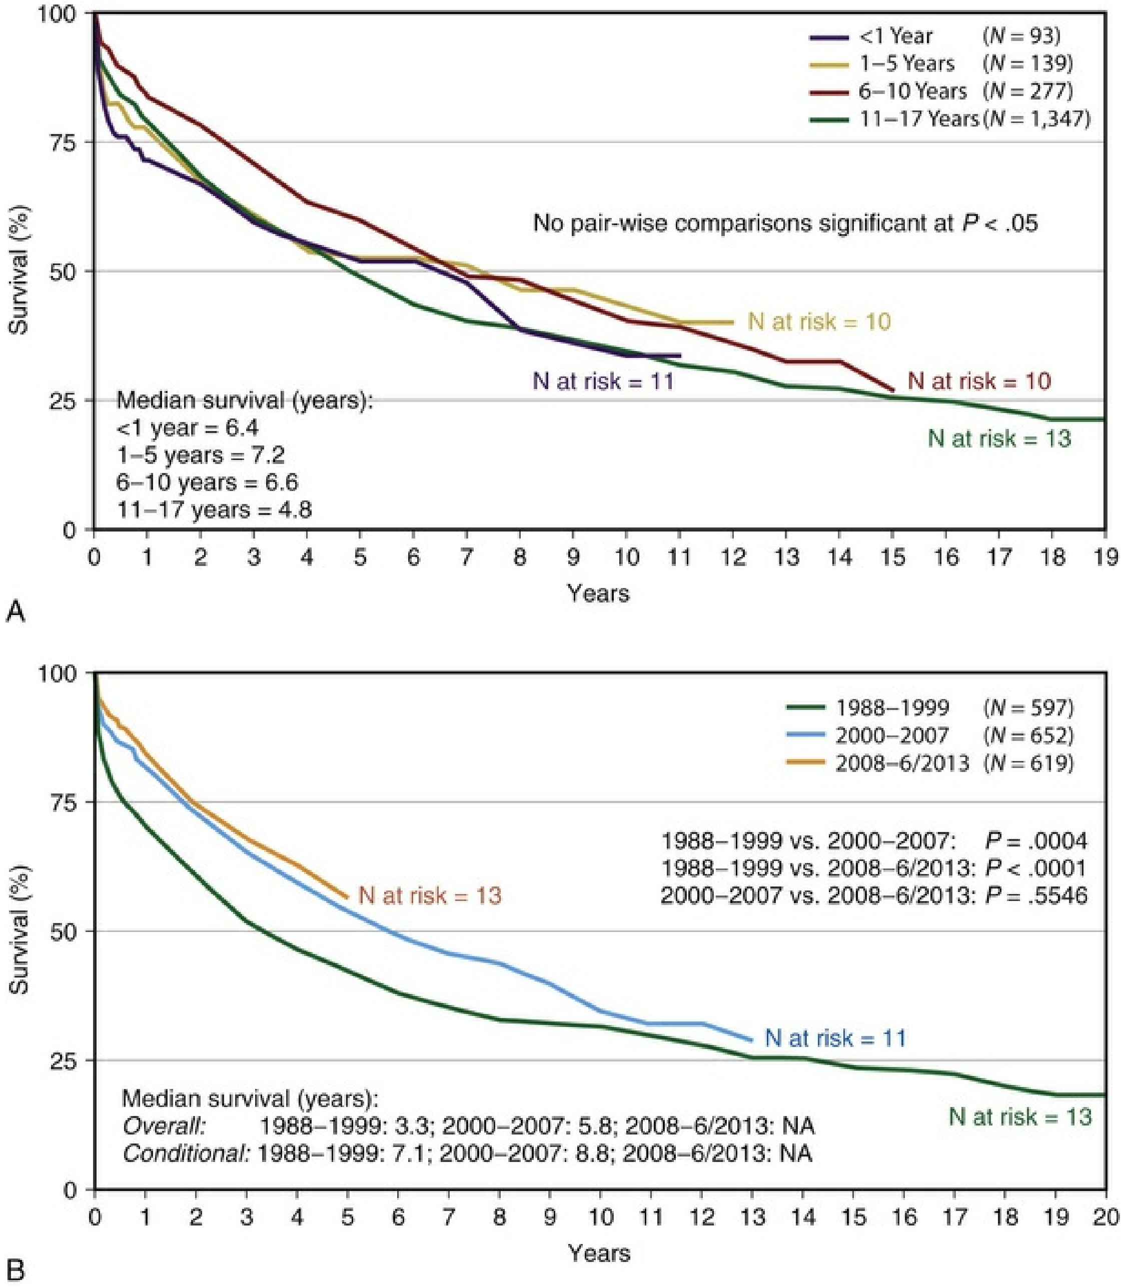

**FIG. 67.3** (A) Survival after pediatric lung transplant, stratified by age (transplants January 1990–June 2013). (B) Survival after pediatric lung transplant, stratified by transplant era ("conditional" survival is contingent on patient surviving 1 year). (Reprinted from Goldfarb SB, Benden C, Edwards LB, et al. The Registry of the International Society for Heart and Lung Transplantation: Eighteenth Official Pediatric Lung and Heart-Lung Transplantation Report—2015; Focus Theme: Early Graft Failure. *J Heart Lung Transplant*. 2015;34(10):1255-1263.)

## Transplant Benefit, Functional Outcome, and

## Quality of Life

Although transplant is generally viewed as a means for prolonging life, a provocative paper by Liou and colleagues[140] challenged the concept that pediatric lung transplant in the United States has achieved that goal. This was in contrast to an earlier report indicating a survival benefit from a group in the United Kingdom.[141] The validity of the recent study was challenged based on the fact that the dataset was biased against transplantation because covariates were obtained well before the time of transplant and estimates of benefit were based on factors that could change between listing and transplant.[142] Nonetheless, an important finding was that 57% of the children listed for lung transplant in the United States had a predicted survival of 5 years or greater,[140] suggesting that the waiting time–based system in the United States may have led to patients being listed well before transplant would have provided a survival benefit. Although the new LAS may have mitigated this concern, better predictors of waiting list mortality for pediatric lung transplant candidates are needed to ensure transplant has a reasonable chance of conferring survival benefit.

The Liou study also reinforced the need for inclusion of objective evaluation of quality of life in assessments of transplant benefit. Perhaps not surprisingly, the quality of life and survival in adult lung transplant recipients was better than candidates who remained on the waiting list.[143–145] Nonetheless, extrapolation to children and adolescents should be approached cautiously. Although 80% of lung transplant survivors report no activity limitations at 1, 3, and 5 years posttransplant, there are few well-controlled studies regarding quality of life in children undergoing lung transplantation. Nixon found a 24% improvement in quality of well-being in a small number of recipients after transplantation.[146] A group of 47 thoracic organ recipients (of whom 6 were lung transplant recipients) scored lower on a health status questionnaire administered to the parent or caregiver compared with a normal population but was similar to children with asthma, juvenile rheumatoid arthritis, or intractable epilepsy.[147] It is worth emphasizing that assessments of quality of life are difficult and affected by the child's baseline capabilities prior to transplant and their expectations after transplant.[146] In addition, measures of childhood development must also be included. Systematic assessment of quality of life and developmental impact of transplant on pediatric recipients remains an underexplored area of pediatric lung transplantation.

## Growth

Somatic growth after lung transplant is an ongoing problem for most transplant recipients, partly because of substandard pretransplant nutritional status and the continued use of systemic corticosteroids after the transplant procedure. Improving nutritional status and maximizing growth is an important goal after transplant.

Since the early reports of successful lung transplantation in young children, concerns have been raised concerning the potential for lung allograft growth.[3] Animal data indicate that allogeneic lung transplantation is associated with an increase in lung volumes and airway size with age.[148] Although spirometry and lung volume measurements following lung transplant have been reported to be normal in infants[149] and older children,[75] these measurements may reflect increased volume of each alveolar unit rather than alveolar tissue growth or increased surface area for gas exchange. Serial CT scan data to support growth of intrathoracic airways over time comes from Ro and colleagues.[150] However, the diffusing capacity of the lungs for carbon monoxide (DLCO) did not show an appreciable increase in a single-center study of pediatric recipients of cadaveric and living donor transplants.[151] Although DLCO provides a better estimate of gas exchange surface area, it is not easily measurable in infants. Thus further study is required to determine whether surface area for gas exchange increases as lung volumes increase in pediatric lung transplant recipients.

## Causes of Death

Causes of death after pediatric lung transplantation are depicted in Fig. 67.4. Graft failure and infection are important causes of death in the first year after transplant. In the first 30 days after transplant, surgical complications are an important cause of death. After the first 30 days and before a year posttransplant, infections from any cause account for approximately 30% of deaths. By 1–3 years after transplant, BO becomes the leading cause of death, accounting for approximately 35% of the mortality. Infection remains a significant cause of death throughout the follow-up period. Although these represent the most recent data available from the ISHLT, there has been little shift in the distribution of causes of death compared with previous registry data.[6]

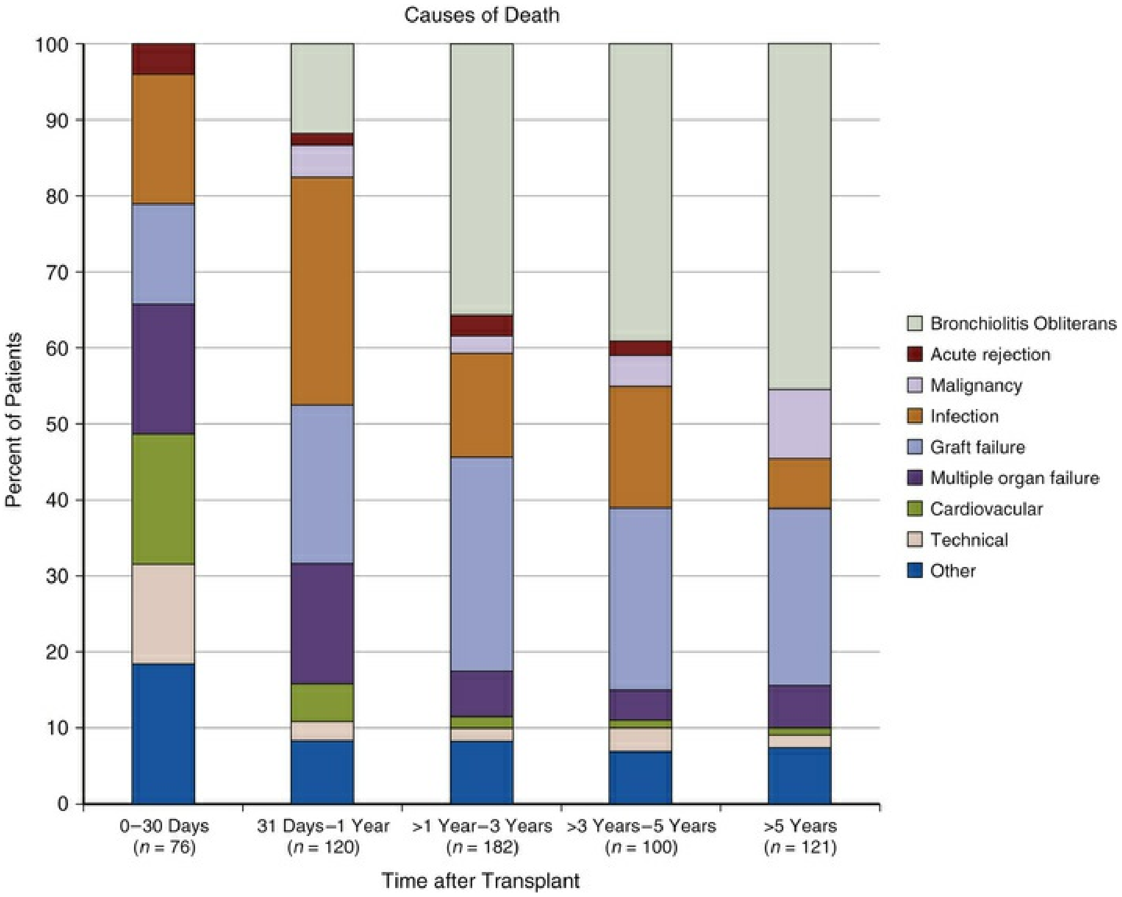

**FIG. 67.4** Causes of death after pediatric lung transplant, January 2000–June 2014. (Data modified from Goldfarb SB, Benden C, Edwards LB, et al. The Registry of the International Society for Heart and Lung Transplantation: Eighteenth Official Pediatric Lung and Heart-Lung Transplantation Report—2015; Focus Theme: Early Graft Failure. *J Heart Lung Transplant*. 2015;34(10):1255-1263.)

## Future Directions

In summary, although presenting unique challenges related to pediatrics, lung transplant is a life-saving option for infants, children, and adolescents with end-stage pulmonary parenchymal and vascular disease. In spite of improvements in survival during the past two decades,[6] long-term survival rates remain poor compared with heart and other solid organ transplants.

Moreover, the shortage of organ donors and of lung transplant centers, coupled with increased numbers of adults receiving lung transplants, will likely limit access to this procedure to fewer than 100 children annually. Efforts to increase awareness about organ donation will likely remain the cornerstone of efforts to increase the number of transplants performed in the United States and worldwide. With improved survival will come increased focus on growth and development, as well as increased need to minimize the deleterious effects of immunosuppression on these critical processes. Improving poor outcomes in the adolescent population will remain an important priority.

Removing CLAD as the key obstacle limiting long-term survival will continue to be a priority in lung transplant research. Uniform treatment strategies and multicenter collaborations will be needed to identify strategies for earlier diagnosis and determine treatment efficacy as few centers perform enough transplants each year to power such studies adequately. A key research opportunity would include identifying environmental factors, such as the lung microbiome, that might directly contribute to—or be used as a biomarker that predicts—allograft failure.[152]

Despite these obstacles, more than 2000 children in the past three decades have been given a chance for long-term survival because of the success of lung and heart-lung transplantation. Although recent improvements in outcome for children with CF and pulmonary hypertension will hopefully reduce the number of children needing lung transplants, those who do should continue to benefit.

# Respiratory Complications of Down Syndrome

*Andrew P. Prayle BMedSci, BMBS, PhD, Harish G. Vyas DM, FRCP, FRCPCH*

## Introduction

Down syndrome (DS; trisomy 21) is the commonest chromosomal abnormality compatible with live birth. There is an incidence of approximately 1/800 live births, translating to approximately 700 live born children in England and Wales per year.[1] In the United States the prevalence is 14/10,000 live births, with approximately 6000 births annually. However, the overall population prevalence is somewhat lower, at approximately 8.3 per 10,000.[2]

The phenotype is characterized by a characteristic facies and stature, variable developmental delay and learning difficulties, and an increased incidence (over the general population) of multiple specific diseases, including respiratory disease, congenital heart defects, gastrointestinal malformations, autoimmunity, endocrine disease (in particular hypothyroidism), hematologic malignancy, and orthopedic, vision, and hearing disorders. Respiratory illness is highly prevalent within the general pediatric population but even more so in children with DS. Within this chapter we discuss the pertinent complications of DS for the respiratory pediatrician.

The lifespan of individuals with DS is gradually improving (Fig. 68.1). In 1983 median age at death was 25 years, significant progress was made in the 1990s, and by 1997 it was 49 years.[3] More recent estimates suggest that a child born in 2000 in Australia with DS had a life expectancy of 60 years.[4] Part of this improved survival is likely related to improved access to care, accompanied by a shift in public, professional, and parental attitudes to care of children with DS in the past few decades.[5]

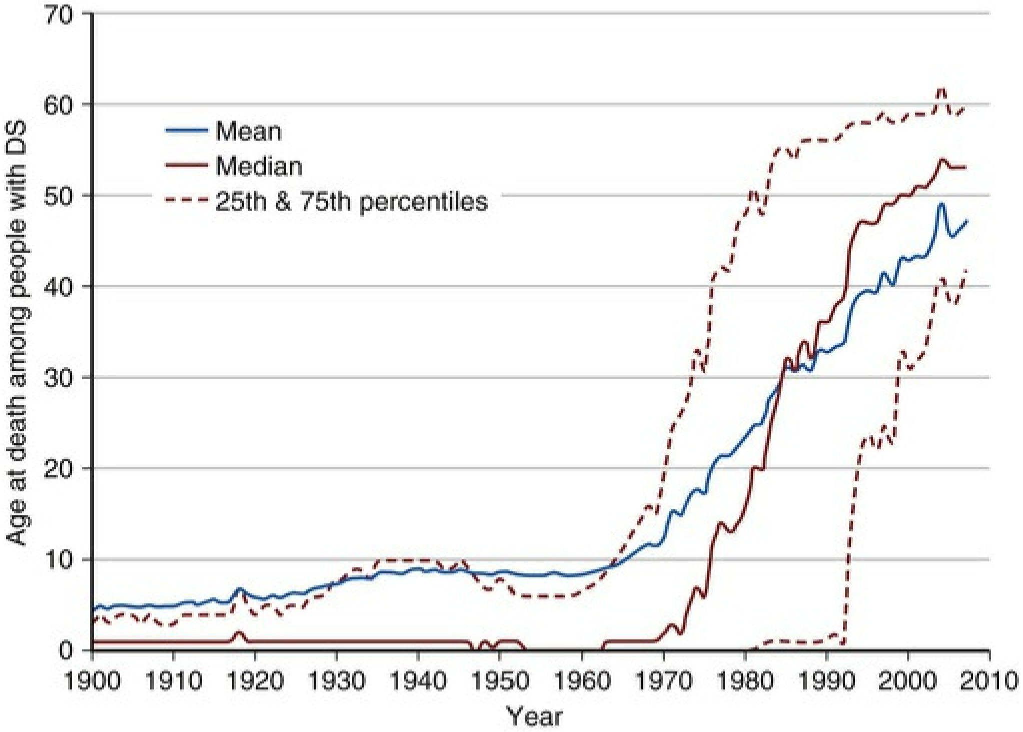

**FIG. 68.1** Improvement in survival in people with Down syndrome (DS) in the United States. Presson and colleagues combined data from live births of infants with DS from 1907 to 2007, published birth prevalence estimates of DS, and mortality data from death certificates to inform a Monte Carlo model of survival over the past century. The improvement in survival commencing in the 1970s is striking. (Presson AP, Partyka G, Jensen KM. Current estimate of Down syndrome population prevalence in the United States. *J Pediatr.* 2013;163(4):1163-1168.)

Within this context of improving life expectancy, efforts should be made to understand and improve the pulmonary health of children with DS. Although some children with DS will unfortunately have devastating illness in childhood (often a combination of cardiac and respiratory disease), much of the respiratory disease either improves with maturity or is amenable to treatment. Therefore respiratory pediatricians need to be vigilant for symptoms of respiratory disease, judicious in investigation, and mindful that the consultation involves careful explanation in a way that the patient and carers can understand.

Children with DS are more likely to develop respiratory disease than their peers without DS, and mortality from respiratory disease in childhood in DS is higher than the general population. Respiratory disease is the second leading cause of death in children with DS, after cardiac disease.[3] The rate of death of children with DS can be compared with the general population with the standard mortality odds ratio (SMOR). The SMOR in children under 10 with DS (compared with children without DS) is 14 for cardiac disease, and 3.0 for a combination of respiratory pathologies including aspiration, pneumonia, and influenza.

Not unexpectedly, children with DS are more likely to be admitted to hospital than the general population. More than half of children with DS have a respiratory related hospitalization, irrespective of presence of congenital heart disease (CHD).[6] Given the increased mortality, an increase in intensive care admissions is also well recognized. Our own work based on the United Kingdom national Paediatric Intensive Care Registry (PICANet) estimates that 25% of children with DS are admitted to pediatric intensive care units (ICUs) by 1 year of age, and approximately half of these admissions are respiratory, although cardiac and respiratory disease often coexist.

The common clinical manifestations of respiratory disease in DS are summarized in Table 68.1. Respiratory symptoms are exceedingly common in infants with DS; however, because most studies of respiratory symptoms to date have been retrospective in nature, the true scale of the problem has not yet been fully characterized. A prospective web-based parent-reported observational study is ongoing in the Netherlands, which seeks to characterize the relationship between respiratory symptoms, health care use, and comorbidities.[7] This study will provide useful information for clinicians.

## Table 68.1

### Respiratory Disease Patterns in Down Syndrome

| Symptom | Etiology |
|---|---|
| Upper airway obstruction | Stridor<br>Obstructive sleep apnea/sleep-disordered breathing.<br>Postextubation stridor |
| Recurrent respiratory infections | Viral upper respiratory tract infections<br>Lower respiratory tract infections (viral/bacterial)<br>Lobar pneumonia<br>Aspiration pneumonia |
| Wheeze | Pulmonary edema/pulmonary hypertension<br>Asthma |

Given the multiple manifestations of respiratory disease in DS, in this chapter we will elaborate on respiratory disease in DS using an anatomically structured approach and categorize disease into that of the upper and lower airways. However, it should be noted that frequently patients with DS may have multiple disease processes of both the upper and lower airways, and there is considerable overlap between symptoms and disease. Therefore it is appropriate to take a holistic "whole respiratory tract" approach to diagnosis and management. In addition, it is important to note that disease of other organ systems (chiefly cardiac, gastrointestinal, immunologic, and neurologic) and obesity in DS can increase the severity of respiratory disease (Table 68.2).

## Table 68.2

### Disease Complicating Respiratory Illness in Down Syndrome

| Organ System | Manifestation |
|---|---|
| Cardiovascular | Airway compression secondary to congenital heart disease<br>Pulmonary hypertension<br>Pulmonary edema (including high altitude related)<br>Complications of cardiac surgery |
| Gastrointestinal | Swallowing dysfunction<br>Gastroesophageal reflux disease<br>Respiratory complications following repair of esophageal atresia |
| Immune system | Recurrent respiratory tract infections<br>Increased severity of respiratory tract infections |
| Neurologic | Hypotonia |
| Other | Obesity |

# Upper Airway Disease and the Trachea

## Anatomy of the Upper Airway in Down Syndrome

In DS the upper airway is narrowed both above and below the vocal folds. Narrowing above the trachea is due to relative macroglossia, midface hypoplasia, narrowed nasopharynx, choanal stenosis, enlarged tonsils and adenoids, lingual tonsils, and a short palate (Table 68.3). Below the vocal folds, the trachea itself is considerably narrowed, with an internal diameter approximately 2 mm narrower than the general population in the pediatric age range.[8] This narrowing likely contributes to the increased incidence of postintubation stridor historically observed in children with DS.[9]

**Table 68.3**

**Upper Airway Anomalies in Down Syndrome**

| | |
|---|---|
| Smaller midface and lower face skeleton | Shorter hard palate length<br>Smaller mandible volume<br>Shorter mental spine–clivus distance |
| Soft tissues | Smaller tonsils<br>Smaller adenoids<br>Smaller tongue |
| Relative impact of skeletal size upon soft tissue to airway size ratio | Higher tongue to skeletal size ratio<br>Reduced upper airway size due to soft tissue crowding |

Modified from Uong EC, McDonough JM, Tayag-Kier CE, et al. Magnetic resonance imaging of the upper airway in children with Down syndrome. *Am J Respir Crit Care Med.* 2001;163(3 Pt 1):731-736 and Guimaraes CV, Donnelly LF, Shott SR, et al. Relative rather than absolute macroglossia in patients with Down syndrome: implications for treatment of obstructive sleep apnea. *Pediatr Radiol.* 2008;38(10):1062-1067.

## Tracheomalacia and Laryngomalacia

Airway abnormalities contribute significantly to symptoms in DS (Fig. 68.2), but this information is largely based on case series naturally representing groups of patients who have particularly serious symptoms. Without background population data, case series can produce incorrectly elevated prevalence of diseases. In addition, case series are usually limited to small numbers of children, and so estimates of prevalence of rarer conditions vary widely between series.

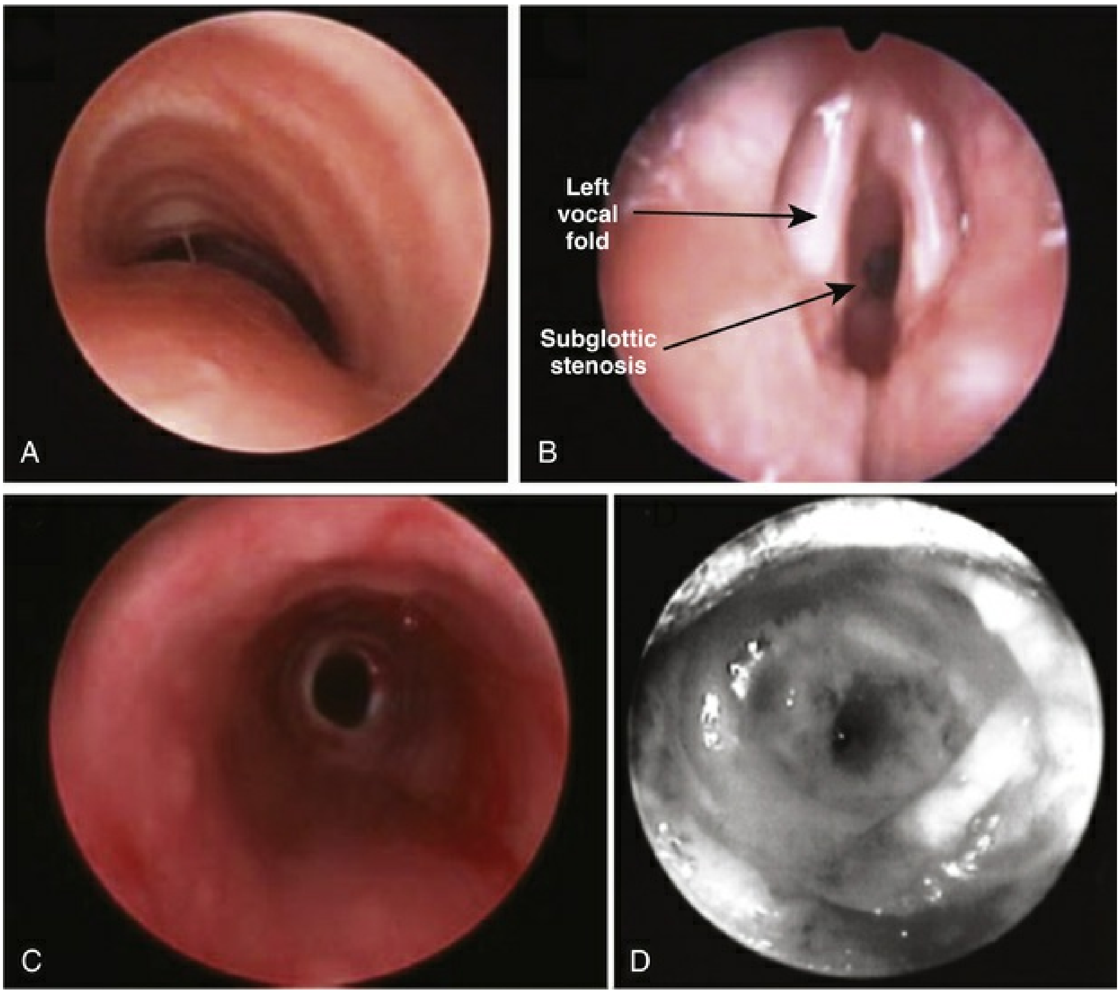

**FIG. 68.2** Airway endoscopy abnormalities in Down syndrome. (A) Lower trachea appearance under general anesthesia, showing severe airway malacia. (B) Appearance of subglottic stenosis immediately below the vocal fold. (C) Midtracheal stenosis due to previous intubation. (D) "Pinpoint" severe tracheal stenosis. ([A–C] From Hamilton J, Yaneza MM, Clement WA, et al. The prevalence of airway problems in children with Down's syndrome. *Int J Pediatr Otorhinolaryngol.* 2016;81:1-4. [D] From Shapiro NL, Huang RY, Sangwan S, Willner A, Laks H. Tracheal stenosis and congenital heart disease in patients with Down syndrome: diagnostic approach and surgical options. *Int J Pediatr Otorhinolaryngol.* 2000;54(2-3):137-142.)

In a series of 239 children with DS of whom 39 (16%) underwent endoscopy for airway symptoms,[10] the most common finding was tracheobronchomalacia (Table 68.4). In approximately half of patient with tracheobronchomalacia, this affected both the trachea and bronchi.[11] Laryngomalacia is common in children with DS and usually presents in the first months of life. Supraglottoplasty is uncommonly performed for laryngomalacia and is reserved for complications such as feeding failure, respiratory distress, and sleep-related symptoms or apnea, often in the context of subglottic stenosis and cardiac surgery. However, surgical failure can occur in up to a third of patients, and in some patients tracheostomy may be required.[12] When undertaking surgery for laryngomalacia, the possibility of further surgical intervention should be considered and discussed with families.

## Table 68.4

## Endoscopic Findings in Down Syndrome

| Series | Hamilton[10] | Bertrand[11] | Estimated Down Syndrome Population Prevalence (%) (From Hamilton[10]) |
|---|---|---|---|
| Number studies | 39 | 24 | |
| Subglottic stenosis | 14 | 1 | 5.9 |
| Laryngeal cleft | 2 | 0 | 0.8 |
| Laryngomalacia | 2 | 12 | 0.8 |
| Tracheomalacia | 14 | 8 | 5.9 |
| Bronchomalacia | 10 | 5 | 4.2 |
| Tracheal stenosis | 2 | 1 | 0.8 |

Data from Hamilton J, Yaneza MM, Clement WA, et al. The prevalence of airway problems in children with Down's syndrome. *Int J Pediatr Otorhinolaryngol.* 2016;81:1-4 and Bertrand P, Navarro H, Caussade S, et al. Airway anomalies in children with Down syndrome: endoscopic findings. *Pediatr Pulmonol.* 2003;36(2):137-141.

Tracheal bronchus (wherein the right upper lobe bronchus originates directly from the trachea rather than the right main bronchus) can predispose to lower respiratory tract infection (LRTI).[13] In a report on bronchoscopy findings in children, 2 of 18 patients with a tracheal bronchus had DS, which would suggest that the incidence in children with DS is elevated. Where recurrent right upper lobe pneumonia occurs in DS, a tracheal bronchus should be considered. When associated with other airway anomalies such as stenosis, tracheal bronchus can cause significant management challenges. This is especially so in the critical care setting where distortion of the usual anatomy can lead to significant hypoxic events in association with changes in the position of the head and neck.[14]

## Subglottic and Tracheal Stenosis

Narrowing can occur at any point in the airways in DS. However, subglottic stenosis deserves particular discussion. The overall prevalence of congenital subglottic stenosis in DS is approximately 1.3%.[10,11] Most subglottic stenosis occurs in the context of previous intubation, although this is not always the case. Laryngotracheoplasty has a good success rate and is presumably undertaken for patients on the more severe end of the spectrum, of whom most have preen previously intubated.[15]

Despite the prevalence of subglottic stenosis, the diagnosis should not be presumed in all cases of postoperative stridor. In children with DS ventilated for cardiac surgery, up to 25% develop postoperative stridor in the absence of subglottic stenosis.[16] These children tended to be less than the 10th centile for weight and younger (with a mean age of 8 months, compared with a mean age of 30 months in those without postoperative stridor).

Tracheal stenosis (narrowing below the subglottic space extending a varying length along the trachea) can be challenging to evaluate in DS. Tracheal stenosis in DS is associated with vascular rings and hypoplasia of the aortic arch. At induction of general anesthetic, it may be that the extent of the stenosis prevents the admission of even a narrow fiberoptic bronchoscope, especially if one or more complete tracheal rings are present. When this occurs, a nonionic tracheobronchogram or thin cut computerized tomography (CT) scan can be used to delineate the extent of the narrowing.[17]

## Clinical Presentation of Upper Respiratory Tract Disease in Down Syndrome

The clinical features of upper respiratory tract disease in DS include cough and parental report of noisy breathing and snoring. Sleep-disordered breathing in DS is discussed later. Parents and carers describe a wide range of breathing-associated sounds, with varying diagnostic utility. Snoring should be specifically asked for because a history of snoring is not always spontaneously volunteered. In more severe disease, upper airway abnormalities can lead to increased work of breathing and failure to thrive. Symptoms often worsen with self-limiting (presumed viral) upper respiratory tract infections and in LRTIs where the increased respiratory rate unmasks previously asymptomatic upper airway disease. A history of stridor, croup, chronic aspiration, and difficulty in extubation should motivate careful assessment and investigation.

## Sleep-Related Breathing Disorders

Sleep-disordered breathing, including obstructive sleep apnea (OSA), is common in DS. There are multiple structural and functional factors contributing to disordered and disturbed sleep in DS, including midfacial hypoplasia, relatively large tongue, small upper airway with superficial tonsils, increased secretions, obesity, and hypotonia (Fig. 68.3).[18] It is worth noting that the tongue in DS is actually smaller than in age- and sex-matched controls on magnetic resonance imaging (MRI) scans. The apparent macroglossia is actually due to small craniofacial parameters, leading to relative macroglossia for the size of the oral cavity.[19] Similarly, adenoid and tonsil volume is actually smaller in children with DS without symptoms of OSA, but there is soft tissue crowding within a smaller midface.[20]

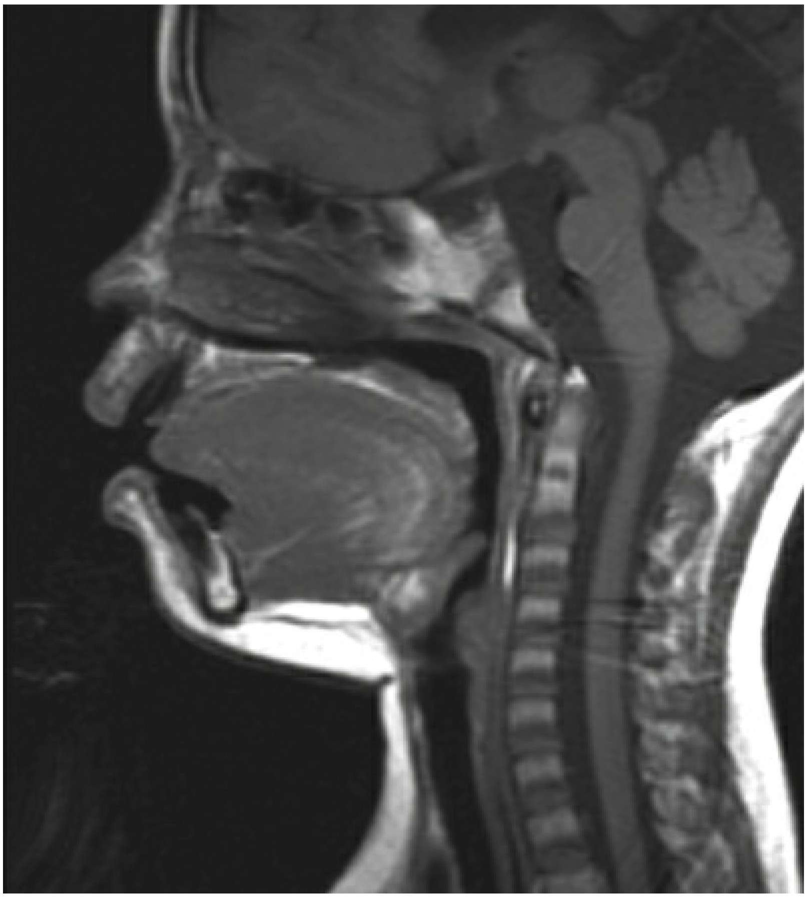

**FIG. 68.3** Sagittal magnetic resonance imaging of the head in Down syndrome. Note the apparent macroglossia caused by the small midface. The tongue is in fact normal in size, and the midface is small. (Courtesy Prof. Lane F. Donnelly MD, Texas Children's Hospital, Baylor College of Medicine Texas Children's Hospital.)

Disturbed sleep behavior is frequently reported in DS. Snoring occurs in half of school-age patients and is accompanied by parental report of restlessness, frequent waking, bedwetting, delay in becoming alert after waking, and challenging sleep behavior. However, there is little correlation between polysomnography findings and parental report.[21]

Sleep-disordered breathing is associated with neurocognitive difficulties, including developmental delay, challenging behavior, tiredness, pulmonary hypertension, and faltering growth. Unfortunately, these are all also associated with DS, and therefore the impact of sleep-disordered breathing may be unrecognized.[22] Sleep disturbance can be assessed with a respiratory disturbance index; in children with DS, there is a significantly higher respiratory disturbance index than in controls (Fig. 68.4).[23] In addition to OSA, the sleep of children with DS demonstrates increased fragmentation, numerous awakenings and arousals, and periodic leg movements. These characteristics are to a certain extent independent of the respiratory system and occur in the presence or absence of OSA.

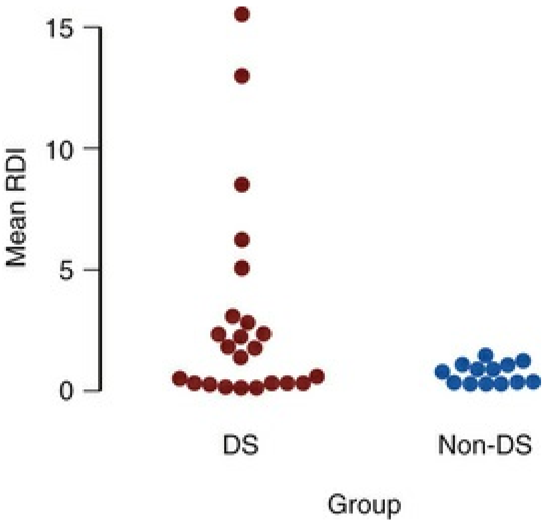

**FIG. 68.4** Respiratory disturbance index (RDI) in children with and without Down syndrome (DS). Comparison of RDI in children with and without DS. 23 children with DS were compared with 13 children with primary snoring. RDI, calculated as the number of obstructive or mixed apneas and hypopneas per hour of sleep. (Data from Levanon A, Tarasiuk A, Tal A. Sleep characteristics in children with Down syndrome. *J Pediatr.* 1999;134(6):755-760.)

The reported incidence of OSA in DS depends to a certain extent on the definition used and how aggressively patients are investigated. In unselected consecutive patients with DS prospectively evaluated with polysomnography, there is evidence of a high background rate of OSA, up to 80%. An increased apnea index and elevated arousal index is found in individuals with a high body mass index (BMI). This is not always associated with snoring.[24,25]

Adenotonsillectomy is usually the first-line treatment for OSA. However, the success rate of adenotonsillectomy is lower in DS than in the general population,[26] with only partial improvement in polysomnogram parameters such as the apnea-hypoxia index. Importantly, OSA is prevalent even after surgery.[27] Thus adenotonsillectomy may not be effective alone in treating OSA in DS.

In addition to surgical management of OSA being less effective in DS, tonsillectomy and adenoidectomy in DS are associated with an increased risk of postoperative complications,[28] and therefore careful postoperative monitoring is required for these patients. For patients with severe OSA it may be prudent that postoperative care takes place on the ICU. In all DS cases, we advocate an inpatient (rather than day case) procedure, to allow for monitoring on the night after the surgery. If adenotonsillectomy is unsuccessful, further therapeutic options can include home oxygen, continuous positive airway pressure (CPAP), further surgery, and tracheotomy in extreme cases.

Central hypoventilation can occur in the absence of upper airway anomalies, and higher rates of central apnea are seen compared with other syndromes of developmental delay such as fragile X.[29] Sleep apnea in DS is multifactorial in origin, and both airway abnormalities and a central mechanism may play a role.

# Lower Respiratory Tract

## Etiology

Like the upper respiratory tract, the lower respiratory tract has multiple recognized malformations in DS. Within this context, even minor superimposed infection becomes more severe than would be anticipated in a child without DS. Pulmonary infection is multifactorial in origin, with contributing factors including decreased pulmonary reserve due to morphologic differences, poor immunologic function, gastroesophageal reflux disease and aspiration, interactions with CHD, and thoracic cage malformations.

## Histopathology of the Lower Respiratory Tract in Down Syndrome

A number of morphologic differences in lung parenchyma contribute to reduced functional reserve in children with DS. The changes can be so severe that an experienced pediatric pathologist may recognize that a sample of lung tissue is from a patient with DS on external macroscopic evaluation alone.

In DS the lung has a diffuse uniform porous pattern, with increased size of alveoli and alveolar ducts.[30] This pattern occurs postnatally; the lung tissue has a more normal appearance in prenatal life. These features are due to a failure of alveolar multiplication within the acinus. The enlarged alveoli and acinar hypoplasia (deficient alveolar multiplication) can be formally characterized by radial count. In late gestation fetuses the radial count in DS is higher than controls. However, postnatally the radial count drops, and this reduction is present throughout life (Fig. 68.5). This causes a reduction in the number of alveoli and the overall lung surface area. This acinar hypoplasia has been suggested to be due in part to the complex interaction of the heart and lungs in patients with severe CHD who undergo mechanical ventilation, because radial counts are known to be low in CHD in the absence of DS. However, acinar hypoplasia appears to occur independently of CHD in children with DS.

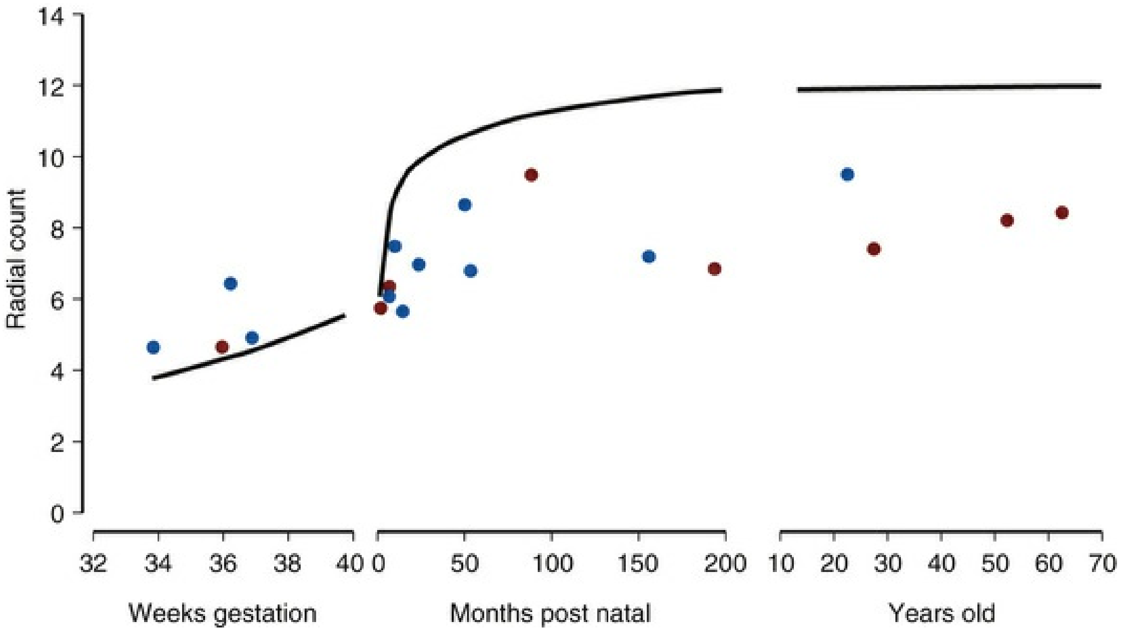

**FIG. 68.5** Comparison of radial count in Down syndrome (DS), cardiac disease, and normal

individuals. Points represent individuals with DS *(solid circles)* or cardiac disease *(hollow circles).* Solid line indicates expected values for people without DS. (Modified from Cooney TP, Wentworth PJ, Thurlbeck WM. Diminished radial count is found only postnatally in Down's syndrome. *Pediatr Pulmonol.* 1988;5(4):204-209.)

Subpleural cysts are well recognized in DS (Fig. 68.6), although the relevance of these to pulmonary disease has not yet been fully elucidated.[31,32] These cysts are approximately 1–2 mm in diameter and are lined by cuboidal epithelium. Up to 20% of patients with DS have them at postmortem, and they have been found in 36% of chest CT scans.[33] They are underrecognized and usually not apparent on chest radiographs. Their development has been suggested to occur secondary to reduced postnatal production of peripheral small airways and alveoli, which likely occurs in early postnatal life.

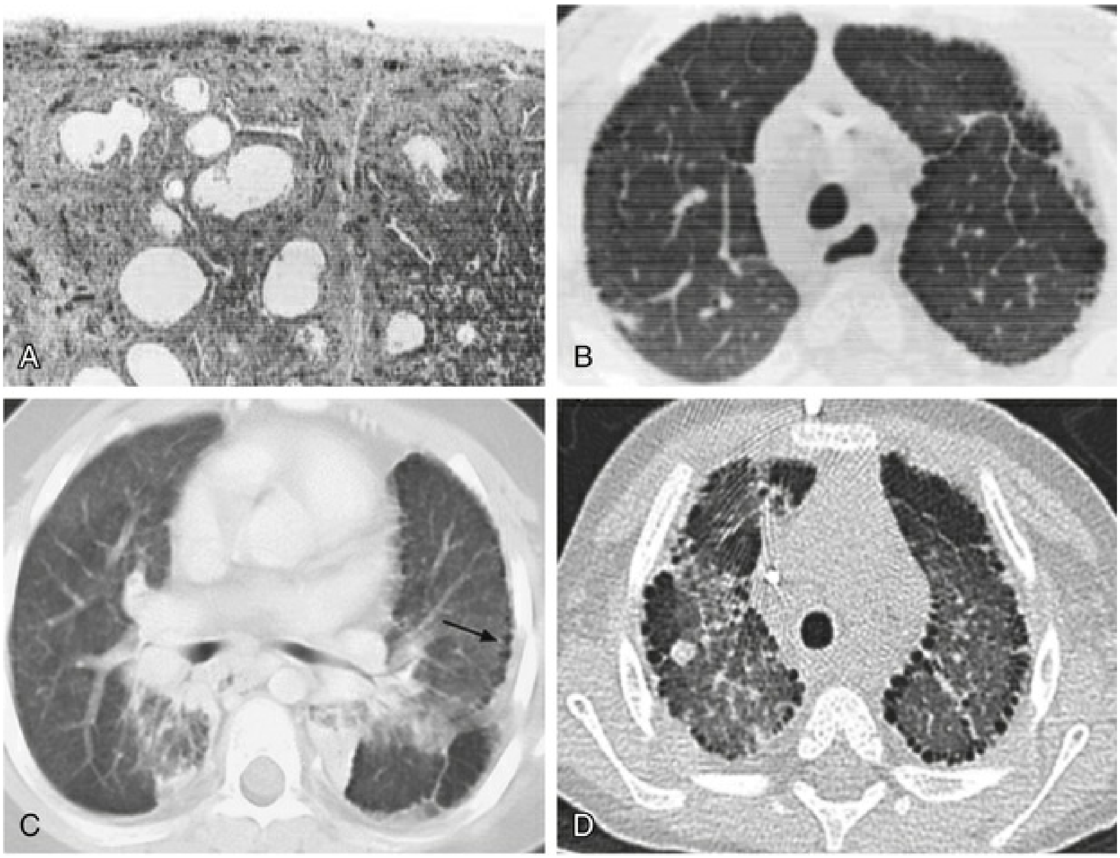

**FIG. 68.6** Subpleural cysts in Down syndrome. (A) Histopathology sample showing cysts lined by a

cuboidal epithelium along the pulmonary surface. (B) Computerized tomography appearance of subpleural cysts, of approximately 3–5 mm in diameter. (C) Subpleural cysts can be unilaterally distributed, in this case in only the left hemithorax, and associated with pleural thickening. (D) Cysts can be diffusely spread over both hemithoraces in the subpleural region.

## Epidemiology of Lower Respiratory Tract Infection in Down Syndrome

Children with DS are at high risk of early hospitalization in the preschool age due to respiratory disease.[6,34] In a cohort of children with DS who survived to discharge from hospital after birth, half were admitted again at least once in their first 3 years of life, with a median number of two further admissions. The most common reasons for admission (in order of frequency) are CHD, pneumonia, acute bronchitis, and bronchiolitis, with respiratory disease occurring in approximately 50%. The length of stay for children with DS is often 2–3 times longer than that of children without DS, and respiratory support is more likely to be required.

The importance of even apparently mild respiratory tract infections in DS should not be underestimated. Recurrent respiratory tract infections can have implications for neurodevelopment in DS.[35] Children with DS whose parents report frequent LRTI have lower developmental scores translating to a 5-month drop in abilities when measured at 8 years of age.

Viral infection is an important cause of respiratory disease in DS, and respiratory syncytial virus (RSV) is particularly troublesome. Between 10% and 15% of children with DS without significant comorbidity are hospitalized due to RSV.[36,37] The odds of a child with DS being admitted with RSV are 6 times higher than the general population, and of those hospitalized approximately 10% require mechanical ventilation. Children with DS and RSV are more likely to have fever and consolidation on chest radiograph and more frequently receive bronchodilators (implying an increased rate of wheeze) compared with children without DS.

Guidelines regarding the use of palivizumab in children with DS vary, and this remains a controversial area.[38] Randomized trials are lacking, but nonrandomized studies from Canada and the Netherlands demonstrate some support for the notion that palivizumab may be beneficial for all children with DS[39]; however, a clinical trial is required.

In addition to increased risk of severe lung disease requiring respiratory support, when receiving intensive care, there is an increased risk of acute lung injury (ALI) and acute respiratory distress syndrome (ARDS)[40]; surprisingly, the overall mortality is not increased. It could be speculated that ALI and ARDS occur in DS with less severe underlying disease, and that it is the underlying disease that ultimately drives mortality.

Overall mortality in DS is low in the pediatric intensive care unit (PICU), with rates of approximately 6%[41] and standardized mortality rates similar to children without DS.[42] However, the scenario changes with sepsis, in which there is an increased risk of mortality.[43] Our interpretation of these results is that respiratory infection in DS, even in critically ill children, does not necessarily confer an increased risk of mortality, although ALI and ARDS are more likely to occur. However, if infection progresses to sepsis, this confers a much poorer prognosis. We therefore aim to treat infection as early as possible in respiratory disease, with the aim of preventing sepsis.

Where standard intensive care is insufficient to rescue patients from severe respiratory failure, extracorporeal membrane oxygenation (ECMO) is an option. Cashen and colleagues report on results from the international Extracorporeal Life Support Organization Registry, which collects data from more than 200 ECMO centers worldwide.[44] They presented data from 623 patients with DS who received ECMO. In keeping with studies on ICU management of respiratory failure in DS, they found no increased risk of mortality for children with DS who received ECMO when compared with children without. Over time the use of ECMO in DS has increased.

## Immune Dysfunction and Severity of Lower Respiratory Tract Infection

Children with DS are at an increased risk of infection. Often this will present as more frequent upper respiratory tract infections, although in general all respiratory infections (including LRTIs) are increased. Mechanical factors, such as the airway abnormalities and gastroesophageal reflux, clearly play a part in this. In addition, there are well-described abnormalities of immune cell function in DS, which are summarized in Table 68.5.[45–49] Research to characterize the immune deficit is ongoing, but the deficit includes reduction of multiple immune cell lines and antibody levels. A maturational component of the immunodeficiency can normalize with age. Studies investigating the correlation between the immune deficit and rates of admission have given conflicting results that appear to depend on which components of the immune system are investigated.

**Table 68.5**

**Immune Function in Down Syndrome**

| | |
|---|---|
| Cell numbers | Mild to moderate reduced T-cell counts |
| | Mild to moderate reduced B-cell counts |
| | Absence of normal lymphocyte expansion |
| | Mild to moderate reduced naïve T-cell percentages |
| Anatomic | Reduced thymus size compared to age-matched controls |
| Antibody production | Suboptimal antibody response to immunization |
| | Decreased total and specific immunoglobulin A in saliva |
| Innate immunity | Decreased neutrophil chemotaxis |

After immunization, the specific antibody response for a wide range of antigens in DS is reduced, including immunization against important respiratory pathogens such as pertussis and pneumococcus. In general, immunization does induce a specific antibody response, albeit with reduced titers. In addition to defects in adaptive immunity, children with DS have abnormalities of innate immunity. These include reduced neutrophil chemotaxis,[50] and reduced killing of Candida, but normal oxidative burst. In addition, absolute levels of natural killer (NK) cells are reduced.[51]

Several underlying mechanisms for the immunodeficiency in DS have been postulated, but a clear unifying genetic mechanism has yet to be defined.[45] Hypotheses that have been considered include overexpression of genes on chromosome 21 (including SOD1, ITGB2, and RCAN1) and a secondary immunodeficiency caused by accelerated aging and zinc deficiency. A better understanding of the immunodeficiency in DS may be useful in the future in stratifying patients according to risk of infectious disease and could help guide therapy.

## Clinical Presentation of Lower Respiratory Tract Infection in Down Syndrome

Infections of the lower respiratory tract present in a similar manner to those without DS. However, in our experience, the onset of disease can be rapid. The hallmark symptoms of cough and fever are accompanied by a varying degree of increased work of breathing—elevated respiratory rate, subcostal and intercostal recession, with tracheal tug, grunting, and use of accessory muscles in older children or head bob in younger infants. Asymmetric chest expansion may be visible. There are crackles sometimes accompanied by bronchial (tubular) breathing over the affected lobes, with or without increased tactile vocal fremitus. Left untreated, respiratory muscle fatigue will lead to respiratory failure. Sputum may be produced or swallowed and vomiting is common; it may be the most prominent feature. Fever may be cyclic, especially in complicated pneumonia. The chest radiograph demonstrates the expected consolidation, although it should be noted that consolidation is common in viral respiratory infections such as RSV. A key role of the chest radiograph is in excluding complicated pneumonia.

## Wheeze in Down Syndrome Appears Independent From Atopy

Children with DS are frequently reported to be “noisy breathers,” and this may often be reported by their caregivers as a wheeze. The parental report of wheeze can of course indicate a wide variety of respiratory noises. It may well be the case that many children reported to wheeze do not have asthma.

Wheeze is diagnosed in up to 30% of children with DS and appears independent from RSV infection, which is a major risk factor in children without DS.[52] If asthma-related wheezing is highly prevalent in DS, one might suspect that markers of atopy such as positive skin prick testing would be highly prevalent. However, this is not the case—the rates of atopy are low in children with DS.[53,54] Lung function tests (especially spirometry) can be difficult to perform in DS, preventing the accurate diagnosis of reversible bronchospasm. However, these data on the discrepancy between the rates of atopy, and rates of wheeze in DS raise the question of whether this wheeze is in fact a manifestation of asthma, or whether there are alternate explanations in many children with DS. Therefore when given a history of wheeze, alternate explanations other than asthma should be considered, including intrathoracic airway malacia, muscle hypotonia with upper airway collapse, and vascular malformations.

## Effusions in Down Syndrome

Effusions (both pleural and pericardial) are frequently seen in DS and can be pleural (chylous or nonchylous) or pericardial. Fetal pleural effusion is a recognized sign of DS. It is worth noting that pericardial and pleural effusions can be presenting features of hematologic malignancy, which have increased incidence in children with DS.[55]

Chylothorax has been associated with DS in several case reports. It can occur spontaneously,[56,57] after cardiac surgery,[58] and in association with congenital pulmonary lymphangiectasia (see later). Chylothorax often presents in the newborn period or in infancy with signs of respiratory distress in the absence of overt infection. Typical features are stony dullness on percussion with reduced breath sounds and a pleural effusion on the chest radiograph. Chylothoraces can be significant and several hundred milliliters of fluid can be produced per day, even in relatively young children. Nonchylous congenital pleural effusions are also described in DS but appear to be uncommon.[59,60]

Cardiac effusions are well recognized in the context of DS and can be clinically significant and cause tamponade. They typically present with dyspnea, respiratory failure, and cyanosis and therefore should be included in the differential diagnosis of respiratory failure in DS.[61,62] The association between effusion and hypothyroidism is described, and some cases respond to thyroxine replacement therapy.[63]

## Rare Diseases of the Lower Respiratory Tract in Down Syndrome

DS is a common variant, and so there are numerous case reports of rare diseases in patients who also have DS. When a child with DS has an unusual respiratory presentation and disease progression does not proceed as normal, this should lead to consideration of a second diagnosis in addition to DS. There are case reports of DS coexisting with idiopathic pulmonary hemosiderosis (where the clue to diagnosis may be recurrent anemia requiring transfusion coincident with presumed pneumonia—Fig. 68.7),[64] cystic fibrosis,[65] primary ciliary dyskinesia,[66] and several interstitial lung diseases.

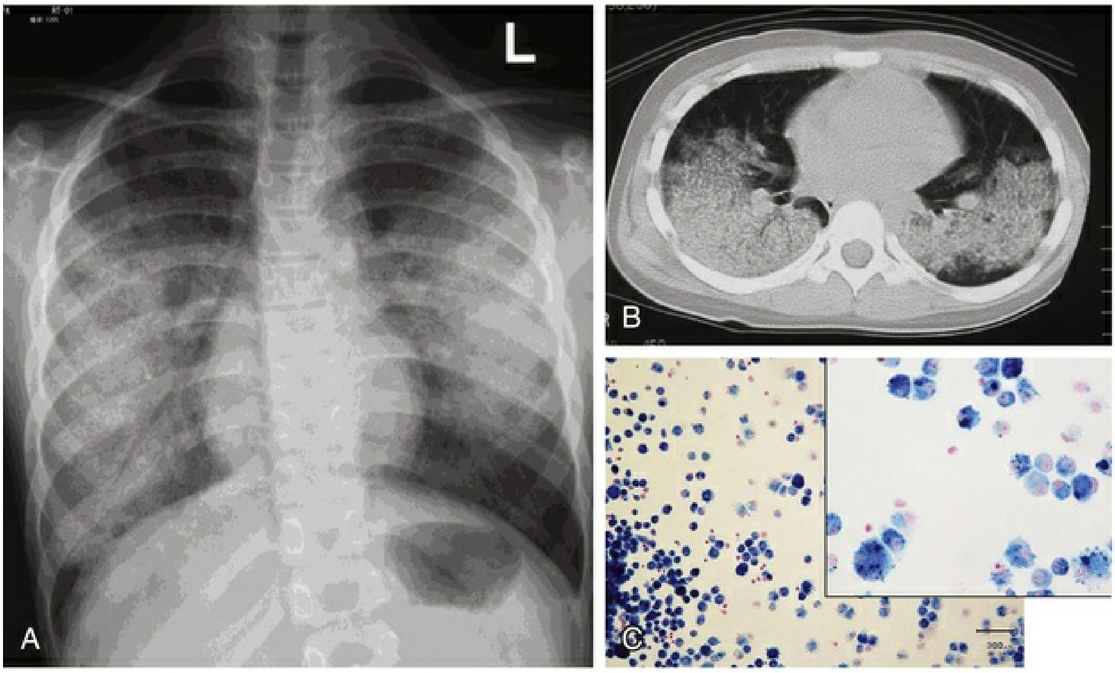

**FIG. 68.7** Pulmonary Hemosiderosis in Down Syndrome. (A) Chest radiograph of a 9-year-old girl with Down syndrome showing bilateral diffuse infiltrates. (B) The computed tomography scan of the chest demonstrated bilateral diffuse infiltrates in the posterior aspects of the lungs. (C) A cytospin of bronchoalveolar lavage fluid stained with Prussian blue revealed many hemosiderin laden macrophages. (From

Hirofumi Watanabe, Mamoru Ayusawa et al., Idiopathic pulmonary hemosiderosis complicated by Down syndrome, *Japan Pediatric Society*, Volume 57, Issue 5 October 2015, Pages 1009–1012.)

Childhood interstitial lung disease (ChILD) appears to be more common in children with DS, although the increased risk is difficult to quantify. Alveolar capillary dysplasia (ACD) or congenital alveolar dysplasia (CAD) has been described in a case series, but the overall frequency in DS is unknown.[67] Given that lung alveolarization is known to be abnormal in DS and that CAD and ACD are primary disorders of lung development, it is tempting to speculate that the lung development in DS is on a continuum with the developmental disorder category of ChILD. Indeed, in their classification scheme, Deutsch and colleagues categorized 46 cases as "growth abnormalities reflecting deficient alveolarization," of which 15 were related to chromosomal disorders.[68] Other entities such as pulmonary interstitial glycogenosis (PIG) (Fig. 68.8)[69–71] and congenital pulmonary lymphangiectasia (Fig. 68.9) are rare in children with DS.[69]

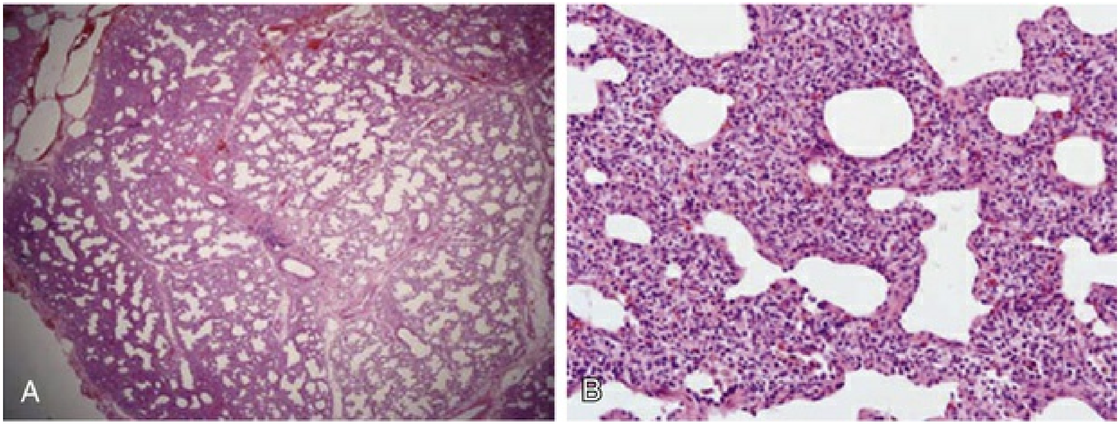

**FIG. 68.8** Histopathology of pulmonary interstitial glycogenosis (PIG). PIG is a recently described manifestation of childhood interstitial lung disease. There is interstitial widening due to increased mesenchyme. (A) Hematoxylin and eosin (H&E) stain showing alveolar simplification and enlarged and poorly septated airspaces. (B) Higher power H&E showing oval nuclei with clear cytoplasm in the interstitium typical of PIG. (From Popler J, Lesnick B, Dishop MK, et al. New coding in the International Classification of Diseases, Ninth Revision, for

children's interstitial lung disease. *Chest.* 2012;142(3):774-780.)

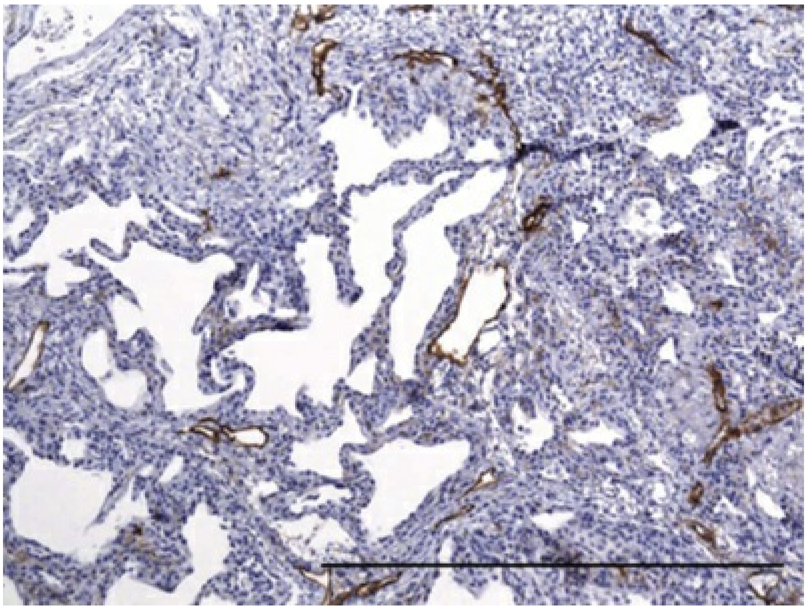

**FIG. 68.9** Histopathology in congenital pulmonary lymphangiectasia. Immunohistochemistry (antibodies against podoplanin) highlighting dilated lymphatic vessels in a child with trisomy 21 and congenital pulmonary lymphangiectasia. (From Reiterer F, Grossauer K, Morris N, et al. Congenital pulmonary lymphangiectasis. *Paediatr Respir Rev.* 2014;15(3):275-280.)

# Imaging of the Lower Respiratory Tract in Down Syndrome

Chest radiograph findings of pneumonia are similar to those in children without DS, including lobar consolidation and collapse. In RSV bronchiolitis, findings include the typical hyperinflated lungs, bronchial cuffing, and streaky perihilar regions (Fig. 68.10A). However, in DS, RSV bronchiolitis is more likely to cause lobar consolidation. In patients with chronic pulmonary disease, the radiograph can show changes of diffuse disease. CT scans may show subpleural cysts, which are typically less than 4 mm in diameter. In addition, CT scans can delineate vascular and lung malformations, such as an aberrant subclavian artery (Fig. 68.11) or a tracheal bronchus (Fig. 68.12). A CT scan can also demonstrate a complete cartilaginous tracheal ring, associated with tracheal narrowing (see Fig. 68.10C). There can be pitfalls in using plain films as the sole imaging modality, and a high index of suspicion has to be maintained for alternate diagnoses—for example diaphragmatic hernia can mimic lung consolidation (Fig. 68.13).

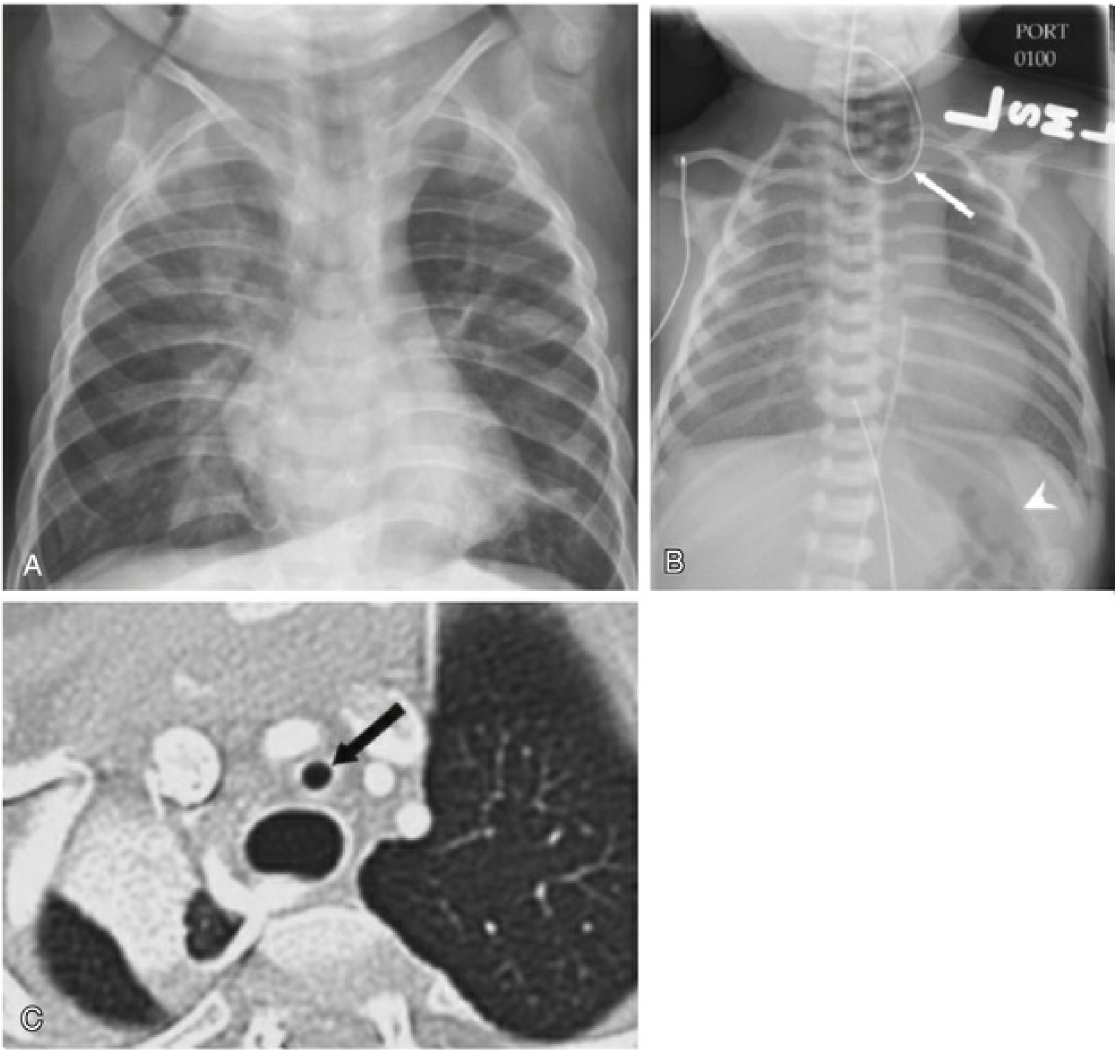

**FIG. 68.10** Imaging abnormalities in Down syndrome (DS). (A) Respiratory syncytial virus bronchiolitis in an infant with DS. (B) Chest radiograph that is highly suggestive of an underlying diagnosis of DS due to abnormal heart shape (tetralogy of Fallot), esophageal atresia (note the coiled nasogastric tube), and bowel gas in the abdomen *(arrowhead)* (indicating a tracheoesophageal fistula). Note also that there are 13 pairs of ribs. (C) Complete tracheal ring *(arrow)* in a

child with DS on computerized tomography. (From Radhakrishnan R, Towbin AJ. Imaging findings in Down syndrome. *Pediatr Radiol.* 2014;44(5):506-521.)

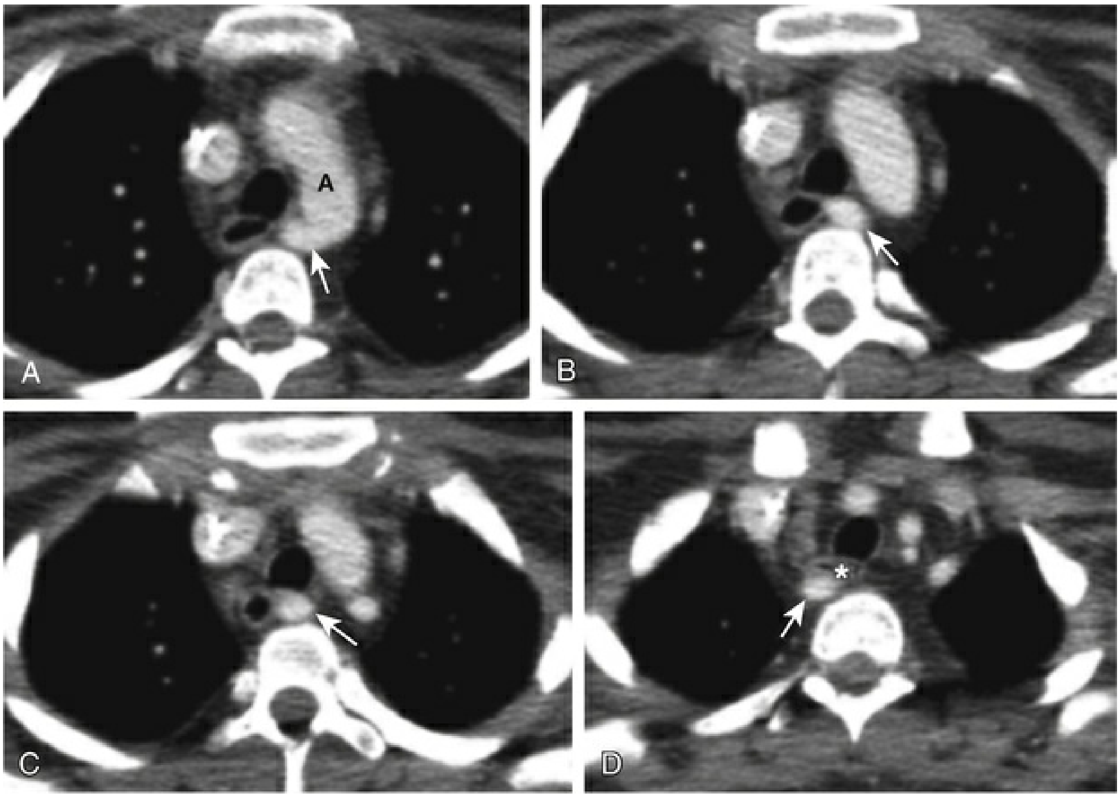

**FIG. 68.11** Aberrant right subclavian artery in Down syndrome. Chest computerized tomography series (proceeding caudally to cranially from panels A–D) demonstrating an aberrant right subclavian artery. The artery traverses posteriorly behind the esophagus (indicated by the * in panel D). (From Radhakrishnan R, Towbin AJ. Imaging findings in Down syndrome. *Pediatr Radiol.* 2014;44(5):506-521.)

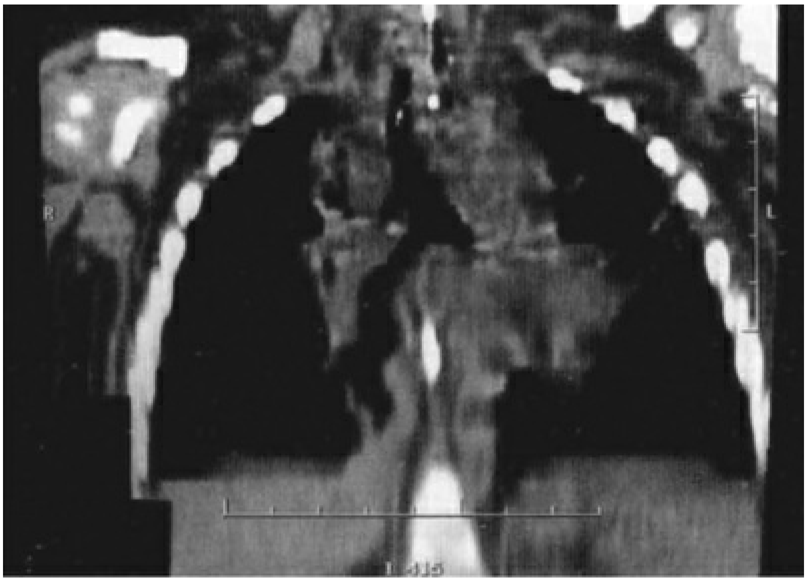

**FIG. 68.12** Tracheal bronchus. Coronal images from a chest computerized tomography in Down syndrome demonstrating a tracheal bronchus. (From O'Sullivan BP, Frassica JJ, Rayder SM. Tracheal bronchus: a cause of prolonged atelectasis in intubated children. *Chest.* 1998;113(2):537-540.)

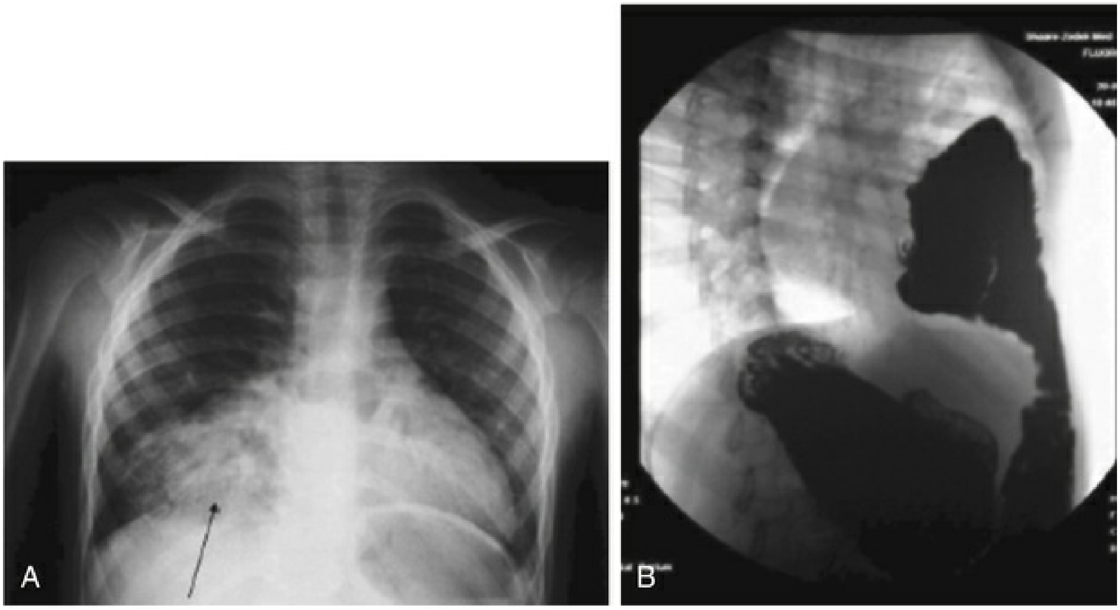

**FIG. 68.13** Unusual pathology in the lung masquerading as pneumonia in Down syndrome. (A) Chest radiograph shows apparent right lower zone consolidation. (B) Barium swallow demonstrating a right-sided anterior diaphragmatic hernia. (From Picard E, Ben Nun A, Fisher D, et al. Morgagni hernia mimicking pneumonia in Down syndrome. *J Pediatr Surg.* 2007;42(9):1608-1611.)

Several features on the newborn chest radiograph are predictive of trisomy 21 (see Fig. 68.10B). In particular, infants with DS tend to have multiple manubrial ossification centers, 11 pairs of ribs, and a bell-shaped chest.[70] If all three of these are present, the probability of the infant having DS approaches 60%.

# Cardiorespiratory Interactions and Pulmonary Vasculature

## Congenital Heart Disease in Down Syndrome

Cardiovascular abnormalities occur in approximately 40% of children born with DS. Overall mortality for CHD has improved significantly over the past decades, and much of the improvement appears to be due to a reduction in mortality in the first 2 years of life.

Within this context of better survival after significant cardiac disease, many patients who are seen in the respiratory clinic have current or a past history of significant cardiac morbidity. Thus care must be taken to consider both primary lung disease and lung disease secondary to cardiac disease. Cardiac surgery complications impacting the respiratory system include chylothorax, recurrent laryngeal nerve palsy, diaphragmatic paralysis, and subglottic stenosis. Patients with DS appear particularly susceptible to pulmonary hypertension. Secondary lung disease in patients following cardiac surgery can result from airway compression, for example from vascular anomalies, atrial enlargement, enlarged pulmonary arteries, or cardiomegaly (see Upper Airway Disease earlier).

The impact of cardiac surgery and postoperative ventilation on the lungs should not be underestimated. Histologic findings of patients with DS, compared with patients without DS, showed that 92% (22/24) of the patients with DS had interstitial emphysema and 96% had overdistension of peripheral air spaces. In contrast, the majority of control patients (who had undergone cardiac surgery but did not have DS) did not have interstitial emphysema or overdistension.[71] Although ventilator technology and strategies have improved significantly since this report, these data speak to the fragility of the lungs in children with DS. Cardiovascular disease can lead to pulmonary edema with a subsequent impact upon pulmonary function, causing a restrictive defect.[72] Numerous cardiovascular diseases can lead to pulmonary edema (Table 68.6).

## Table 68.6

### Cardiac Disease Leading to Pulmonary Edema in Down Syndrome

| | |
|---|---|
| Pulmonary venous hypertension | Pulmonary veno-occlusive disease<br>Pulmonary vein stenosis<br>Cor triatriatum<br>Supramitral ring<br>Left ventricular dysfunction<br>Transposition of the great arteries<br>Hypoplastic left heart (with intact atrial septum) |
| Decreased lymphatic flow | Lymphangiectasia<br>Superior venacaval syndrome<br>Single ventricle physiology<br>Tricuspid valve stenosis<br>Failing right ventricle<br>Right ventricular outflow tract obstruction |
| Left-to-right heart shunts | Ventricular septal defect<br>Atrial septal defect<br>Patent ductus arteriosus<br>Partial anomalous pulmonary venous connection<br>Systemic arteriovenous malformations<br>Aortopulmonary connections including surgical shunts |

Cardiac surgery can result in trauma to the respiratory system, causing chylothorax (due to direct injury to the thoracic duct, high central venous pressure, or central vein thrombosis) and recurrent laryngeal nerve injury (from direct trauma, stretching of the nerve or disruption of the blood supply) leading to diaphragmatic paralysis, and subglottic stenosis (Table 68.7).

## Table 68.7

### Pulmonary Complications of Cardiac Surgery

| Pulmonary Complication | Etiology |
|---|---|
| Chylothorax | Direct injury to the thoracic duct or smaller vessels<br>High central venous pressure<br>Central vein thrombosis |

| | |
|---|---|
| Recurrent laryngeal nerve palsy | Surgery involving the ductus arteriosus, descending aortal, or left pulmonary artery<br>Manipulation of right common carotid artery or internal jugular vein for extracorporeal membrane oxygenation |
| Diaphragmatic paralysis | Direct trauma to the phrenic nerve<br>Stretching of the phrenic nerve<br>Disruption of blood supply to the phrenic nerve |
| Subglottic stenosis | Compression of the trachea by the endotracheal tube, in particular given the small size of the trachea in Down syndrome |

Modified from Healy F, Hanna BD, Zinman R. Pulmonary complications of congenital heart disease. Paediatr Respir Rev. 2012;13(1):10-15.

## The Pulmonary Vasculature and Respiratory Disease in Down Syndrome

In tandem with the alveolar growth disruption seen in DS, there is also disturbance of the pulmonary vasculature. Infants with DS who died in the first year of life demonstrated persistence of the double capillary layer from fetal development and thickened pulmonary arteries. All of these patients had intrapulmonary bronchopulmonary anastomoses.[73]

Given the developmental anomalies of the pulmonary vasculature, it is not surprising that there is a predisposition for pulmonary hypertension in DS. Weijerman and colleagues reported a recent series from the Dutch Paediatric Surveillance Unit (DPSU). The overall population rate of CHD in DS is 43%, within which the incidence of persistent pulmonary hypertension of the newborn (PPHN) was 5.2%, compared with 0.1% in the general population.[74] Atrioventricular septal defect is recognized to be particularly associated with pulmonary hypertension.[75]

In DS, even in the absence of CHD, there is increased risk of PPHN, which is present in up to 10% of admissions to the neonatal ICU.[76] Reassuringly, the majority of patients demonstrate resolution of pulmonary hypertension. We advocate treating comorbidities such left-to-right shunts, upper airway obstruction, and hypoxia to prevent the establishment of pulmonary hypertension. Treating upper airway abnormalities is particularly helpful because adenotonsillectomy can reduce the prevalence of pulmonary hypertension from 85% preoperatively to 5% postoperatively.[77]

It is speculated that the reduced alveolar count, the abnormal fetal capillary network, and the reduced pulmonary vascular bed seen in DS significantly increase the risk of pulmonary hypertension.

High-altitude pulmonary edema (HAPE) at moderate altitudes appears more common in children with DS compared with normal children.[78] Intriguingly, it has been suggested that HAPE could be an initial sign of developing pulmonary hypertension.[79]

## Gastrointestinal–Respiratory Interactions in Down Syndrome

Gastrointestinal–respiratory interactions are particularly important in DS. Within this, it is common to distinguish between functional (dysmotility, reflux, and swallowing dysfunction) and structural (e.g., esophageal atresia) abnormalities, recognizing that these often coexist. As research progresses, the underlying pathogenesis of functional disorders is gradually being elucidated. The role of the respiratory pediatrician is to minimize this impact on the pulmonary health; so much of the work done in this domain is aimed at assessing and treating functional disorders irrespective of antecedent structural defects.

Congenital gastrointestinal defects are common in DS. In a large US study of 1892 children with DS, gastrointestinal malformations occurred in 6.7%.[80] The most common malformations were duodenal stenosis or atresia (3.9%), anal stenosis or atresia (1.0%), Hirschsprung disease (0.8%), esophageal atresia with or without tracheoesophageal fistula (0.4%), and pyloric stenosis (0.3%).

Esophageal atresia is particularly associated with increased respiratory problems long term postsurgery, even in children without DS.[81] Respiratory disease is multifactorial from tracheomalacia, aspiration, gastroesophageal reflux disease, tracheoesophageal fistula recurrence, and chest wall deformities. Large case series of outcomes in children with DS are lacking.

Functional disorders of gastrointestinal motility are particularly important in DS. DS is associated with disordered development of the enteric nervous system, which is thought to underlie the spectrum of functional disorders of the gastrointestinal tract that are prevalent in DS.[82] Animal models of DS have shown evidence of disordered neuronal migration and dendritic development. In people with DS, there are reduced numbers of esophageal plexus ganglia neurons, and this decreased ganglion cell population likely extends over the complete length of the gut. In addition to reduced neuronal cell numbers, there is also evidence of altered physiology —differences in action potential and ion channel kinetics have been identified.

Gastroesophageal dysmotility and reflux disease (GERD) is common in the DS population.[83] Approximately 50% patients with DS are asymptomatic, but the other 50% have symptoms such as dysphagia, regurgitation, and chest pain. We suspect that GERD also occurs without reported symptoms, where the patient may not recognize the symptoms, or it may be truly asymptomatic. Approximately 25% have dysmotility and retention of food in the esophagus. In children following major cardiac surgery, such as a VSD repair, medical management of GERD has a high readmission rate due to aspiration, failure to thrive, and poor feeding. However, the outcomes of surgical management of GERD are also unsatisfactory, with a significant rate of revision of fundoplication due to bloating. The choice of medical versus surgical therapy is difficult and requires balancing the risk of inadequate medical therapy versus operative risk and the chances of requiring further surgical procedures.

Swallowing dysfunction occurs in DS and causes aspiration pneumonia.[84,85] Pharyngeal dysfunction occurs commonly and is associated with cardiac surgery and failure to thrive; it often requires a gastrostomy.

## Obesity and Its Impact on the Lung in Down Syndrome

Obesity is increasingly present in the general population. A recent US series of 303 children with DS found that up to 50% of children have a BMI greater than the 95th percentile for age and sex,[86] whereas a Dutch study, which used different definitions, found a prevalence of overweight of 25%–32% and of obesity of 4%–5%.[87] Obesity is not solely due to changing demographics and increased obesity in the general population, because in both studies children with DS had higher BMI than the general population. In DS the BMI is increased most in children over the age of 12 years, and high BMI is a risk factor for OSA. Although obesity prevalence varies from country to country, children with DS are consistently more obese than the general population. Both inactivity and overeating may contribute to this problem. Overeating or hyperphagia can be assessed with standard questionnaires such as those used in Prader-Willi syndrome. When formally assessed, children with DS have hyperphagia scores somewhat between children with lifestyle-related obesity and children with Prader-Willi syndrome.[88]

In general, obesity has a negative impact on health, and this is particularly the case for respiratory health in DS. In children, obesity has a negative effect on pulmonary mechanics, prevalence of asthma, and sleep-disordered breathing.[89] In obesity, increased abdominal volume pushes the diaphragm upward, reducing the functional residual capacity, and this is made worse in DS by the effect of hypotonia on the chest wall. Thus the combination of DS and obesity has a significant impact on lung function, and obesity exacerbates the already high rates of sleep-disordered breathing.

## Treatment of the Respiratory Complications of Down Syndrome

Children with DS are frequently seen within the context of pediatric respiratory/pulmonology clinics. The approach to the history includes a focus on current and past symptoms, including cough, wheeze, upper airway noises, and snoring. The impact of current and previous comorbidities on pulmonary health should be considered, along with the limitations that respiratory disease causes to the patient's lifestyle. Specific points to consider include hospital admissions, respiratory tract infections, daytime somnolence, and missed school or other life opportunities. Growth should be monitored carefully, with attention to faltering growth in infancy, and obesity in later life. Multiple clinicians are often involved in patients with DS, and it should be clear where responsibility lies for routine surveillance, such as for thyroid disease. With respect to respiratory symptoms, there is a fine line between overinvestigating children and missing important symptoms of treatable conditions such as airway malformation, sleep-disordered breathing, and GERD. In particular, it is important to carefully consider alternative diagnoses before making a diagnosis of asthma. Success in being able to perform lung function testing is variable. Many treatments for children with DS are extrapolated from treatment of the same condition in children without DS, and this may not always be the best approach.

## Considerations When Treating Upper Respiratory Tract Disease in Down Syndrome

Treatment of upper airway disease requires a close liaison between the respiratory pediatrician, otolaryngologist, anesthesiologist, and intensive care team. One approach is to undertake joint bronchoscopies (as rigid bronchoscopies are more frequently in the domain of the otolaryngologist and flexible in the domain of the respiratory physician). The surgical, ICU, and respiratory management of patients with upper airway disease can be challenging.[90]

In intensive care and anesthetic practice, care must be taken to use an endotracheal tube of appropriate diameter (Table 68.8). Care should also be taken to ensure that after intubation there is a leak around the endotracheal tube. The presence of subglottic stenosis or a narrowed trachea also has implications for the appropriate size of the pediatric flexible bronchoscope if this is undertaken via an endotracheal tube. Anecdotally, if severe airway anomalies are anticipated (such as in children with DS who have noisy breathing, or those who have previously had long periods of intubation), it may be sensible to undertake flexible endoscopy prior to intubation to look for airway anomalies such as subglottic stenosis and to allow informed decisions regarding the size of the endotracheal tube to use.[90]

**Table 68.8**

**Size of Endotracheal Tube Diameter in Down Syndrome**

| Age | Down Syndrome | Non-Down Syndrome |
|---|---|---|
| Premature | 2.0–2.5 | 2.5–3.0 |
| Full-term newborn to 9 months | 2.5–3.0 | 3.5–4.0 |
| 9–18 months | 3.0–3.5 | 4.0–4.5 |
| 1.5–3 years | 3.5–4.0 | 4.5–5.0 |
| 4–5 years | 4.0–4.5 | 5.0–5.5 |
| 6–7 years | 5.0 | 5.5–6.0 |
| 8–10 years | 5.5 | 6.0–6.5 |
| 10–11 years | 5.5 | 6.5–7.0 |
| 12–13 years | 6.0 | 7.0–7.5 |
| 14 years and older | 6.5 | 7.5–8.0 |

From Shott SR. Down syndrome: analysis of airway size and a guide for appropriate intubation. *Laryngoscope.* 2000;110(4):585-592.

## An Approach to Prevention and Treatment of Lower Respiratory Tract Infection in Down Syndrome

Much of the treatment of respiratory disease in DS is centered on the treatment and prevention of LRTI. Frequent LRTIs are an important source of morbidity and may well impact developmental progress. Although LRTI does not usually progress to sepsis, given the serious nature of sepsis when it occurs, we advocate a general position of aiming to reduce the risk of LRTI. The general approach consists of immunization, parent and patient education for early signs of infection, careful surveillance for modifiable risk factors, and early treatment.

It should be ensured that patients are up to date with the current immunization schedule at each clinic visit. Consideration should be given to checking immunoglobulin levels, functional antibodies, and lymphocyte subsets either as a routine or for DS patients with frequent respiratory tract infections. These should be checked in individuals who have had an episode of sepsis or a history of four or more infections over 6 months, even if the patient was managed in the community. Consultation with an immunologist is often useful for individuals with specific functional antibody deficiency, especially with respect to repeating the relevant immunizations and consideration of further immunologic workup. Yearly influenza immunization is recommended unless contraindicated. Due to the increased risk of pneumococcus, in addition to administering the pneumococcal conjugate vaccine in infancy, we recommend the administration of pneumococcal polysaccharide vaccine after the second year of life. Functional antibodies (such as pneumococcal and *Haemophilus*) should be undertaken, with reimmunization considered where necessary.

For children with frequent infections, we consider prophylactic antibiotics. Strategies include administering them throughout the year or for the winter months only. One approach is to use the frequency of symptomatic infections to guide when to stop, and we generally consider a trial off antibiotics in the late spring.

There is an extensive differential diagnosis of respiratory disease in DS, especially when the patient's course is unusual. Treatment of gastroesophageal reflux disease (see Gastrointestinal–Respiratory Interactions in Down Syndrome), and swallowing disorders leading to aspiration can lead to a resolution of respiratory symptoms. Where respiratory symptoms are chronic or recurrent, consider pulmonary and airway malformations, external compression of the airway, and rarer parenchymal disorders and organize appropriate radiologic investigation and bronchoscopy.

Liaison between the respiratory clinic and emergency department (ED) is useful. Some institutions are able to put an “alert” on patient's case notes informing the ED of the diagnosis of DS and emphasizing the need for prompt and aggressive therapy on arrival to the ED. One approach to an episode of infection is to increase (usually double) the duration of the course of antibiotics. For individuals who present with respiratory failure or sepsis, early consultation with pediatric intensive care is essential, especially given the overall excellent prognosis from respiratory failure but poor prognosis in sepsis.

## Treatment of Gastrointestinal Disorders in Down Syndrome—the Pulmonologists View

Given the increased prevalence of swallowing dysfunction, dysmotility, and GERD, careful assessment for functional gastrointestinal disorders should be undertaken. Involvement of speech and language therapists is often helpful. Initial treatment of reflux disease is usually medical, proceeding to surgical management if there is failure of medical management.

Careful counseling of parents with regard to the risks of surgical management is important but should be put into the context of the risks of untreated chronic aspiration. Treatment of gastroesophageal reflux is undertaken with the expectation that this will prevent episodes of pulmonary infection and reduce the chance of significant pulmonary hypertension.

At present there are no clinical trials to guide the best approach to management of GERD in DS. In young infants, milk thickeners are a first step, with elevation of the thorax as much as possible during and after feeds. Pharmacologic therapies include antacids, prokinetics, H2 blockers, and proton pump inhibitors. Surgical management includes Nissen fundoplication (positioning the distal esophagus intraabdominally, hiatus hernia repair, and a fundal wrap). It can be undertaken with varying degrees of fundal wrap and can be performed laparoscopically. Alternatives to fundoplication include gastrojejunal tube feeding and jejunostomy; these procedures reduce food reflux but do not prevent reflux of swallowed saliva and stomach contents.

## Conclusions

Providing respiratory care for children with DS requires a long-term approach to lung disease throughout the pediatric period, with different pathologies presenting at different ages. Given the intellectual impairment that is often present, there are challenges throughout in terms of managing disease, in ensuring that children are able to understand and adhere to a treatment program, and that parents are supported in undertaking this treatment.

## Other Genetic Anomalies

Several other genetic disorders can be associated with significant pulmonary manifestations, and these are mostly associated with pulmonary hypoplasia. Table 68.9 lists selected genetic syndrome known to be associated with pulmonary hypoplasia. The chromosomal abnormalities Edwards (trisomy 18) and Patau syndrome (trisomy 13) are recognized to have pulmonary hypoplasia. Page reported on a series of more than 700 postmortem examinations and identified multiple cases of pulmonary hypoplasia on histopathologic grounds, of which three had trisomy 13, one trisomy 18, and one deletion of the long arm of chromosome 13.[91] In this series of pulmonary hypoplasia, there were also cases of arthrogryposis multiplex, osteogenesis imperfecta, thanatophoric dysplasia, and spondyloepiphyseal dysplasia congenita. Pulmonary hypoplasia is also recognized to occur in Larsen syndrome,[92] lethal pterygium syndrome,[93] and Roberts-SC phocomelia syndrome.[94] Unfortunately, the outcome of major syndromic malformations associated with pulmonary hypoplasia is very poor, with death occurring either in utero, in the neonatal period, or in early infancy.

## Table 68.9

## Rare Syndromes Associated With Alveolar Simplification

| Syndrome | Cause | Survival | Reference |
|---|---|---|---|
| Patau | Trisomy 13 | Death in neonatal period early infancy | 91 |
| Edwards | Trisomy 18 | Death in neonatal period and early infancy | 91 |
| Arthrogryposis multiplex congenital | AMCN (5q35) OMIM %208100 (though is genetically heterogeneous) | Heterogeneous prognosis—survival to adulthood has been described for those without significant pulmonary or cardiac involvement. | 91 |
| Spondyloepiphyseal dysplasia congenital | COL2A1 (12q13.11) OMIM #183900 Autosomal dominant | Wide clinical variability, survives to adulthood | 91 |
| Larsen syndrome | FNLB Mutation (3p14) Autosomal dominant OMIM #150250 | Variable severity—adult cases reported. | 92 |
| Lethal pterygium syndrome | Autosomal recessive CHRNG, CHRND, CHRNA1 (2q) OMIM 253290 | Lethal in the fetal stage of development | 93 |
| Roberts syndrome/SC phocomelia syndrome | Autosomal recessive ESCO2 (8p21.1) OMIM #269000 | Survival poor after the neonatal period. | 94 |
| Pulmonary hypoplasia | Preterm rupture of | Survival depends on | 95 |

| | | | |
|---|---|---|---|
| associated with oligohydramnios | membranes, or renal agenesis. | extent of hypoplasia. | |
| Fetal akinesia deformation sequence (FADS), Pena Shokeir syndrome | Autosomal recessive<br>DOK7 (4p16.3)<br>MUSK (9q31.3)<br>RAPSN (11p11.2) | Lethal congenital syndrome | 95 |
| Asphyxiating thoracic dystrophy/short-rib thoracic dysplasia 11 (SRTD)/Jeune syndrome | WDR34 (9q34.11)<br>Autosomal recessive | Lethal in neonatal period. The SRTD of which Jeune syndrome is a well-known member of the group, are a group of autosomal recessive skeletal dysplasias, and within this group there is phenotypic variability. Some forms are less severe with survival to later life. | 95 |
| Thanatophoric dysplasia | FGFR3 (4p16.3)<br>Autosomal dominant<br>OMIM #187600 | Fatal in early infancy | 95 |
| Spondylocostal dysotosis 1 | The spondylocostal dysostoses are a group of usually autosomal recessive disorders which include Jarco-Levin syndrome. Rib abnormalities are common leading to pulmonary hypoplasia.<br>Autosomal recessive<br>Mutation in Notch signaling gene DLL3 at 19q13.1 | The prognosis is variable within the group, with some forms having normal lifespan, and others dying early in infancy. | 95 |
| Cerebrocostomandibular syndrome | Autosomal dominant, autosomal recessive<br>SNRPB (20p13)<br>OMIM #117650 | Rib gaps are associated with pulmonary hypoplasia. | 96 |
| Pulmonary agenesis/dysgenesis/hypoplasia, micropthalmia/anopthalmia and diaphragmatic defect (PDAC) syndrome (also termed *Spear syndrome* and *Matthew-Wood syndrome* | Autosomal recessive<br>STRA6 (15q24.1)<br>OMIM #601186<br>There is genetic heterogeneity. | Usually die shortly after delivery, although some survival to early childhood occurs. Not all cases show pulmonary hypoplasia. | 97 |

*AMCN*, Arthrogryposis multiplex congenita; *CHRNA1*, cholinergic receptor, nicotinic, alpha polypeptide1; *CHRND*, cholinergic receptor, nicotinic, delta polypeptide; *CHRNG*, cholinergic receptor, nicotinic, gamma polypeptide; *COL2A1*, collagen Type II; Alpha-1; *DLL3*, delta-like 3; *DOK7*, downstream of tyrosine kinase 7; *ESCO2*, establishment of cohesion 1, S. Cerevisiae, Homolog of, 2; *FGFR3*, fibroblast growth factor receptor 3; *FNLB*, filamin B; *MUSK*, muscle, skeletal, receptor tyrosine kinase; *OMIM*, online mendelian inheritance in man; *RAPSN*, receptor-associated protein of the synapse; *SNRPB*, small nuclear ribonucleoprotein polypeptides B and B1; *STRA6*, stimulated by retinoic acid 6; *WDR34*, WD repeat-containing protein 34.

# Air and Fluid in the Pleural Space

*Bernadette Prentice BSc, MB BS, MPH, Adam Jaffé BSc(Hons), MBBS, MD, FRCPCH, FRCP, FRACP, FThorSoc*

The pleural space plays an essential role in the normal physiology of respiration. It consists of a layer of lubricated fluid that prevents friction between the two pleural layers and creates a negative pressure gradient to allow alveolar expansion and gas transfer. The balance of fluid, air, and pressure forces within the pleural space is very delicate, and when this is disrupted by the accumulation of air or fluid, there may be a significant impact on the cardiorespiratory system. Disorders of the pleura cause significant morbidity and mortality in children.

## Embryology and Anatomy

In the developing fetus, by the fourth week of gestation a primordial intraembryonic body cavity has developed in the shape of a horseshoe. This cavity develops from the lateral plate mesoderm and is termed the *intraembryonic coelom* (embryonic body cavity).[1] It is lined by simple squamous epithelium, or *mesothelium,* made up of two layers. The outermost parietal layer is derived from somatic mesoderm, and the inner visceral layer of mesothelium is derived from splanchnic mesoderm (Fig. 69.1).[1] Eventually this horseshoe-shaped cavity elongates, forming the bilateral pericardioperitoneal canals, which are then subdivided into pleural, pericardial, and peritoneal spaces. External to the developing cavities, the laryngotracheal diverticulum develops a "bud" that pushes into the pleural cavity and continues to branch 22 times to form the segments of the bronchial airway. The numerous branches deliver an increased surface area throughout which gas exchange can occur.[2] The preceding formation of the pleural cavities provides a space in which the lung parenchyma can grow.

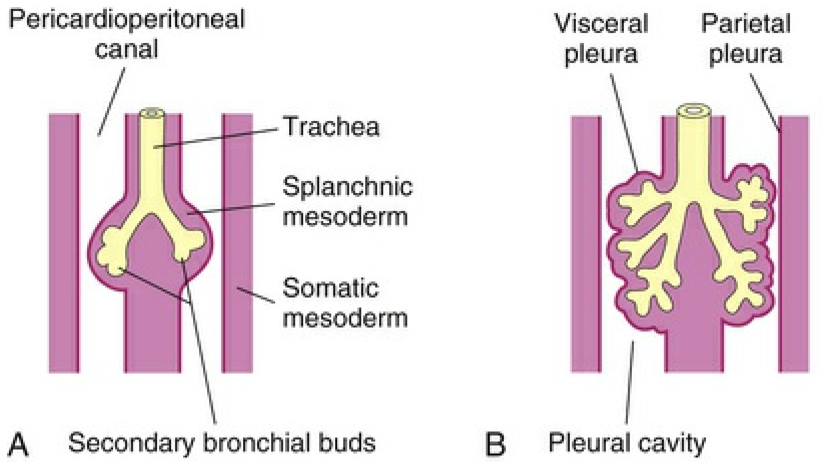

**FIG. 69.1** The developing lungs. (A) Bronchial buds are seen forming within the splanchnic mesoderm. Somatic mesoderm forms the external boundary of the pericardioperitoneal canals (primordial pleural cavity). (B) Development of the pleural layers. (Reproduced with permission from Moore K, Persaud T, Torchia M. *The Developing Human: Clinically Oriented Embryology*. 10th ed. London: Elsevier Health Sciences; 2015:F10-F18.)

In the second month of development, lymphatic channels begin to form, first in the shape of lymphatic "sacs" throughout the upper and lower regions of the body. These sacs are joined by lymphatic vessels, which form from vascular precursor cells and ultimately drain into the venous circulation. The early lymphatic system consists of two lymphatic channels (right and left thoracic duct precursors), which drain the jugular, iliac, retroperitoneal, and the cisterna chlyi lymphatic sacs and are connected by an anastomosis.[1] The two major lymphatic channels then undergo significant remodeling and partial obliteration such that the resulting thoracic duct is derived from the primordial right caudal lymphatic vessel, the cranial left lymphatic vessel, and the anastomosis between the original channels (Fig. 69.2).[3] If the thoracic duct is damaged—for example, during cardiothoracic surgery—the side of the chest in which a chylothorax develops will depend on whether or not damage has occurred in the lower portion of the duct (the original right-sided channel) or the upper portion of the duct (the original left-sided channel). Given the significant remodeling that the lymphatic system undergoes, there are numerous anatomic variations in the origin, termination, and passage of the thoracic duct. This variability may contribute to the difficulty often found in attempting to surgically identify the exact site of thoracic duct injury.

Churchill Livingstone; 2015:F13-F27.)

The embryonic pleural space is formed by two layers: the visceral pleura attached to the lung parenchyma and interlobar fissures and the parietal pleura attached to the chest wall and the superior aspect of the diaphragm. The visceral pleura is a tightly adherent membrane made up of a single layer of flattened cuboidal mesothelial cells.[4] The superior surfaces of these mesothelial cells are lined with apical microvilli, which play a key role in fluid movement across the visceral surface.[5,6] The apical portion of the visceral pleura is relatively thin, with flattened mesothelial cells. This thinner pleura is also the site of potential bleb and bullae formation. If these blebs and bullae rupture, a spontaneous pneumothorax ensues, as discussed later in this chapter.[7] Basal areas of the lung demonstrate greater movement with chest expansion than more apical areas and exhibit thicker visceral pleura and a higher density of mesothelial cell microvilli to assist with lubrication.[7] The visceral pleura is predominantly supplied by bronchial arteries, with only a minor contribution from the pulmonary circulation. There is no somatic sensory innervation of the visceral pleural layer, and this is often reflected clinically when pain is detected only once disease processes involve the parietal pleura.[8] Underlying the mesothelial layer of the visceral pleura is a fibrous supportive structure that is contiguous with the fibrous ultrastructure of the lung parenchyma. This fibrous tissue, which extends into the lung parenchyma, forms septae.[4] The normal lymphatic fluid filtration from the alveolar or pulmonary interstitial space drains via lymphatic capillaries that coalesce into lymphatic vessels along the lobular and lobar fibrous septae of the lung or superficial surface of the visceral pleura. These vessels drain toward the hilar region of the lung. In physiologic conditions, filtration across the visceral pleura toward the pleural space is essentially nonexistent, limited by the presence of “tight junctions” between the visceral mesothelial cells. However, in disease states, the endothelial and mesothelial barriers are disrupted and may result in the abnormal accumulation of fluid in the pleural space as either a transudate or an exudate.[7]

The parietal pleura is also formed by a single layer of mesothelial cells overlying a connective tissue support structure.[5] There are small voids, each called a *stoma* (from the Greek meaning "mouth"), in the cellular layer of the parietal pleura, which provide a direct connection to the parietal lymphatic drainage network via small lymphatic spaces, *lacunae,* in the submesothelial connective tissue layer.[6] The majority of physiologic pleural fluid drains from the pleural space via these stomata and lacunae.[9] Maximum filtration into the pleural space occurs from the parietal pleura in the apical region of the lung and maximum drainage occurs in dependent regions of the parietal pleura, particularly diaphragmatic and mediastinal surfaces.[9] The increased drainage achieved in the lower regions of the pleural space occurs because of the greater density of stomata on the diaphragmatic and mediastinal surface of the parietal pleura.[9] There are so many stomata on the mediastinal portion of the pleura that it is called the *cribriform membrane* (from the Latin *cribrum* meaning "sieve"). The stomata of the parietal pleura vary in size with respiration; they increase in size with inspiration, which creates a negative pressure gradient drawing fluid and particles from the stoma to within the draining lacunae. This process, combined with positive pressure from the expanding lung, allows pleural drainage into the lymphatic circulation to occur with each respiratory cycle. On expiration, the parietal pleural stomata decrease in size as the chest wall contracts, thus expelling the lacunar contents into the draining lymphatic system.[7] Once fluid is within the lymphatic channels, retrograde flow is prevented by intravascular valves. The key role in pleural space drainage played by the parietal pleura is illustrated in patients with mesothelioma. On autopsy, "black spot" asbestos fibers, too large to be drained, are found lining the inner parietal layer around the stomata.[9] The parietal pleura is supplied by the intercostal and internal mammary arteries and is innervated by the intercostal and phrenic nerves.

The two pleural layers form a closed sac on either side of the chest, with each layer contiguous at the hilum.[5] The internal space formed by the "sac" is called the *pleural cavity.* This cavity is filled with a small amount of pleural fluid, the volume of which is maintained by specific hydrostatic and oncotic pressures; this keeps the pleural layers separated and provides a lubricated surface on which the lung can move.[10] Ventilatory movements allow for the constant redistribution of fluid to further minimize contact between the pleural layers.[11]

## Physiology

In physiologic conditions, the amount of fluid in the thorax is preserved by a very precise balance: the parietal pleura lymphatic system manages pleural space fluid, and the intraparenchymal lymphatic drainage system ensures that excess intrapulmonary interstitial fluid does not restrict the surface area of gas exchange.[9] Several key forces are required to maintain this balance and allow the mechanics of respiration to occur. During normal tidal breathing, alveolar pressure is more negative than atmospheric pressure in order to create a gradient that allows airflow in the direction of the lower pressure (i.e., toward the airways and alveoli). This gradient is called the *transpulmonary pressure.* The negative pressure gradient is created by contraction of the muscles of inspiration, thus increasing the volume of the alveoli and lowering alveolar pressure.[12]

The pleural fluid is constantly under negative pressure, estimated to be approximately −3 to −5 cm of water[12]; the transmural gradient is the difference in pressures across the alveolar wall. This negative pressure gradient is a consequence of the inward alveolar elastic recoil and pressure to collapse, acting in concert with the passive elastic recoil of the chest wall forcing chest expansion. The resulting negative pressure in the pleural space, often termed *negative intrathoracic pressure,* persists even when inspiratory muscles are resting and then increases with inspiratory effort, thus increasing the transmural gradient.[13] The negative pressure in the pleural space creates an increasingly negative airway pressure, thus increasing airflow into the airways.

Normal pleural fluid is alkaline and has low protein levels, approximately 1–2 g/dL.[7,14] In normal physiologic states it contains a small number of cells, predominantly mesothelial cells, macrophages and lymphocytes. The cellular balance varies in different pleural diseases, and this may be a useful diagnostic clinical tool in some conditions such as lymphangiectasia and empyema. The depth of the pleural fluid layer is up to 30 μm in an adult when well; however, the negative pressure in the pleural space and the depth of pleural fluid within the cavity vary, demonstrating a gravity-dependent distribution.[9]

Pleural fluid is sterile, colorless and approximately 0.1–0.3 mL/kg in volume.[14] It is a microvascular filtrate with solute contents similar to that of interstitial fluid in other areas of the body.[7] The fluid is filtered from the apical regions of the parietal pleura, where parietal vessels lie closer to the mesothelial surface as compared with more dependent regions.[7] The pleural filtrate is governed by Starling's forces, namely tissue and capillary pressure, in addition to plasma and tissue colloidal osmotic pressure[7]; as a result, fluid drains according to the net hydrostatic and oncotic pressure gradient from the high-pressure systemic parietal pleural capillaries into the negative-pressure pleural space.[7] Pleural fluid turnover is approximately 0.2 mL/kg per hour, and complete fluid renewal is estimated to occur every hour in healthy adults.[9] The main control mechanism maintaining volume of the pleural space is the pleural lymphatic drainage system, which increases in response to increased filtration and provides an efficient negative feedback regulation system.[9] The lymphatic system is adaptive and can increase flow by up to 30 times; but when normal filtration from the parietal pleura increases or abnormal filtration from the visceral pleura occurs and exceeds the drainage capability of the lymphatic system, an effusion will result.[7] The main mechanism by which fluid accumulates is determined by the etiology of the effusion, which also influences the characteristics of the fluid and whether it is a transudate or an exudate.[15,16] A transudate occurs when mechanical forces or a variation in osmotic, systemic or pulmonary hydrostatic pressure causes pleural fluid to accumulate by altering the filtration or reabsorption capability of the pleura, but the capillary permeability to proteins remains normal. The primary pathology does not involve the pleural surfaces—for example, in hypoalbuminemic states or cardiac pathology. An exudate demonstrates a higher level of protein as a result of abnormal capillary permeability because of pathology involving the pleura, such as inflammation, malignancy, or infarction.[17]

In the setting where a breach occurs in the visceral pleura, as in the development of a bronchopleural fistula, or externally via the parietal pleura (e.g., during trauma), air may accumulate as it flows toward the negative-pressure pleural environment, causing a pneumothorax.

## Air in the Pleural Space: Pneumothorax

A pneumothorax occurs when air collects in the chest cavity outside of the lung parenchyma but underlying the parietal pleura. Air may accumulate in the pleural cavity via a breach in the chest wall and parietal pleura or if there is an intrapulmonary breach in the visceral pleura. Pneumothorax can occur spontaneously, as a result of chest trauma, or it may be iatrogenic.[18] When it occurs in an otherwise well child, it is called a *primary* pneumothorax. In a child with a respiratory condition such as cystic fibrosis, it is classified as a *secondary* pneumothorax (Table 69.1).[18]

**Table 69.1**

**Causes of Secondary Pneumothorax in Children**

| Category | Causes |
|---|---|
| Airway disease | Asthma, cystic fibrosis |
| Postinfectious | Measles, *Pneumocystis jirovecii*, tuberculosis, necrotizing pneumonia or abscess, parasitic |
| Interstitial lung disease | Sarcoidosis, Langerhans cell granulomatosis |
| Connective tissue disease | Marfan, Ehlers–Danlos, rheumatoid arthritis, systemic lupus erythematosus, polymyositis, dermatomyositis |
| Malignancy | Lymphoma, metastasis, sarcoma |
| Aspiration of foreign body | |
| Catamenial (in conjunction with menstruation) pneumothorax | Thoracic endometriosis |
| Congenital pulmonary malformations | Congenital pulmonary adenomatoid malformation, congenital lobar emphysema |
| Neonatal pneumothorax | Respiratory distress syndrome, pulmonary hypoplasia, meconium aspiration |

Modified from Robinson PD, Cooper P, Ranganathan SC. Evidence-based management of paediatric primary spontaneous pneumothorax. *Paediatr Respir Rev*. 2009;10(3):110-117; quiz 7.

The incidence of pneumothorax in children is difficult to ascertain, given the relative lack of available data, but the most recent estimate is approximately 4 per 100,000 in boys and 1.1 per 100,000 in girls.[19] Spontaneous pneumothoraces classically occur in tall, thin boys.[20] Pneumothoraces are more common in neonates than in older children, and risk factors include respiratory distress syndrome (RDS), meconium aspiration and mechanical ventilation.[21] Congenital renal malformations that result in oligohydramnios—such as renal agenesis, polycystic kidneys, or obstructive uropathy—are also known risk factors for pneumothorax in neonates.[22,23] It is likely that oligohydramnios causes developmentally abnormal hypoplastic lungs that can be associated with spontaneous air leak.[22,23] Investigation for obstructive renal abnormalities should be considered in any neonate with an unexplained pneumothorax.

The pathophysiology of spontaneous pneumothoraces remains controversial. Pulmonary "blebs" or larger "bullae" (Fig. 69.3) are developmentally abnormal enlarged airspaces and have historically been cited as risk factors for pneumothorax in children. They do not appear to occur in pediatric healthy controls but are found relatively frequently in children who have undergone computed tomography (CT) after a primary spontaneous pneumothorax (PSP).[24,25] However, in healthy adult controls, these bullae are found in about 15% of those who have undergone chests CT.[26] In a retrospective analysis of 114 children with spontaneous pneumothorax managed conservatively (with supplemental oxygen or chest tube drainage), those with visible bullae on chest x-ray (CXR) or "air-containing lesions" on high-resolution CT, had an increased risk of ipsilateral recurrence as compared with those without bullae.[27] However, in a study of 70 episodes of pneumothorax in 46 children, CT abnormalities did not reliably predict recurrence[28]; thus the evidence remains inconclusive as to whether or not the presence of blebs found on CT after the first PSP should guide treatment decisions. Given the limited data in children, routine chest CTs after first PSP to attempt to predict which pediatric patients will have a recurrent spontaneous pneumothorax is not currently recommended. However, there are no universally accepted specific pediatric guidelines.[18]

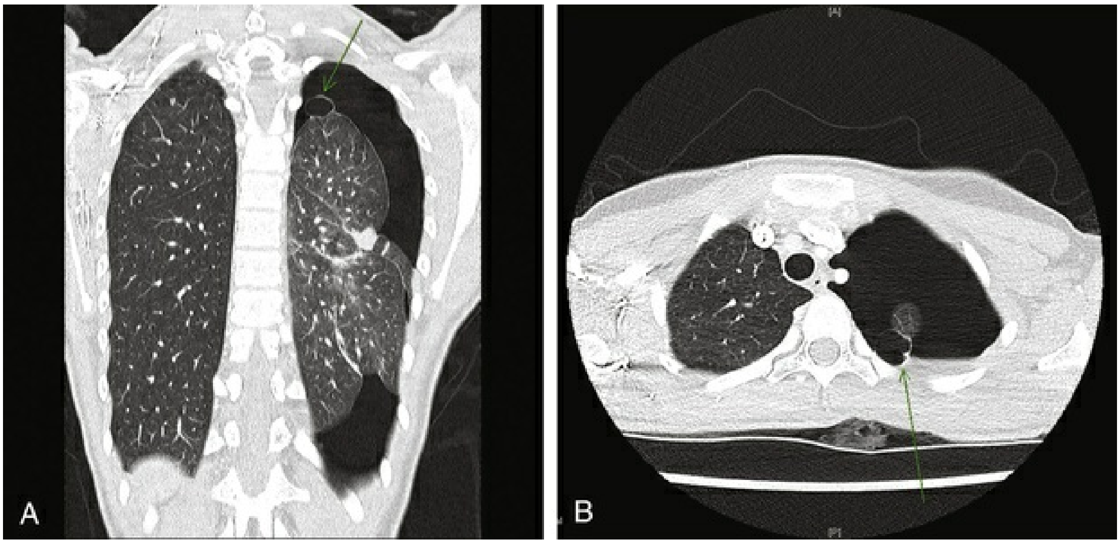

**FIG. 69.3** Computed tomography scan of a 14-year-old female patient demonstrating left-sided pneumothorax with a 17-mm apical bleb. Axial (A) coronal (B) sections of the same patient for comparison. Blebs are identified by *green arrows.* (B) Abnormal pleural reaction at the site of a previous chest drain (placed 4 weeks earlier) for ipsilateral pneumothorax.

Bullae and blebs may not be the only contributing factors to the development of pneumothorax. It has been reported that areas of disrupted mesothelial cells in the visceral pleura, termed *pleural porosity,*[29] may contribute to the risk, as it has been noted that blebs are frequently intact at the time of thoracoscopy or surgery. This inherent abnormality of the visceral pleura may explain the relatively high rates of recurrence of pneumothorax following surgical management that includes bullectomy without concurrent pleurodesis.[29] Other factors that contribute to the risk of pneumothorax include genetic connective tissue disorders such as Marfan syndrome,[30] Birt-Hogg-Dubé[31] or other folliculin gene mutations[19] as well as environmental factors such as exposure to tobacco smoke.[32]

When a pneumothorax occurs, air accumulates under the parietal pleura external to the lung parenchyma, causing direct compression of the lung. PSP classically occurs at rest but may be precipitated by a maneuver that increases intrathoracic pressure, such as the Valsalva maneuver or by lifting and straining.[19] Typically, pneumothorax presents as chest or back pain, dyspnea, or shortness of breath. Initial pain is often pleuritic in nature but may change to become a dull or a constant ache and may resolve after a few days, even without intervention.[19] Examination findings will vary depending on the size of the pneumothorax and may include tachypnea, tachycardia, low oxygen saturations, tracheal shift away from the side of the pneumothorax, hyperresonance on percussion and decreased air entry of the side of the pneumothorax. Small pneumothoraces may be difficult to detect clinically.

On rare occasions, air leaks into the pleural space and if it is unable to drain, a "ball and valve" effect develops. In this circumstance air will accumulate with each inspiratory effort and collect under "tension," forming a tension pneumothorax. This process may also occur with trauma to the chest wall and is a medical emergency, requiring immediate intervention, as it may ultimately result in decreased cardiac output and cardiorespiratory arrest. The patient will have the classic symptoms of pneumothorax but may also develop significant cardiorespiratory compromise manifest as progressive tachypnea, tachycardia, and eventually mediastinal shift with tracheal deviation away from the side of the pneumothorax.

In patients with a pneumothorax that is not under tension, CXRs demonstrate lung collapse and hyperlucency of air in the pleural space. This will often be more obvious on the expiratory film, but general recommendations are to quantify the size of the pneumothorax on an inspiratory film (Fig. 69.4).[18] More recent studies have demonstrated that ultrasonography may be a useful tool to diagnose pneumothorax.[33] A meta-analysis by Ding and coworkers indicates that, when performed by skilled operators on adult patients, ultrasonography had a higher sensitivity and similar specificity compared with CXR.[34] It may be a particularly useful technique in cases of trauma, where a supine CXR would otherwise be performed,[35] or in neonates with respiratory distress.[36] A CXR should never be performed when a tension pneumothorax has developed because it delays intervention, with potentially catastrophic consequences.

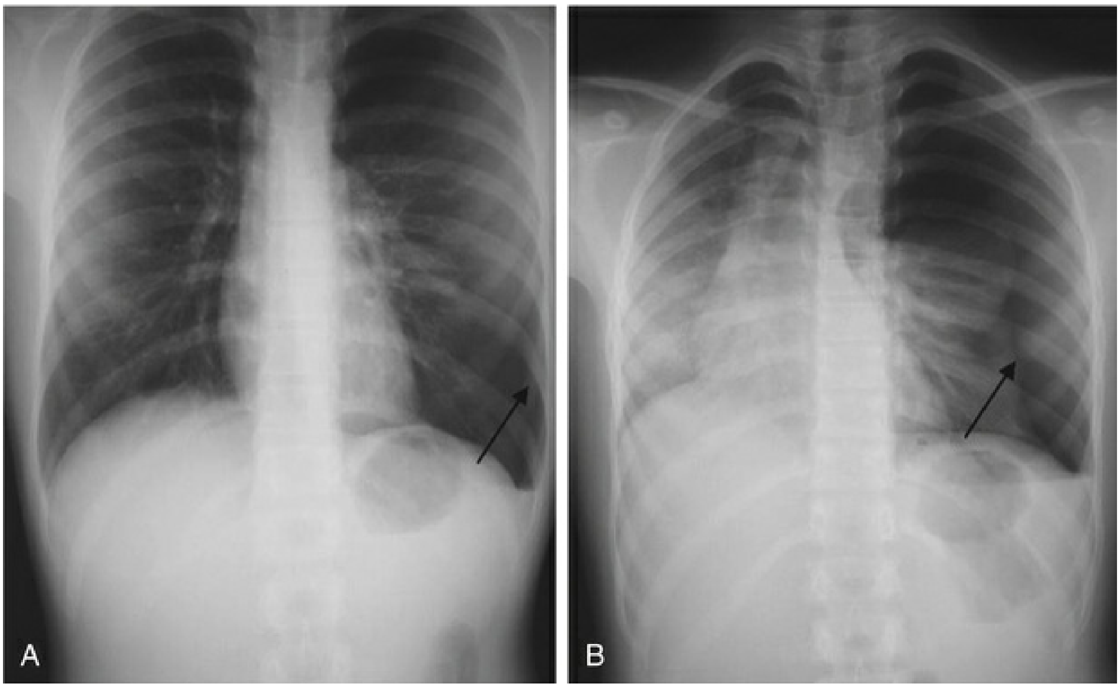

**FIG. 69.4** Chest x-ray (CXR) images of pneumothorax in a 12-year-old child. CXR images of primary spontaneous pneumothorax taken at the same time. (A) Inspiratory view. (B) Expiratory view. The two images demonstrate the significant change in the size of the pneumothorax with respiration. Despite the mediastinal shift seen in (B), this pneumothorax was not under tension. (Reused with permission from Robinson PD, Cooper P, Ranganathan SC. Evidence-based management of paediatric primary spontaneous pneumothorax. *Paediatr Respir Rev*. 2009;10(3):110–117, quiz 7.)

The treatment of pneumothorax depends on the clinical status of the patient, whether it is primary, secondary, or under tension and its size. A tension pneumothorax should be treated immediately with needle thoracentesis to the affected side.[37] In cases of pneumothoraces not under tension, quantifying the size in order to select the optimal course of management may be helpful. However, the size of the pneumothorax does not always correlate with clinical manifestations.[38] Several methods may be used to quantify the size of the pneumothorax, including measuring the distance to the cupola or apical dome of the lung (considered large if greater than 3 cm to the apex),[39] distance to the lateral edge (considered large if >2 cm) (Fig. 69.5)[38] or complete dehiscence.[40] Other methods used to quantify size include the Light method, Rhea method or the Collins method (Table 69.2).[18] However, there is often variation in the results of these calculations, as the shape of the pneumothorax can affect accuracy.[18] The British Thoracic Society (BTS) guidelines recommend that large pneumothoraces be identified "by the presence of a visible rim of >2 cm between the lung margin and chest wall at the level of the hilum."[38]

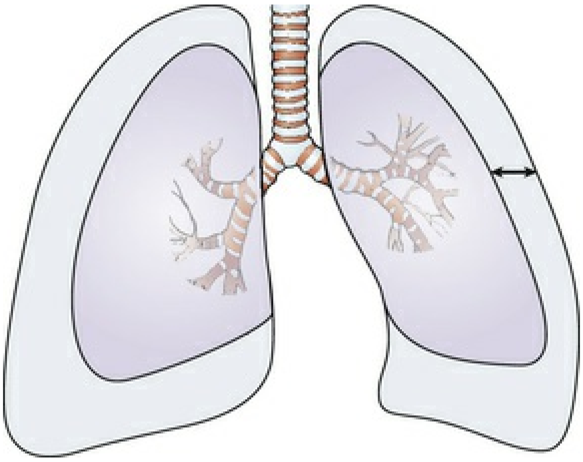

**FIG. 69.5** Measurement of the pneumothorax by the interpleural distance at the level of the hilum as described in the British Thoracic Society Pleural Disease Guideline.[38]

## Table 69.2

## Methods Used to Quantify Pneumothorax

| | Method of Calculation |
|---|---|
| Light method | Volume (%) = 100 − [(average diameter lung)$^3$/(average diameter hemithorax)$^3$ × 100] |
| Rhea method | Average of interpleural distances (cm) at three points on erect chest x-ray:<br>1. Apex<br>2. Midpoint upper half of lung<br>3. Midpoint lower half of lung<br>Use nomogram to convert into volume |
| Collins Method | Size (%) = 4.2 + 4.7 [sum of interpleural distances at apex, midpoint upper half of collapsed lung, and midpoint lower half of collapsed lung] |

From Robinson PD, Cooper P, Ranganathan SC. Evidence-based management of paediatric primary spontaneous pneumothorax. *Paediatr Respir Rev*. 2009;10(3):110-117; quiz 7.

The treatment of a small primary pneumothorax may be conservative, including high-flow oxygen and observation in an emergency department. Normal oxygen saturations do not preclude the use of oxygen therapy. Concurrent oxygen therapy may decrease the length of time taken for a pneumothorax to reinflate after intervention and may hasten the reinflation process by up to four times in the case of larger pneumothoraces.[41] The mechanism by which oxygen helps resolve a pneumothorax is thought to be by decreasing the partial pressure of nitrogen in the pleural space to hasten the reexpansion on the lung. However, the evidence for this recommendation comes from animal studies, and limited evidence is available to support this theory in humans. Although current guidelines still recommend the use of oxygen even if the patient is not hypoxic, the recommendation is derived from weak evidence and may not be appropriate in all cases.[42]

The treatment for a large nontension PSP may include a trial needle aspiration prior to proceeding to an intercostal drain, but universal agreement among guidelines is lacking.[39] The BTS guidelines[38] propose this intervention as first-line therapy for PSPs greater than 2 cm requiring intervention; however, needle aspiration in children is not commonly undertaken and is not yet considered the standard of care universally. There is an increasing body of evidence in adult patients with pneumothorax suggesting that needle aspiration may be just as effective, less invasive, and associated with a lower rate of complications and length of stay in hospital compared with thoracentesis[43,44]; however, care should be taken in extrapolating this evidence to children. Recent studies suggest that needle aspiration success rates in children are lower than those for adult patients with pneumothorax, and failure rates of up to 50% have been reported.[45,46] Needle aspiration is painful and, because of a significant risk of failure in children who would require a second intervention, it may not be appropriate in this population.

The treatment of a secondary pneumothorax generally requires insertion of a drain[47] because of the additional impact on respiratory function of the underlying disease. The recommended technique may depend on the area of collection but will generally be via the axillary or “safe triangle”[48] to avoid the internal mammary artery or anteriorly above the second rib on the ipsilateral side of the air accumulation. Small-bore chest drains (<14F) have been found to be just as successful as large-bore catheters, with less pain, and as such should be used routinely.[38] Catheter insertion should be done by an experienced clinician and may be helped by ultrasound guidance (Fig. 69.6).[38] Chest drains may be inserted by a blunt dissection technique or by the less traumatic Seldinger approach using small percutaneous drains. In inserting a chest drain, care must be taken to avoid the neurovascular bundle that runs on the inferior aspect of the ribs. Children will require analgesia, and conscious sedation should be considered. Nitrous oxide should be avoided owing to the risk of nitrous gas entering the pleural space and increasing the size of pneumothorax. Once a chest catheter is in place, it should not be put on immediate suction because of the increased risk of persistent air leak and the theoretical risk of reexpansion pulmonary edema (RPE), which has been seen in younger adults (20–40 years) with large pneumothoraces.[18] There is a paucity of evidence regarding the risk of RPE in children, but in adult patients it appears to correlate with the duration of lung collapse and size of the pneumothorax.[49] If there is minimal improvement with conservative management after 48 hours, high-volume, low-pressure suction may be considered.[38] Pressures of −10 to −20 cm $H_2O$ are recommended in the BTS adult pneumothorax guidelines.[38]

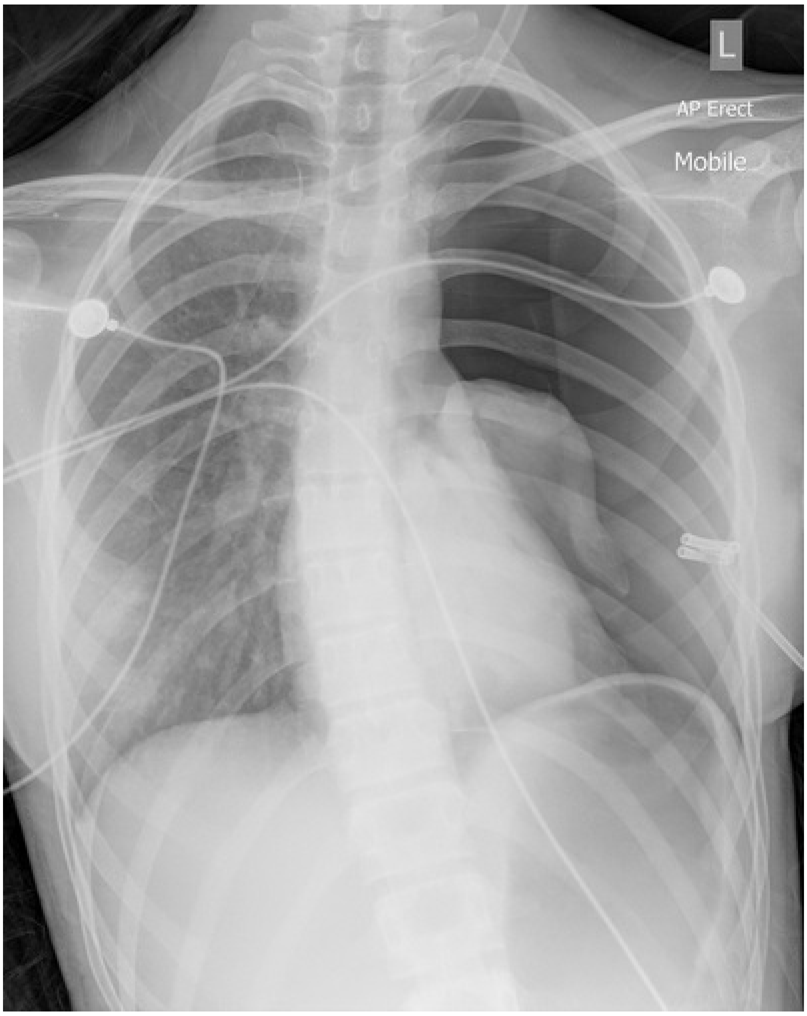

**FIG. 69.6** Chest x-ray of a 15-year-old male patient with left-sided primary spontaneous pneumothorax. The image demonstrates a large left-sided pneumothorax and an inserted pigtail chest tube. The lung remained deflated despite the pigtail catheter and suction was required to reinflate the lung.

In adults, the risk of recurrence after the first episode of pneumothorax averages 30%[50] and increases with each subsequent recurrence. In children, the risk of recurrence after a single spontaneous pneumothorax appears to be greater than that in adults, possibly closer to 60%,[20,51] although Seguier-Lipszyc and coworkers found that the risk after the first and second episodes of pneumothorax in children remained unchanged at about 50%.[28] If the pneumothorax is treated conservatively, the risk of recurrence does not appear to be altered by the method of treatment: oxygen alone or with a chest drain.[28]

Definitive treatment for a spontaneous pneumothorax may include bullectomy with pleurodesis, which has been shown to decrease the recurrence rate; but surgical intervention is associated with significant pain and morbidity. Methods of pleurodesis include those using a chemical (such as talc, minocycline, or glue) or mechanical pleurodesis, which is done by abrading the pleural surfaces to create an inflammatory process, causing the two pleural membranes to adhere.[52] Pleurodesis with mechanical abrasion appears to involve less morbidity and lower recurrent rates.[28] Video-assisted thoracoscopic surgery (VATS), as an alternative to open thoracotomy, is becoming more popular in children, as it is minimally invasive and has been shown to have good outcomes in those with PSP; however, it does rely on the availability of local expertise.[28,51,53] Ideally a definitive surgical intervention would occur at the time of presentation to avoid multiple procedures. But until patients with the highest risk of treatment failure or recurrent pneumothorax can be reliably identified, VATS cannot be recommended as routine first-line therapy.[54,55]

## Flying and Diving After Pneumothorax

Patients who have had a spontaneous pneumothorax must be cautioned against scuba diving. Adult pneumothorax guidelines recommend avoiding scuba diving unless a definitive surgical procedure, such as a bilateral pleurectomy, has been undertaken[38] and normal lung function and chest CT have been confirmed postoperatively. This recommendation is made because of the risk of contralateral pneumothorax, and patients who have had a spontaneous pneumothorax are at risk of a recurrent pneumothorax during a dive.[56] There is a risk that if a pneumothorax occurs while the diver is under water, it will enlarge during the ascent in accordance with Boyle's law, and the diver may develop a rapidly enlarging pneumothorax—a potentially life-threatening situation.

Patients with a closed pneumothorax should not fly owing to low cabin atmospheric pressure. There should be no increased risk of developing a recurrent pneumothorax with flying after a PSP; however, the pneumothorax must be entirely resolved, with radiologic confirmation.[47] There is no consensus regarding travel postpneumothorax in children; adult pneumothorax guidelines recommend delaying flying anywhere between 7 days and 6 weeks postresolution.[47] The BTS air travel guidelines recommend that complete resolution of the pneumothorax be confirmed on CXR and that then a minimum 7 days should elapse prior to flying, with a longer delay if the pneumothorax was traumatic or if the patient has underlying lung disease.[57] Without a definitive surgical procedure, the risk of recurrence from pneumothorax may remain elevated for at least a year, particularly in patients with secondary pneumothorax, and such patients should be advised of the risk of recurrence.[38]

# Fluid in the Plural Space

## Effusions

As discussed earlier, in the healthy state, a small amount of fluid lies between the parietal and visceral pleural layers. The fluid continues to be filtered and reabsorbed by the lymphatic system within a very delicate balance of hydrostatic and oncotic pressure forces. When an imbalance occurs, fluid will accumulate at a rate faster than the lymphatic system is capable of draining. The etiology of the fluid accumulation will determine the nature of fluid. A transudate results from a change in the transpleural pressure balance,[6] and the resulting fluid will have a relatively low leukocyte count, lower levels of protein and be relatively alkalotic[58] as is seen in hypoalbuminemic states and cardiac failure. Alternatively, an exudative accumulation results from either increased vascular permeability of pleural capillary beds or impaired lymphatic drainage, such as seen in infection.[6] The resulting exudate will be more acidic, high in white blood cells (neutrophils, lymphocytes, eosinophils), protein, and lactate dehydrogenase (LDH) but relatively low in glucose[59] (see Table 69.3 for causes of pleural effusions). Light's appear to be the most robust criteria applied to differentiate a transudate from an exudate, and they are used to guide treatment in adult patients. Although useful, these criteria are not 100% specific (Table 69.4).[17,60] Criteria such as these are not routinely used in the management of children, partly because children rarely undergo a “diagnostic” tap, as the causes of pleural effusion are generally fewer than adults; by far the most common type of pleural effusion in children is a parapneumonic effusion.[59] This occurs when the equilibrium between pleural fluid secretion and pleural lymphatic drainage is disrupted because of an underlying pneumonia. It classically presents as a syndrome of progressive pneumonia not responding to treatment and can be divided into three stages[61]:

## Table 69.3

### Common Causes of Pleural Effusions

| Transudate | Exudate |
|---|---|
| Cardiac disease (e.g., congestive heart failure, congenital heart disease, pericarditis)<br>Renal disease (e.g., nephrotic syndrome)<br>Hypoalbuminemia (e.g., secondary to liver failure)<br>Superior vena cava obstruction<br>Hepatic cirrhosis | Infectious<br>Malignancy (e.g., leukemia, lymphoma)<br>Lymphatic abnormalities and chylothorax<br>Postoperative surgical complications (e.g., scoliosis surgery)<br>Pulmonary infarction<br>Connective tissue and vasculitic disorders (e.g., rheumatoid pleurisy, Churg-Strauss, sarcoidosis)<br>Abdominal pathology (e.g., pancreatitis, viral hepatitis, subphrenic abscess)<br>Endocrine (e.g., hypothyroidism) |

Modified from Light RW, Macgregor MI, Luchsinger PC, Ball JWC. Pleural effusions: the diagnostic separation of transudates and exudates. *Ann Int Med*. 1972;77(4):507-513.

## Table 69.4

### Lights Criteria: Pleural Fluid Is an Exudate if the Following Criteria Are Met

| | |
|---|---|
| Pleural fluid protein/serum protein | >0.5 |
| Pleural fluid LDH/serum LDH | >0.6 |
| Pleural fluid LDH | >2/3 upper limit normal serum LDH |

*LDH,* Lactate dehydrogenase.

From Light RW, Macgregor MI, Luchsinger PC, Ball JWC. Pleural effusions: the diagnostic separation of transudates and exudates. *Ann Int Med*. 1972;77(4):507-513.

1. Exudative stage—simple parapneumonic effusion with low leukocyte count.
2. Fibrinopurulent stage—deposition of fibrin resulting in

septations and loculations (Fig. 69.7). An increase in leukocytes occurs and microorganisms invade the pleural space, resulting in purulent material filling the pleural cavity. A parapneumonic effusion that contains pus is defined as an empyema.

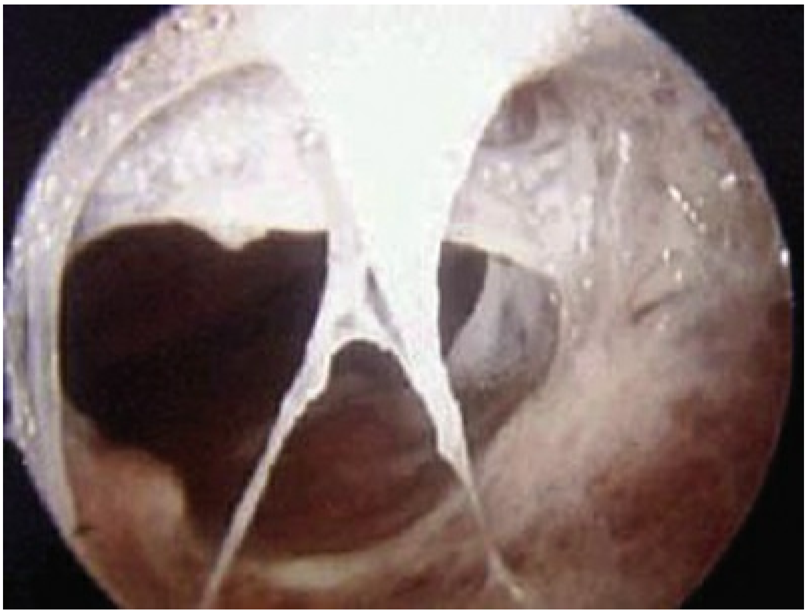

**FIG. 69.7** Thoracoscopic image of fibrinous septations taken in a child with empyema. (Image reprinted with permission from Professor Gordon Cohen.)

3. Organizational stage—fibroblasts enter the pleural cavity, forming tight fibrous membranes.

Nonparapneumonic pleural effusions in children can occur as a result of congenital heart disease, renal and liver disease, connective tissue disorders, malignancy, or as postoperative surgical complications.[59]

# Empyema

## Etiology

The most common cause of parapneumonic effusion and empyema is bacterial pneumonia. Parapneumonic effusions can occur as a complication of a viral or *Mycoplasma pneumoniae* infection and are more likely to be simple and less likely to require surgical intervention.[62] Although empyema is relatively rare in children, up to 28% of those requiring hospitalization for pneumonia may have an associated effusion.[63] The process of pleural fluid accumulation is mediated by increased vascular permeability secondary to mesothelial cell cytokines including interleukin (IL)-1, IL-6, IL-8, tumor necrosis factor (TNF)-$\alpha$, and platelet activating factor.[64] Initially the fluid accumulating in the pleural space is an exudate resulting from the inflammatory process involving the pleura in response to an underlying pneumonia. The pleura leaks proteins and fluid and eventually leukocytes. As the disease progresses, the number of leukocytes increases, and eventually the pleural cavity is infiltrated by organisms. When the fluid becomes purulent, it is called an empyema (from the Greek *empuein,* meaning "to suppurate"). As the disease progresses, there is increasing deposition of fibrinous material, which leads to septation and the formation of loculations. This fibrinous material can obstruct the free flow of fluid and block the draining lymphatic stomata, thus preventing spontaneous resolution of normal lymphatic draining and often requiring an intervention to drain the fluid (▶Video 69.1). In the later "organizational" stage in the disease process, fibroblasts penetrate the pleural cavity and can form a membrane called a *peel.* This peel is made of firm fibrous material that can impair lung function by "trapping" the lung and limiting recovery if not identified. Although lung trapping is often seen in adult patients, it rarely occurs in children with empyema.[65]

## Epidemiology

The incidence of parapneumonic effusions and empyema has been reported to be up to 10 per 100,000 children in the United States[66] and appears to have increased, particularly in the younger age groups,[67] following the introduction of pneumococcal conjugate vaccine (PCV7)[66,68–70] against serotypes 4, 6B, 9V, 14, 18C, and 19F[71] despite a reduction in invasive pneumococcal disease.[72] Similarly, one study in Australia found that the overall hospitalization rate for pneumonia had decreased after the introduction of the 7-valent vaccine, but the percentage of empyema as a proportion of pneumonia increased from 0.27% to 0.7% of hospitalizations.[73] The reason for the increase is unknown but may reflect replacement of serotypes by those that are particularly virulent with a predilection for the pleural space, such as serotype 1, 3 and 19A.[72] Following the recent introduction of PCV13 into national vaccination schedules, which includes six additional serotypes (1, 3, 5, 6A, 7F and 19A),[71] the rates of invasive pneumococcal disease have further decreased.[74] More recent studies after the introduction of the 13-valent pneumococcal vaccine have described a decrease in the rates of pediatric empyema, with the greatest reduction in children below 4 years of age.[75] Ongoing enhanced surveillance is required to ensure that serotype replacement does not occur in the future.

Empyema occurs more commonly in boys, infants, and younger children[76] and is seen more frequently in the spring and winter months, given that this is when bacterial pneumonia is more likely to occur. Mortality, more common in the adult population, is uncommon in children but still occurs rarely.[68,77] Children with certain risk factors—including immunodeficiency, malignancy, genetic conditions such as Down syndrome, congenital heart disease, and cystic fibrosis—are at an increased risk of empyema[76,78,79]; the presence of comorbid conditions increases the risk of death.[79] Although it is unknown why empyema occurs in healthy children, evidence from adult studies suggests that there may be a genetic predisposition. Transcription factor nuclear factor (NF-κB) plays a key role in host innate and adaptive immune responses and may play a role in the development of empyema.[80] Inhibitors of NF-κB (IκB) control the nuclear factor activity, and rare mutations in IκB are known to cause immunodeficiency syndromes complicated by severe infections.[81] Chapman and coworkers demonstrated that more common IκB polymorphisms are associated with invasive pneumococcal disease, which may determine why invasive pneumococcal disease does not occur in all patients when pneumococcal colonization in the nasopharynx is known to be relatively widespread.[81] Alternatively, bacterial virulence and load may be a factor that results in invasive disease. Esposito and coworkers demonstrated that in their cohort of 72 otherwise well children less than 5 years old with *Streptococcus pneumoniae* community-acquired pneumonia, those with high bacterial loads were more likely to have an associated parapneumonic effusion.[82] Furthermore, Munoz-Almago and coworkers were able to show that bacterial load correlated with serum inflammatory markers (c-reactive protein [CRP]), hospital length of stay, and number of hours of pleural drainage.[83] Another factor implicated in why some healthy children develop an empyema may be a delay in accessing appropriate antibiotic therapy.[84] However, empyema can complicate pneumonia even if the children have been appropriately treated with antibiotics. Empyema as a result of delayed initiation of treatment is reflected in the greater burden of empyema in communities that have poorer access to antibiotics, and it is an ongoing cause of pediatric morbidity worldwide as well as of potential mortality, particularly in the low- and middle-income settings.[85] In one study, use of ibuprofen was noted to be a potential risk factor for the development of empyema.[86]

Another factor that may contribute to the development of empyema is a precipitating viral respiratory tract infection.[87] During influenza pandemics an increase in hospitalizations has been noted, with children suffering respiratory complications including bacterial pneumonia and empyema.[88] One U.S. center noted that, although rare, 2% of the children hospitalized with influenza also had positive bacterial cultures, most commonly *S. pneumoniae* and *Staphylococcus aureus,* and several eventually developed lung abscesses or empyema.[89] The exact mechanism by which a preceding viral infection potentially increases the risk of empyema is not yet clear, but the viral infection with associated increased secretions may create an environment in which bacterial coinfection can occur.

As the incidence of childhood empyema has increased, a concurrent increase in the rates of pneumococcus-associated hemolytic uremic syndrome (P-HUS) has been described. P-HUS causes hemolytic anemia, thrombocytopenia, and acute renal failure. P-HUS has been associated with considerable morbidity and prolonged hospital stay[90] in addition to high rates of mortality.[91] A retrospective review undertaken in the United Kingdom reported P-HUS to have occurred in 7.5% of patients with pneumococcal empyema, and children less than 2 years of age were particularly at risk.[90]

## Microbiology

The bacterial cause of empyema depends on several patient-specific and environmental factors. These include the health status of the child, risk of immunocompromise, immunization history, geographical location and the local prevalence of bacteria. *S. pneumoniae* (and to a lesser extent *S. aureus*) has historically been the primary causative organism. The development of newer antibiotics and the introduction of newer vaccinations in recent decades have changed the profile of bacteria causing empyema. There also appears to be a significant increase in the number of cases caused by penicillin- and cephalosporin-resistant *S. pneumoniae,*[92] which may have led to an increasing number of complicated cases of necrotizing pneumonia. As already described, following the introduction of the 7-valent pneumococcal conjugate vaccine, several studies have demonstrated an increase in the prevalence of *S. pneumoniae* serotypes 1, 3, 7F and 19A, causing empyema. These serotypes were not included in the 7-valent vaccine but are now included in the 13-valent conjugate vaccine, which has been introduced into the national vaccination schedules of many countries.[71] Other than the streptococcal species, *S. aureus* is an important cause of empyema in children.[93] Methicillin-resistant *S. aureus* (MRSA) has also been described in empyema, and rates of occurrence appear to be increasing.[92,94] In some cases, the cause of chronic empyema is pulmonary tuberculosis, which should be considered along with parasitic causes if the empyema is bilateral.[95] Other causes of empyema include *Streptococcus pyogenes* and other streptococcal species, including *S. viridans* and *S. milleri.* Other parapneumonic effusion–causing organisms include *Haemophilus influenzae, M. pneumoniae,* and *Pseudomonas aeruginosa.* The Australian Research Network in Empyema (ARNiE) prospectively described the bacterial causes of empyema in Australia between 2007 and 2009 and confirmed that the streptococcal and staphylococcal species continue to be the most common causes of empyema in children (Box 69.1).[96] Gram-negative anaerobic organisms and specific fungi[59] are known to cause empyema in rare cases but usually represent complications of risk factors such as aspiration, immunocompromise or nosocomial infection.

Modified from Strachan RE, Snelling TL, Jaffé A. Increased paediatric hospitalizations for empyema in Australia after introduction of the 7-valent pneumococcal conjugate vaccine. *Bull World Health Organ*. 2013;91(3):167-173.

The prevalence of the microbiologic causes of pediatric empyema is difficult to ascertain accurately because there is extensive variation in the ability to identify the infectious organism.[59,97] This is further complicated by treatment with antibiotics, which may sterilize the fluid prior to sampling.[59] With the advent of molecular techniques such as polymerase chain reaction (PCR), the identification of a causative organism in sterile fluid is enhanced,[98–101] and this technique is more sensitive than traditional culture methods.[100] Strachan and coworkers were able to culture streptococcal species in only 5.9% of pleural fluid samples from children with empyema, but PCR identified streptococcus as the causative organism in 54.4%.[101] In the case of *S. pneumoniae,* latex agglutination appears to be the most sensitive and specific test that can identify pneumococcal antigen in pleural fluid and is more sensitive than PCR.[102] However, unlike culturing the organism, a limitation of PCR or pneumococcal antigen detection is the lack of information regarding antibiotic resistance.

## Clinical Manifestations of Empyema

Empyema classically presents as a clinical syndrome including fevers, lethargy, productive cough, respiratory distress, and toxicity resulting from the underlying pneumonia. Examination reveals a febrile child in respiratory distress, possibly requiring oxygen or ventilatory support.[59] The child may be tachypneic, with shallow breaths to minimize the pleuritic pain caused by deep inspiration. Infection in the lower lobes may present as abdominal pain and must be considered as part of the differential diagnosis in children presenting with acute abdominal pain. Empyema typically causes pleuritic pain in the chest and back. The child may splint the painful side by lying on the affected side or by refusing to move and change position. Chest examination reveals decreased chest expansion, dullness to percussion, classically described as “stony dullness,” and decreased or absent breath sounds over the affected side. Depending on the size of the effusion, the child may exhibit scoliosis, often confirmed on CXR, which resolves spontaneously when the empyema resolves.[103] In children who present with pneumonia and a scarlatiniform rash, who appear toxic, and who have signs of circulatory failure or low leukocyte levels, consideration should be given to the possibility that the infective organism may be group A streptococcus (GAS), resulting in streptococcal toxic shock syndrome (STSS).[104] Risk factors for GAS empyema include recent corticosteroid usage and varicella infection.[104] The treatment in this instance is to use an antitoxin antibiotic such as clindamycin, as this is a particularly aggressive, potentially fatal disease that causes severe sepsis and hypotension, often requiring inotropic support.

## Investigations

The first-line treatment of bacterial pneumonia includes antibiotics and respiratory support. Empyema should be considered in children who do not respond to appropriate antibiotics within 48 hours, as evident by ongoing fevers, toxicity, and respiratory distress. In this scenario a CXR should be undertaken to assess for progression of the pneumonia or pleural fluid collection. Fluid will collect in dependent regions, so an erect or lateral decubitus film may allow easier identification of a dependent opacification, loss of the costophrenic angle or a meniscus suggestive of fluid (Fig. 69.8). An effusion on CXR that is performed in the supine position may show a more subtle increase in generalized opacification, reflecting the underlying layer of fluid behind the lungs or showing opacification throughout the pleural space (Fig. 69.9). A routine lateral chest film is not required and is associated with unnecessary exposure to ionizing radiation.[105] In the setting of infrapulmonary effusion, where the effusion collects between the inferior surface of the lung and the dome of the diaphragm, an elevated lateral hemidiaphragm may be demonstrated on CXR (Fig. 69.10). Ultrasound is the investigation of choice,[106] but if unavailable, a CXR may be helpful in identifying whether a pleural effusion has become loculated. In this situation, when an erect CXR is compared with a decubitus film, failure of the fluid to shift with a change in position is suggestive of loculated fluid (Fig. 69.11). Given the additional radiation with repeat CXRs and the poor sensitivity of x-ray as compared with ultrasound, multiple CXRs in different positions should not be routinely undertaken. Within the context of pneumonia, any air in the pleural space suggests a complicated effusion that may involve a bronchopleural fistula or perforated viscus.

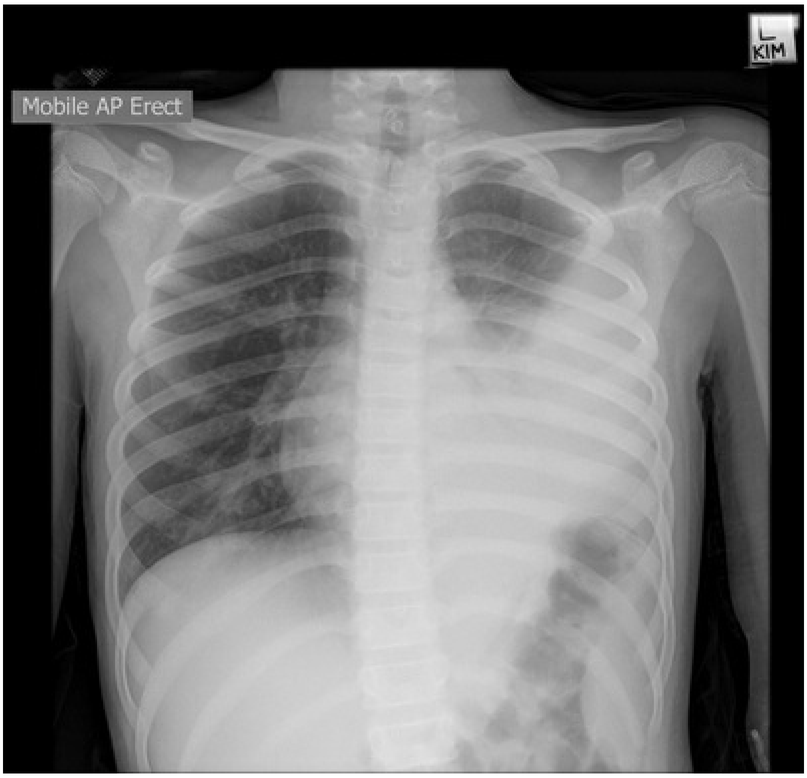

**FIG. 69.8** Chest x-ray (CXR) of empyema, erect image. CXR of a 7-year-old female with left-sided empyema. There is extensive opacity in the left middle and lower zones consistent with a combination of left-lower-lobe consolidation with collapse and a moderate to large pleural effusion, which was confirmed on ultrasound.

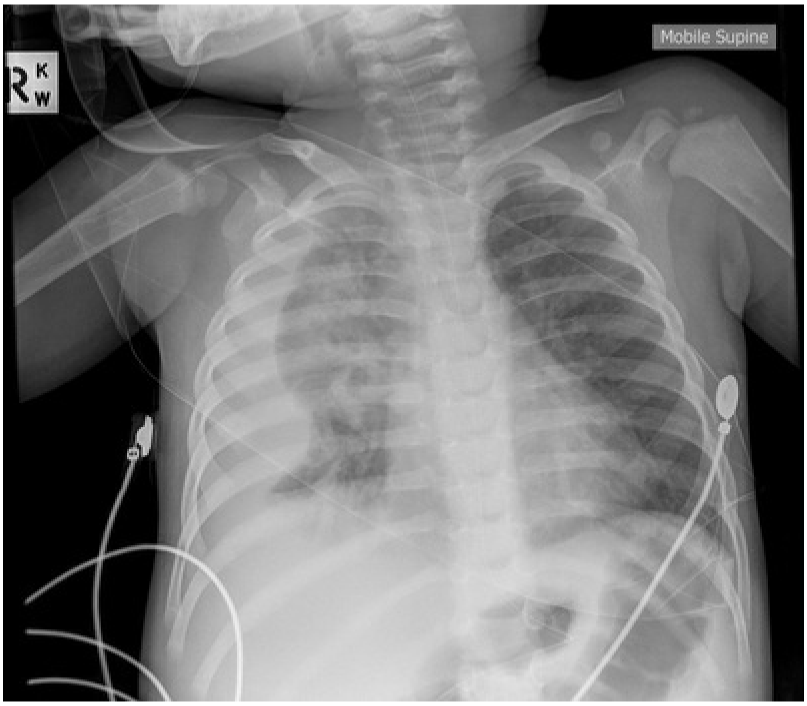

**FIG. 69.9** Chest x-ray (CXR) of empyema, supine image. CXR of a 22-month-old female with empyema. There is a large, dense, right-sided pleural collection extending up the lateral chest wall with an associated reduction in the volume of the right lung. There is patchy consolidation within the aerated right lung and collapse consolidation of the right lung base.

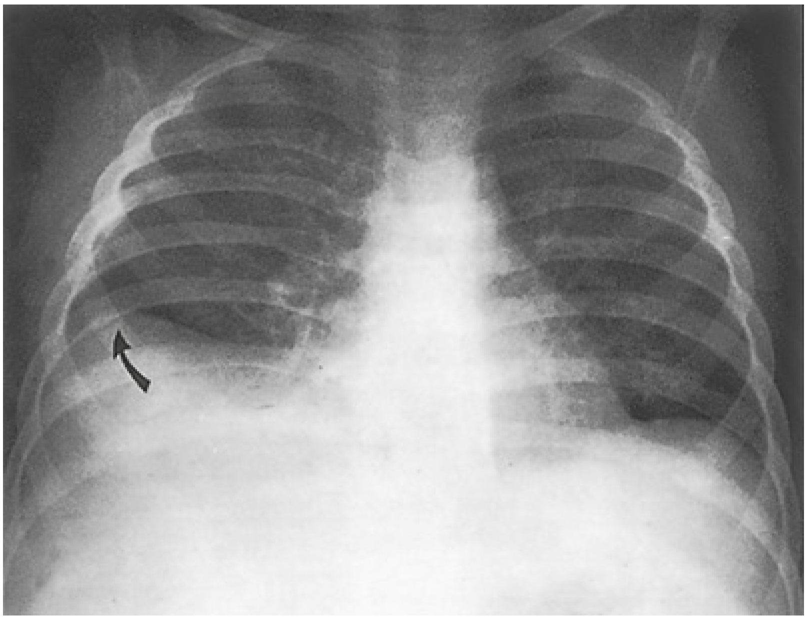

**FIG. 69.10** Chest x-ray demonstrating infrapulmonary/subpulmonary effusion. The right

hemidiaphragm has a lateral peak with relative lucency of the costophrenic angle.

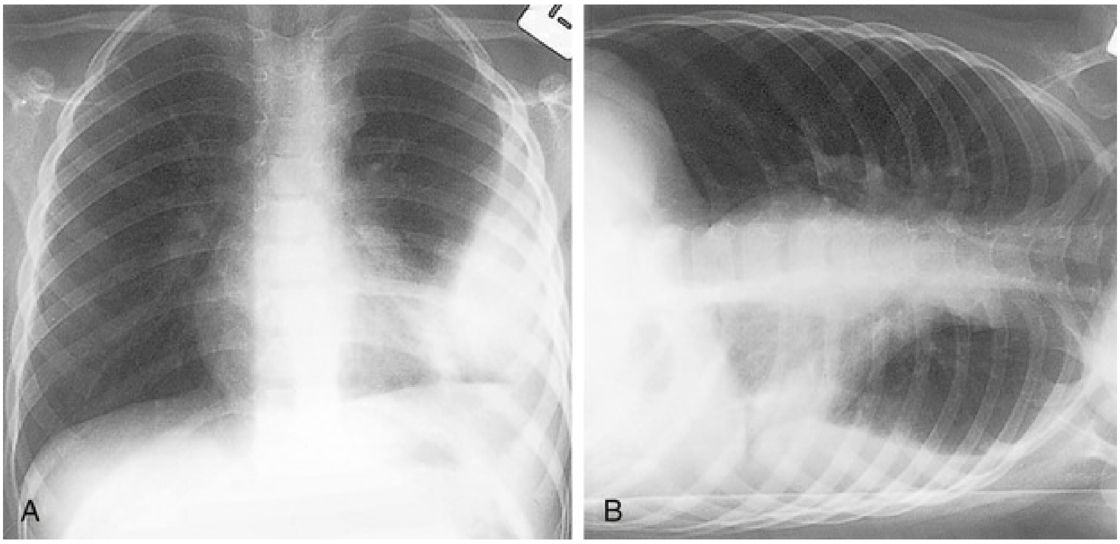

**FIG. 69.11** Comparison of chest x-ray (CXR) of empyema taken in erect and left lateral decubitus positions. (A) Posteroanterior erect CXR of a large left empyema and adjacent atelectasis. (B) Left lateral decubitus CXR demonstrating no change in the configuration of the effusion, suggesting a loculated empyema.

Children who are not clinically improving or who have a CXR suggestive of an effusion should undergo a chest ultrasound. This will allow a more accurate assessment of pleural fluid volume and will also better characterize the fluid (Fig. 69.12). Ultrasound will enable grading of the empyema.[107] Jaffe and coworkers developed an ultrasound scoring system for children with empyema based on complexity. Grades 1 and 2 effusions did not have septations; grade 1 fluid was defined as anechoic and grade 2 defined as echoic fluid without septation. Grade 3 and 4 empyemas were more complex, grade 3 defined as having thick septations and grade 4 had greater than one-third of the effusion comprising solid components.[107] These ultrasound findings are clinically relevant and may help determine which effusions need further intervention, including those that are less likely to resolve with antibiotics alone. If the fluid is found to be complex and loculated, further interventions such as insertion of a chest drain or surgical intervention should be considered.[107,108] Furthermore, ultrasound allows fluid volume to be estimated and enables the identification of optimal sites for chest drain insertion[105]; it is also more sensitive than CT in detecting early loculations and septations.[108] Ultrasound can be performed without sedation, which is required in some young children undergoing a CT scan. Importantly, ultrasound does not expose the child to radiation.

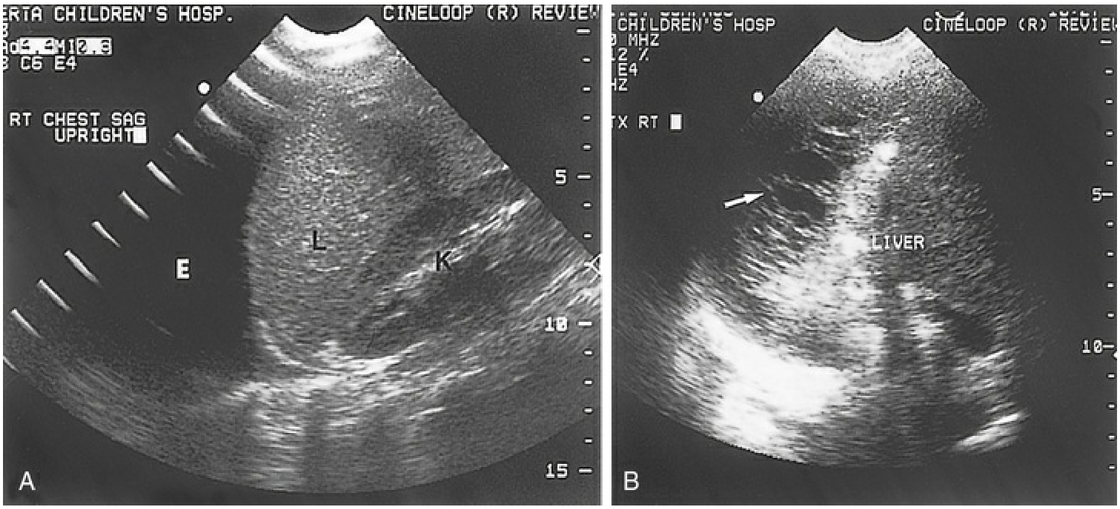

**FIG. 69.12** Ultrasound images of lower right hemithorax and upper quadrant of abdomen. (A) A large anechoic right pleural effusion *(E)* with liver *(L)* and kidney *(K)* identified. (B) Repeat sonogram 6 days later with mixed echogenicity consistent with an empyema *(arrow).*

During a clinical trial comparing VATS versus chest drain with fibrinolytics,[107] Jaffe and coworkers assessed the utility of routine CT scans in children with empyema; all subjects underwent a CT of the chest. Unsurprisingly, CT scans were able to demonstrate more parenchymal changes with greater sensitivity, such as cavitary necrosis and pneumatoceles, than CXRs. However, no abnormality detected on CT led to a change in management. Thus, although CT scans demonstrate greater detail of the underlying lung pathology, the performance of routine CT of the chest in empyema does not alter management; therefore this should not be performed routinely.[59,105] However, there are a few circumstances in which CT of the chest may be useful; these include specific evaluation of parenchymal disease,[107] cases involving concerns about an underlying malignancy and assessment for abscess formation. Neither ultrasound nor CT, nor a combination of the two, is reliably able to predict length of hospital stay for children with empyema.[107]

Initial blood investigations often demonstrate raised white cell count, inflammatory markers such as CRP, erythrocyte sedimentation rate (ESR), or procalcitonin. Secondary hypoalbuminemia from loss of protein into the pleural space or malnutrition may occur with large effusions.[109] Reactive thrombocytosis is also very common and resolves after approximately 3 weeks; it does not require any treatment.[59] Blood cultures should be drawn and may be positive in up to 22% of cases of empyema in children.[110] An antistreptolysin O titer (ASOT) may also be helpful to guide rationalizing antibiotics. The role of routine repeat blood investigations is limited and they are not recommended in empyema. If a child is not responding to treatment, repeat inflammatory markers may play a role in guiding the clinician in further management of the disease process, but these cannot differentiate bacterial from nonbacterial causes.[59] In older children who are able to expectorate, sputum samples may help with organism identification; however, there is no indication for routine bronchoscopy in empyema unless there is a specific concern about an inhaled foreign body.[59]

The BTS and Australian guidelines for pleural infection in children do not recommend that all otherwise healthy children routinely undergo immunologic testing in the setting of a single empyema.[59,105] However, the guidelines acknowledge that immune deficiency syndromes have been diagnosed in this way, and investigations should certainly be undertaken in the setting of a child with a history of repeated infections, unusual infections or a family history of immune deficiency. Guidelines recommend that if *S. aureus* or *P. aeruginosa* is identified as the causative organism, a sweat test to exclude cystic fibrosis should be arranged.[59]

Thoracentesis is rarely undertaken for diagnostic purposes in children with empyema; if it is performed, the simultaneous placement of a chest drain should be considered to minimize the number of invasive procedures.[105] Mitri and coworkers have demonstrated that children undergoing thoracentesis had significantly higher reintervention rates as compared with children who had chest catheters inserted.[111] If a drain is inserted for clinical reasons, pleural fluid should be sent for analysis, including Gram stain and culture, cytology and molecular testing such as PCR (if available). Pleural fluid is often sterile owing to prior administration of antibiotics; however, the use of PCR significantly improves the identification of bacteria.[101] A differential cell count may help in differentiating between bacterial, mycobacterial, or noninfectious causes, as lymphocytes rather than neutrophils may predominate in the last two conditions.[112] There is currently no role for biochemical analysis of pleural fluid in the setting of empyema to guide management in children, although this is the norm in adults.[59,105]

## Management

The aim of empyema treatment is to treat the microbial cause, sterilize the pleural fluid, and allow reexpansion of the lung to support the return to normal lung function. This occurs either through gradual reabsorption of excess pleural fluid over time or by active drainage by tube thoracostomy or surgery.[59] All children with empyema should be admitted to the hospital and treated with high-dose intravenous (IV) antibiotics and respiratory support (as required).[59,105] Ideally this should occur in a tertiary pediatric center with care by respiratory physicians in conjunction with pediatric surgeons, or at least with their consultation. The choice of antibiotics will depend on the severity of the clinical presentation, local incidence of microorganisms, and whether or not the child has any specific risk factors such as immunocompromise, aspiration, or hospital-acquired infection. Ideally the choice of antibiotic should be guided by microorganism identification from sputum, blood, or pleural fluid. As discussed earlier, diagnostic pleural aspiration for biochemical or microbiologic examination is not routinely undertaken.

In the absence of an identified causative organism, the choice of antibiotic should be determined by local community-acquired pneumonia guidelines and should include coverage for *S. pneumoniae, S. pyogenes,* and *S. aureus*.[59,105] Some communities have a high incidence of MRSA; this should be taken into consideration in choosing the appropriate antibiotic regimen. A macrolide should be added if there is high suspicion or confirmation of *M. pneumonia.*[59] If pneumatoceles are seen on CXR, the antibiotic chosen should specifically include cover for *S. aureus.*[113]

IV antibiotics are given until the child is afebrile; failure to respond to antibiotics should warrant consideration of an alternative regimen. There are few data regarding the duration of IV antibiotics required after defervescence, but the BTS guidelines note that IV therapy is generally given until the patient has been afebrile for at least 24 hours and that it should continue until the chest drain is removed.[59] Ongoing oral antibiotics are recommended for a minimum of 1 week, with some guidelines advocating up to 6 weeks of oral antibiotics.[59,65,105] The choice of oral antibiotic should be determined on the basis of the organism identified or the class of IV antibiotic that led to clinical improvement.[105]

Other aspects of management of empyema in children include management of hydration with IV fluids as required, analgesia, and antipyretics for comfort. The analgesic regimen should be optimized to encourage early mobility and maximize opportunities for lung reexpansion.[59] The patient will require titration of oxygen therapy and ventilatory support. Supplemental oxygen should be given if saturations fall below 93% in room air.[105] Chest physiotherapy does not play a role in the management of empyema,[59,105] but physiotherapy support—with early mobilization, deep breathing and coughing—is important.

Most cases of empyema will respond to conservative management, defined as antibiotics alone or with chest drain insertion, particularly for patients with small effusions and no respiratory compromise.[59] The rates of response to conservative management are varied; in one case series Gocmen and coworkers reported a 92% success rate in treating empyema with antibiotics and simple tube drainage.[114] However, most centers do not report success rates this high. Even if conservative management is successful, this approach results in a more prolonged stay in hospital compared with treatment by surgery or with fibrinolytics.

In a child with an empyema, the decision on when to intervene actively with pleural fluid drainage is often difficult, as some children, even with large effusions, improve spontaneously without chest drain insertion. Children who are acutely unwell, with severe respiratory distress, who are hypoxic or have moderate to large empyemas should not be managed with antibiotics alone; surgical intervention should be considered early.[59,113] Carter and coworkers performed a retrospective review of 180 otherwise healthy children with empyemas and found that the strongest predictors of a requirement for pleural drainage was admission to an intensive care unit or having a large effusion (comprising more than half of the thorax) or a mediastinal shift.[115] It was possible to treat half of these children with empyemas with antibiotics alone and they had shorter lengths of stay in hospital if they did not have the mentioned risk factors.[115] The specific intervention performed will depend on the level of service and clinical experience of the treating staff. The most commonly performed interventions include insertion of a chest drain (Figs. 69.13 and 69.14) or thoracoscopic VATS. Open thoracotomy has essentially been superseded by VATS but may be required in centers with limited access to thoracoscopic equipment or experienced staff.[105]

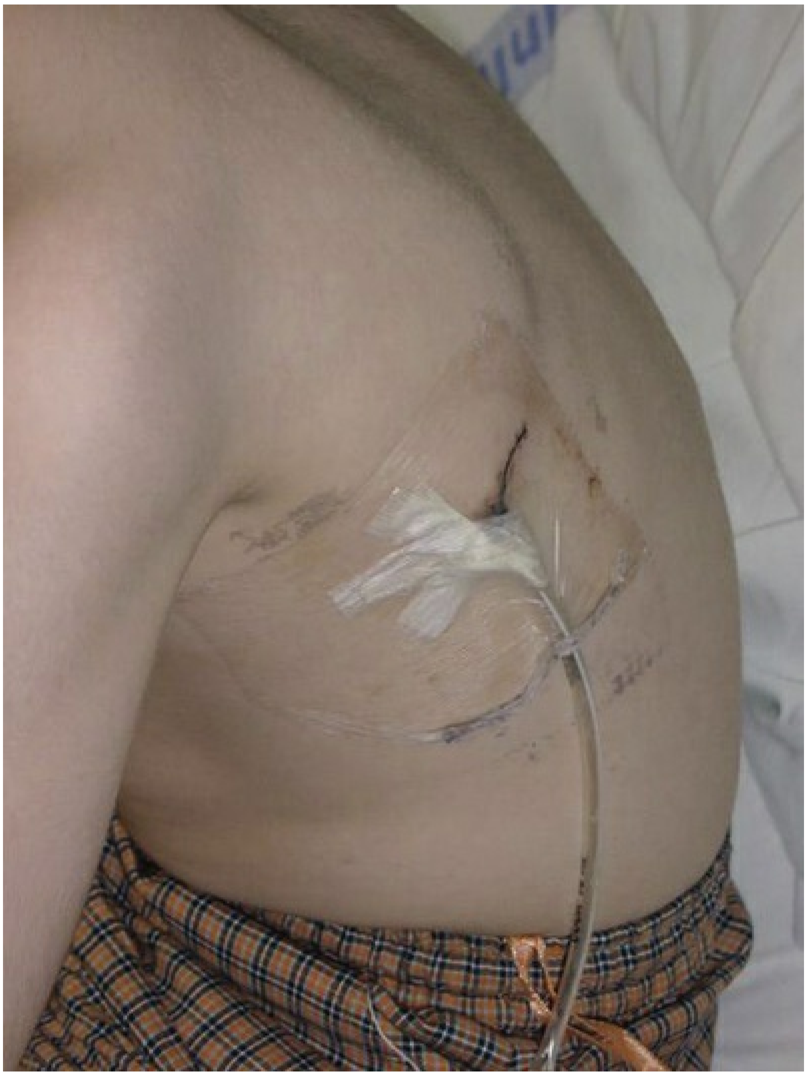

**FIG. 69.13** Pediatric patient with chest drain inserted.

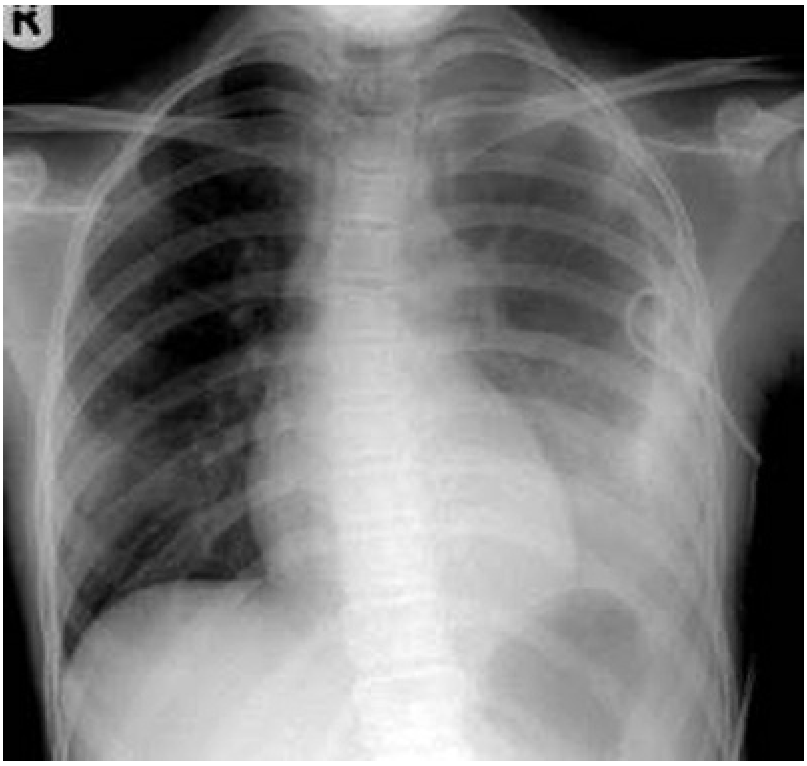

**FIG. 69.14** Chest x-ray (CXR) image of empyema with visible chest drain catheter. CXR image of left sided empyema with increased opacification and loss of costophrenic angle. Chest drain catheter in situ.

There is sufficient evidence to suggest that a smaller chest tube (<14F or pigtail) is sufficient to drain an empyema.[59] Smaller percutaneous drains have the advantage that they can be inserted easily under sedation by the Seldinger technique and are less painful than large-bore drains, allowing earlier mobilization. Furthermore, they can be inserted under ultrasound guidance by experienced staff such as emergency physicians or radiologists. The initial drainage rate should be monitored, as rapid rates of drainage have been known to cause RPE in adults[116]; however, this is rare in children. All chest drains should be connected to an underwater drainage system, which must be kept below the level of the patient's chest.[59] The drain should only be removed if there is clinical resolution and should never be clamped if bubbling, as this is an indication of air leak and clamping of the drain will precipitate the development of a pneumothorax.

If a chest drain is inserted, intrapleural fibrinolytics are recommended, as they have been shown to shorten the hospital stay compared with standard chest drainage.[59] Fibrinolytics are infused via the chest catheter into the pleural space to allow lysis of pleural septations and fibrinous strands and to clear lymphatic stomata so as to reestablish physiologic drainage from the pleural space.[113] Of the fibrinolytics used in adults with empyema, urokinase, streptokinase, tissue plasminogen activator, and alteplase have all undergone randomized controlled trials in children and were proven to be safe.[117–121] The use of recombinant human DNase with tissue plasminogen activator has proven successful in adults,[122] but there are no data for children. The BTS guidelines recommend urokinase twice daily for 3 days.[59]

Historically, surgical intervention was recommended only once conservative management with antibiotics alone had failed, or in the case of chest tube drainage and fibinolytics with disease progression or if there was ongoing clinical toxicity. This is still the recommended approach in the BTS guidelines as there are no evidence-based criteria for the timing of surgical intervention. There is no difference in clinical outcome between children who are treated with chest catheter drainage and fibrinolytics and VATS,[123,124] but fibrinolytic usage is significantly cheaper.[125,126] A VATS procedure enables the surgeon to drain the purulent material and debride fibrinous septations and loculations under direct vision using a thoracoscopic minimally invasive approach. This approach is preferred to a minithoracotomy approach or open posterolateral thoracotomy (Fig. 69.15) as it involves fewer complications, such as scarring, pain and infection. Early VATs may be the preferred option in some children, if they can be identified, who are at greatest risk for failed fibrinolytic treatment. Livingston and coworkers have reported that children with a positive blood culture, requirement for immediate intensive care admission, and those without complex septations on ultrasound may be at greater risk of fibrinolytic treatment failure.[127] Inflammatory markers such as CRP and necrosis on initial CXR have little prognostic value.

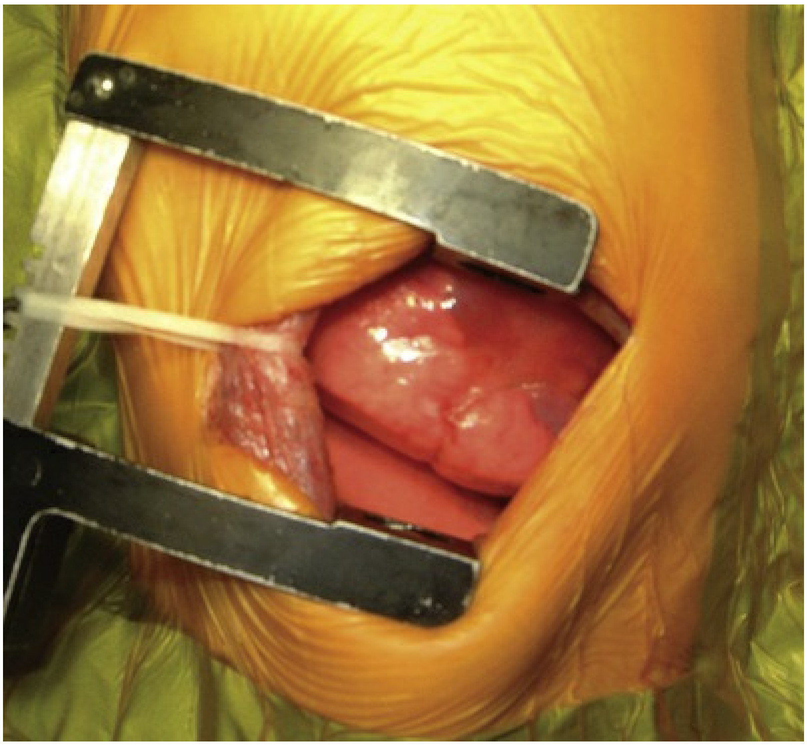

**FIG. 69.15** Photograph of open thoracotomy. Note the size of the incision made and the visible underlying lung. (Image reproduced with permission from Professor Gordon Cohen.)

## Monitoring Progress

Routine daily imaging such as chest CXR is not recommended for monitoring the progress of empyema, as it does not alter management.[105] CXR findings lag behind clinical improvement and may point to significant abnormalities that are not manifest clinically. More useful indications of improvement include defervescence, decreased respiratory distress, and decreasing oxygen requirements and respiratory support. Clinical findings may be supported by improving inflammatory markers such as CRP, ESR, or procalcitonin but should not be performed routinely.[59]

## Complications of Empyema

Empyema is commonly associated with cavitary pneumonia—up to 20% in some series.[128] Less commonly, empyema may be complicated by the development of a bronchopleural fistula and pneumothorax, lung abscess (particularly with organisms such as *S. aureus*) and rarer still, empyema necessitans when purulent material perforates through the chest wall.[59] If the empyema is diagnosed late, the effusion may have become increasingly organized, so that the underlying lung becomes “trapped,” which warrants surgical intervention to clear the loculations and fibrinous peel from the lung pleura and allow complete reexpansion. Fortunately, this development is rare in children.[65]

## Follow-Up of Empyema

Unlike the case with adult cohorts, where mortality rates can be as high as 30%,[129] the outlook for children with empyema is usually excellent.[113,130] CXRs will usually be abnormal at the time of discharge and do not alter management, so they should not be routinely performed.[59] A delayed CXR should be performed in all children approximately 6 weeks after the event to ensure that the condition is resolving (Fig. 69.16).[105] Most CXRs will have returned to near normal by 6 months[114,131] and nearly all by 12 months.[130] Complications of empyema can still occur if not treated appropriately; they include the recurrence of empyema, osteomyelitis of the rib, bronchopleural fistulas, and death.[132] However, these are all exceedingly rare in children.

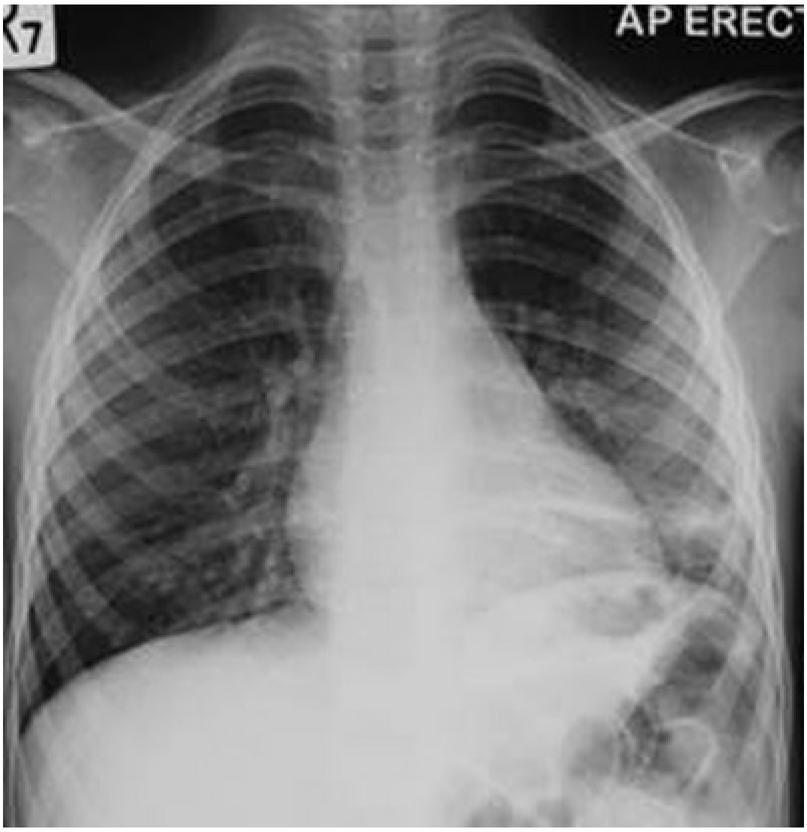

**FIG. 69.16** Chest x-ray (CXR) image taken 4 weeks after treatment of a left-sided empyema. This patient underwent insertion of a pigtail chest drain and fibrinolysis with urokinase. The empyema is resolving on CXR but is not completely back to normal after 4 weeks, as expected.

Healthy children managed with appropriate antibiotic courses are unlikely to have a repeat episode or any long-term consequences from empyema. Parents should be reassured that their child will have an excellent long-term outcome. After the follow-up CXR, unless there are concerns about secondary complications, no further imaging is required if the child is asymptomatic.[105] A recent study using chest MRI performed many years after empyema demonstrated persistent pleural abnormalities including pleural scarring, thickening, and subpleural nodules; the clinical significance of these findings is unknown (Fig. 69.17).[133] Spirometry performed after empyema is usually normal; however, some asymptomatic children do demonstrate abnormal lung function on subsequent testing.[134] There are insufficient data on cardiopulmonary exercise testing in children postempyema to determine if there are any effects at high levels of activity, but there does not appear to be a significant difference in exercise tolerance.[135]

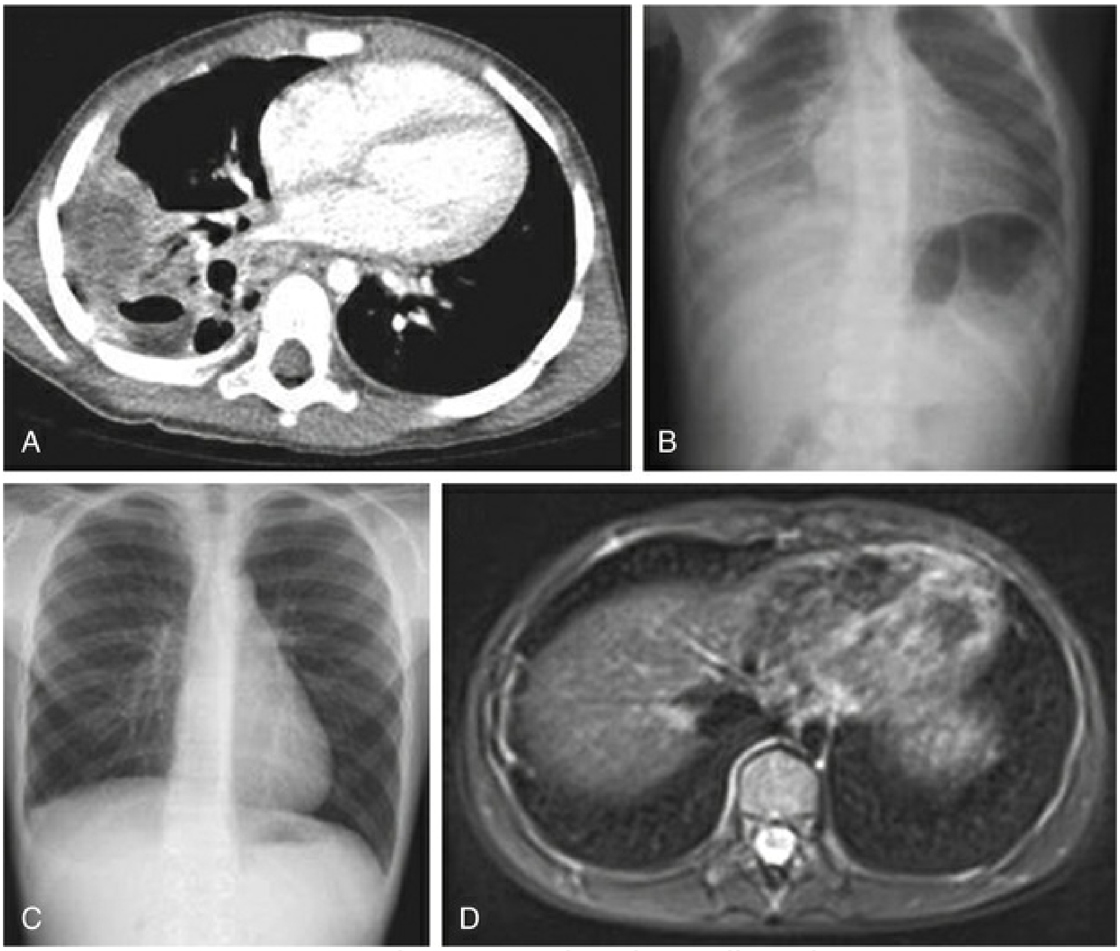

**FIG. 69.17** Images demonstrating the radiologic course of empyema in a 2-year-old boy. Pneumonia complicated by *Streptococcus pneumoniae* empyema in a 2-year-old boy treated with antibiotics and surgery. (A) Initial chest computed tomography demonstrating pleural fluid in the right hemithorax. (B) The initial chest x-ray (CXR) shows increased opacification of the right thoracic infiltrate with pleural thickening. (C) 6½ years later, CXR demonstrates pleural scarring in the right lateral recess. (D) The follow-up lung magnetic resonance image shows pleural thickening (5 mm × 30 mm × 20 mm) in the right lung, pleural scarring (30 mm × 4 mm × 10 mm) in the right lateral recess, and a subpleural micronodule (<5 mm) in the left-upper-lobe lingula. # Other Causes of Effusions—Chylothorax

## The Lymphatic System

The function of the lymphatic system is to transport lipids and lipid-soluble vitamins from the gastrointestinal system into the systemic circulation, to circulate lymphocytes and to allow fluid and protein in the interstitial space to be returned to the systemic circulation.[136] Chyle fluid is lymphatic fluid that contains chylomicrons drained from the intestinal lacteal system. Chlyomicrons are formed from long-chain triglycerides, cholesterol, phospholipids, and protein to enable water-insoluble long-chain-fatty-acid triglycerides to be absorbed from the gastrointestinal tract. The chyle fluid also contains lipid-soluble vitamins, electrolytes, protein, glucose, and numerous lymphocytes[137] (see Box 69.2), with smaller amounts of other cell types including erythrocytes. Chylomicrons give chyle fluid a "milky" appearance (Fig. 69.18), but this classical appearance may occur in only 50% of cases with chylothorax.[138] The thoracic duct is the main conduit by which the chyle fluid is transported from the gastrointestinal system via the lymphatic drainage system into the systemic circulation. There is significant day-to-day variability in the lipid content (and color) and flow through the thoracic duct, as it changes with food intake.[138] During periods of fasting, the lipid content will be lower, and after meals and water the flow will increase.

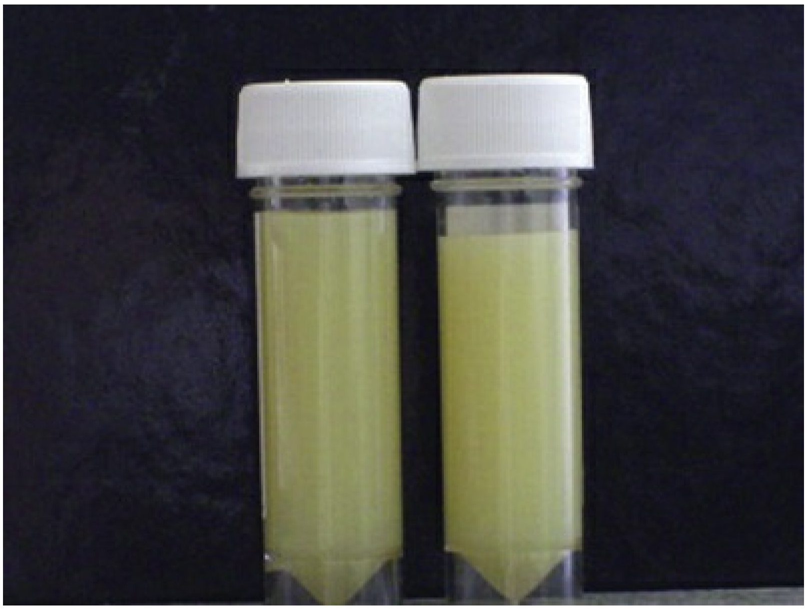

**FIG. 69.18** Image of chyle sample. Classic "milky" appearance of chylous fluid. (Used with permission from McGrath EE, Blades Z, Anderson PB. Chylothorax: aetiology, diagnosis and therapeutic options. *Respir Med*. 2010;104(1):1–8.)

As described earlier, the thoracic duct has many normal anatomic variations, but typically it arises from the coalescing lumbar and intestinal lymphatics and proceeds superiorly in the posterior mediastinum up to the level of the cervical vertebrae, eventually terminating between the left jugular and subclavian veins.[136] Numerous collaterals are often present. The right lymphatic duct, which drains the right upper limb, liver surface and the right side of the head, neck, and thorax, does not contain chyle.[137] The thoracic duct drains all the other regions of the body.

## Etiology

A chylothorax is defined as an accumulation of lymphatic fluid (chyle) in the pleural space,[136] which accumulates if the thoracic duct is disrupted by a congenital anatomic abnormality, a change in pressures within the duct or trauma (e.g., during cardiothoracic surgery). The level at which the duct is damaged will determine at which side of the thoracic cavity the chylothorax will occur or if bilateral chlyothoraces will form. The chylothorax occurs on the left if the thoracic duct is damaged above the level of the fifth thoracic vertebra and on the right if the damage is lower, between the fifth thoracic vertebra and the diaphragm.[137]

Chylothorax is a rare cause of fluid in the pleural space except during the neonatal period, when it is the most common cause of pleural effusion.[136] The etiology is varied and the incidence in children unknown, but the most common presentations of chylothorax in children are postoperative complications, congenital forms secondary to birth trauma, or in association with genetic syndromes such as Noonan or Down syndrome.[138–140] Congenital abnormalities such as lymphatic malformations, including lymphangiectasia and lymphangiomas, can result in a chylothorax.[140] The incidence varies with age and is more common in neonates than older children because of the association with congenital malformations and birth trauma.[138,141]

There are many causes of chylothorax (Table 69.5).[136] In the antenatal setting, if the chylothorax occupies a significant proportion of the pleural space, it may also result in pulmonary hypoplasia.[137] Chylothorax can occur secondary to direct or indirect trauma to the thoracic duct, and iatrogenic causes include thoracic surgery, particularly cardiac surgery (classically post-Fontan procedures),[142] scoliosis surgery, and repair of congenital diaphragmatic hernia.[143] Chylothorax also results from high central venous pressure, as in the case of superior vena cava obstruction and thrombosis[144] or severe vomiting.[145] Chylothorax can be associated with cancer, most commonly lymphoma in children, as thoracic lymphadenopathy can place significant pressure on the thoracic duct, causing disruption and leakage of contents. There are also several case reports of chylothorax occurring with child abuse, in some cases related to rib fractures.[146–148] Lymphadenopathy from nonmalignancy causes that obstruct the thoracic duct can also present as chylothorax.

### Table 69.5

**Etiology of Chylothorax in Children**

| | |
|---|---|
| Congenital | *Congenital lymphatic malformations:* Lymphangiomatosis, lymphangiectasia, atresia of the thoracic duct<br>*Associated with various syndromes:* Down Syndrome, Noonan Syndrome, Turner Syndrome<br>Hydrops fetalis |
| Traumatic | *Surgical:* Cervical surgery (e.g., lymph node excision), thoracic surgery (e.g., congenital heart disease or lung malformations)<br>Subclavian vein catheterisation<br>Hyperextension of chest wall or thoracic spine<br>Forceful coughing or vomiting<br>Childbirth |
| High central venous pressure | Thrombosis of the superior vena cava or subclavian vein<br>Post-Fontan surgery |
| Malignancies | Lymphoma<br>Teratoma<br>Sarcoma<br>Neuroblastoma |

## Clinical Manifestations of Chylothorax

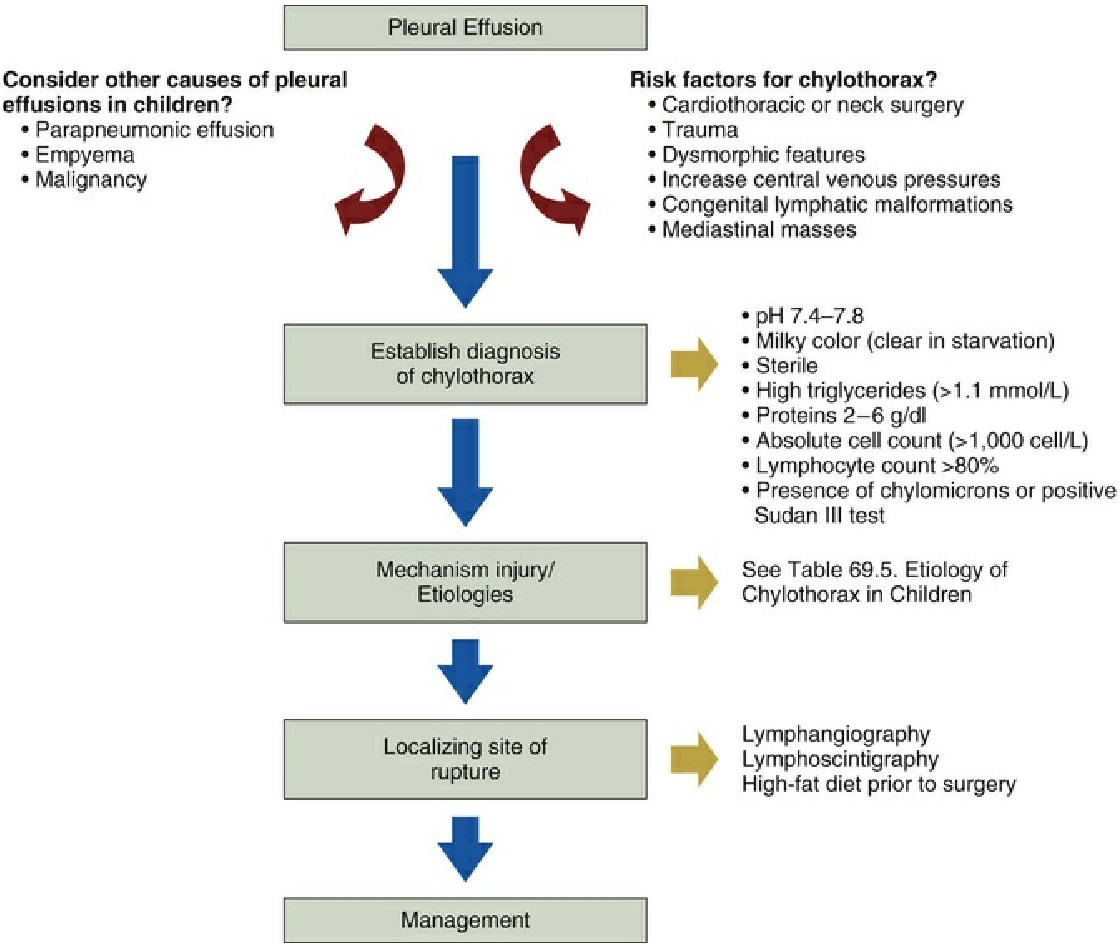
Chylothorax may have a similar presentation to other causes of pleural effusions in children, but without signs of infection or toxicity unless the chyle is secondarily infected. The presentation is varied and may reflect the size and clinical effects of the chylothorax, or it may be a manifestation of the underlying etiology. Classically children present with dyspnea and cough, but many children are asymptomatic. The degree of respiratory distress is determined by the size and rate of fluid accumulation; in cases of large and rapid accumulation, chylothoraces can lead to significant cardiorespiratory complications.

In traumatic chylothorax, there is often a significant delay between damage to the thoracic duct and clinical symptoms, which may not develop for up to a week.[138] Once the duct is damaged, fluid will leak directly into the posterior mediastinum, with eventual breach of the pleura and a gradual accumulation of fluid in the pleural space.

As in the case of clinical findings with other causes of pleural effusion, examination of the child reveals a dull percussion note on the affected side and reduced breath sounds on auscultation. The patient may be hypoxic, tachypneic, and have increased work of breathing. There may be other signs that indicate the cause or complications of chylothorax; malnutrition and immune dysfunction can cause opportunistic infections owing to the failure to recirculate lipids, chylomicrons, or lymphocytes.[136,138]

## Investigations

Investigations will include those that confirm the presence of a chylothorax and those used to determine the underlying etiology (Fig. 69.19). The pleural fluid is identified on a CXR, which demonstrates the size and location of the fluid (Fig. 69.20).[149] An ultrasound helps to delineate the nature of the fluid. Thoracentesis is necessary to determine if the effusion is chylous. The fluid is generally described as “milky” but cannot be differentiated from empyema on sight alone. The physical and chemical characteristics of chyle are listed in Box 69.2. A chylothorax is confirmed on biochemical analysis of pleural fluid which, when stained with Sudan III,[138] will confirm the presence of chylomicrons. In a setting where this analysis is not possible, surrogate measurements may be helpful, such as the triglyceride concentration (diagnostic if >1.1 mmol/L)[150] or finding other products in chyle such as a high T-lymphocyte count or immunoglobulins.[138]



Pleural Effusion
Consider other causes of pleural effusions in children?
• Parapneumonic effusion
• Empyema
• Malignancy
Risk factors for chylothorax?
• Cardiothoracic or neck surgery
• Trauma
• Dysmorphic features
• Increase central venous pressures
• Congenital lymphatic malformations
• Mediastinal masses
Establish diagnosis of chylothorax
• pH 7.4–7.8
• Milky color (clear in starvation)
• Sterile
• High triglycerides (>1.1 mmol/L)
• Proteins 2–6 g/dl
• Absolute cell count (>1,000 cell/L)
• Lymphocyte count >80%
• Presence of chylomicrons or positive Sudan III test
Mechanism injury/ Etiologies

Localizing site of rupture
Lymphangiography
Lymphoscintigraphy
High-fat diet prior to surgery
Management

**FIG. 69.19** Diagnostic algorithm for chylothorax.

(Reproduced with permission from Soto-Martinez M, Massie J. Chylothorax: diagnosis and management in children. *Paediatr Respir Rev*. 2009;10(4):199-207.)

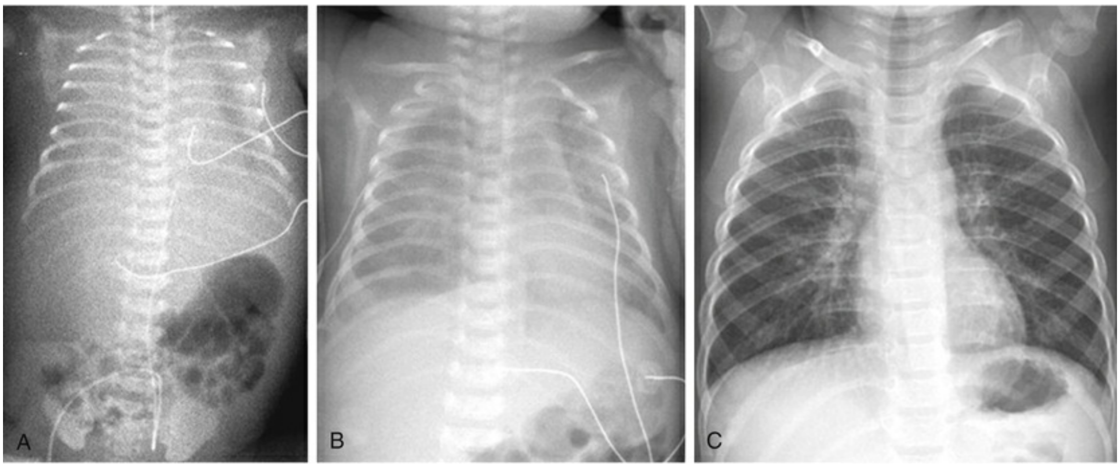

**FIG. 69.20** Serial chest x-rays of a neonate with chylothorax. (A) Male newborn with congenital bilateral chylothorax. (B) 12 days later, with improvement in the bilateral pleural effusions. (C) 12 months later, normal

thorax. (Reproduced with permission from Lopez-Gutierrez JC, Tovar JA, Chylothorax and chylous ascites: management and pitfalls. Semin Pediatr Surg; 2014; 23(5):298-302.)

Once a chylothorax is confirmed, a search for the etiology should be undertaken. In some cases this will be obvious from the history, as in a postoperative case or after trauma. In other cases it is important to exclude malignancy, granulomatous conditions, and congenital malformations and to perform a thorough examination to exclude nonaccidental injury.

Identification of the specific site of the chylous leak is important. Lymphangiography, lymphoscintigraphy and CT scans may be helpful but are generally available only at specialist centers.[137,138] Lymphangiography requires a skilled clinician to cannulate the lymphatic vessel and inject contrast to perform a radiologic scan (CT or MRI) to outline the course of the vessel, identify any breaches, and demonstrate contrast in the pleural space. Lymphoscintigraphy is the injection of radionuclides into the dermis or subcutaneous tissue; it utilizes nuclear medicine techniques to demonstrate the lymphatic draining system.

In some cases the patient may need to undergo a surgical procedure to identify the source of the chyle leak; this can often be done thoracoscopically and may be part of a definitive intervention.

## Management

The management of a chylothorax will include identification and treatment of the cause, appropriate management of any complications, such as malnutrition and immune deficiency, and prevention of ongoing leak. The management approach will be determined by the size and clinical effects of the chylothorax, but it generally includes a period of conservative “medical” management before surgical intervention. The latter is recommended after 4 weeks of failed medical treatment[136,137] or if there is significant nutritional decline or chylothorax progression during conservative medical management. Medical therapeutic options are aimed at decreasing the flow through the thoracic duct and “switching off” the chylous leak to allow the damaged surfaces of the duct to oppose and to enable spontaneous healing. This is done by limiting the consumption of long-chain fatty acids and their conversion to chylomicrons absorbed via the intestinal lymphatics.[136] In order to maintain nutrition in a patient who may already be suffering consequences of malnourishment, the patient is placed on a diet of medium-chain fatty acids.[137] Medium-chain triglycerides are absorbed directly into the portal system and thus bypass the intestinal lymphatics. In cases where dietary management fails, the patient may be trialed on total parenteral nutrition with complete enteric rest.[137] If children are going to respond to enteral or total parenteral nutrition, most will have done so by 3 weeks.[151]

Somatostatin is an endogenous hormone, and octreotide (its synthetic analogue) has been used in the medical management of chylothorax.[152] The mechanism of action remains unclear but is presumed to be the result of vasoconstriction of the splanchnic circulation, causing a decrease in intestinal blood flow, and by decreasing gastrointestinal secretions, thus ultimately diminishing lymph production.[137] As a result, the decreasing lymph flow allows time for the thoracic duct breach to heal. In up to 80% of cases,[153] medical therapy will allow the chylothorax to resolve, but this may take several weeks. The timing and duration of therapy remains uncertain.

If pharmacologic therapy of chylothorax fails, surgical options may be considered. Ideally the site of the chyle leak is identified with preoperative or intraoperative techniques that highlight the lymphatic flow. These options include injection of dye or having the patient drink a mixture of milk and cream a few hours prior to surgery to enable visualization of the site of leakage intraoperatively[136]; the identified breach is then ligated surgically. Unfortunately, the exact site may not always be easily identified, and ligation of the duct and surrounding tributaries may have to be considered. Surgical access may be open or thoracoscopic, and VATS has proven successful.[142] Alternatively, should the thoracic duct not be amenable to ligation, pleurodesis has enabled resolution of the chylothorax in some cases.[137,142] There are some small neonatal case series of intrapleural injection of povidone-iodine via chest drains for chemical pleurodesis.[154] The procedure appears to be well tolerated, but the risk of hypothyroidism must be considered. A particular clinical challenge in neonates with bilateral chylothoraces requiring pleurodesis is deciding whether to treat only one side in the first instance in the hope that the second side will resolve spontaneously. However, with this approach there is the potential risk that the contralateral effusion may worsen.

Fluoroscopically guided embolization of the thoracic duct has been successful in some patients[155,156] but requires specialized techniques that are not available in all centers. Radiotherapy may be an option for patients with chylothorax secondary to lymphatic malformations such as lymphangiomatosis,[157] where radiation impairs the function of the lymphatic tissue function and inhibits further excess drainage.

As a last resort, if the chylothorax is not corrected with the mentioned interventions or there is significant hemodynamic compromise, a pleuroperitoneal shunt may be considered,[149] which allows recirculation of chyle contents and prevents further respiratory compromise secondary to fluid accumulation in the pleural space.

## Hemothorax in Children

Hemothorax in children is a rare occurrence but is a relatively common complication of serious thoracic trauma and is associated with a high mortality rate.[158,159] Children have more compliant thoracic cages than adults because of ligamentous laxity and developing bones; as a result, significant intrathoracic trauma can occur with minimal external signs of injury[160]. Therefore hemothorax should be considered in all cases of blunt and penetrating chest trauma in children. Hemothoraces can also be iatrogenic, occurring after chest drain insertion,[161] intrathoracic surgery, or with inappropriate placement of central lines.[162] Hemothoraces can cause significant cardiorespiratory effects, including cardiac arrest, and can be complicated by secondary infection and fibrosis, causing “trapped lung,” although these complications appear to be less frequent than the rates seen in adult patients with hemothorax.[160] Hemothorax can be diagnosed on CXR or in the setting of trauma. A focused assessment with sonography for trauma (FAST) ultrasound scan may be considered and may be more sensitive than CXR.[163] Treatment will depend on the nature of the injury (either penetrating or blunt force), size of the hemothorax, and clinical status of the patient. Some pediatric patients with hemothorax can be managed conservatively with close observation. Others, particularly those with penetrating chest injuries or large hemothoraces, will require tube thoracostomies or open thoracic surgery to stop the bleeding.[160] The hemothorax may develop from blood draining into the pleural space from the lung, airway, esophagus, heart, or chest wall[159] and may occur in conjunction with a pneumothorax.

## Conclusion

Pleural diseases in children are not common, but they cause significant morbidity and may require prolonged hospital admissions, often with significant interventions. Evidence to guide therapy is still lacking in some areas and will require significant collaboration between pediatric centers to provide the best evidence-based clinical guidelines.

# Atelectasis

*Kai Håkon Carlsen MD, PhD, Suzanne Crowley DM, Bjarne Smevik MD*

The word *atelectasis* stems from two Greek words: *ateles,* meaning "imperfect," and *ektasiz,* meaning "expansion." Atelectasis thus means imperfect expansion, and the word is used to describe incomplete expansion of a lung or lung tissue. After inventing the stethoscope in 1816, René Laennec was the first to describe atelectasis as a finding during an autopsy in 1819.[1] There are many causes of atelectasis, which is a common complication of both acute and chronic lung disease affecting patients of all ages. It may be congenital or acquired. Congenital atelectasis is usually due to incomplete expansion of the lungs, including primary and secondary congenital atelectasis. The most common cause of atelectasis is loss of air in lung tissue that was previously expanded, thus resulting in the collapse of a lung or lung tissue.

## Etiology and Pathogenesis

Several mechanisms associated with a variety of pulmonary and extrapulmonary diseases may cause atelectasis. Pulmonary causes include obstruction of the bronchial lumen (the most common cause) and increased surface tension of the fluid lining the respiratory tract and alveoli. Extrapulmonary causes include compression of airways and lung tissue from outside the lung and weakness of respiratory muscles in neuromuscular disease. Obstruction of the bronchial lumen by mucus may have several causes, such as airway inflammation and impaired clearance of airway mucus caused by increased mucous viscosity (cystic fibrosis), reduced ciliary function, or a weak cough reflex secondary to neuromuscular disease. Box 70.1 shows the causes of atelectasis.

**Box 70.1**

## Causes of Atelectasis

### Intraluminal Causes

- Airways inflammation with increased bronchial mucus and formation of mucus plug due to
  - Bronchial asthma
  - Respiratory tract infection
    - Bronchiolitis, Pneumonia
  - Bronchopulmonary dysplasia
  - Cystic fibrosis (increased viscosity of the mucus)
  - Primary and secondary ciliary dyskinesia (impaired mucociliary clearance)
  - Immunodeficiency
  - Tracheoesophageal fistula or esophageal atresia
- Foreign body in the lower respiratory tract
  - Nuts, plastics, other foreign bodies, misplaced tracheal tube

### Compression of the Airways

- Lobar emphysema
- Lymph node enlargement
- Vascular ring
- Complex congenital heart disease (e.g., enlargement of left atrium compressing left main bronchus)

### Bronchial Wall Involvement

- Airway stenosis
  - After aspiration or inhalation injury

    - After intubation
    - Complete cartilaginous rings
- Bronchiectasis
- Tracheobronchomalacia
- Bronchial tumor

### Compression of Lung Tissue

- Pneumothorax
- Congestive heart failure with cardiac enlargement
- Hemothorax
- Chylothorax
- Lung tumor

### Surfactant Dysfunction

- Respiratory distress syndrome of the newborn
- Adult respiratory distress syndrome
- Other

### Primary Atelectasis

- Congenital malformation

## Pathogenic Mechanisms

Congenital pulmonary airway malformations may prevent the normal aeration of parts of the lungs at birth due to lack of communication of the main bronchial tree with the affected parts of the lungs that have never been inflated, thus causing primary atelectasis. However, a secondary atelectasis may develop shortly after birth if a congenital malformation occludes or narrows the bronchial lumen, thus presenting as a differential diagnosis to primary atelectasis.[2]

Secondary atelectasis is most often caused by collapse of normal lung tissue due to obstruction or alternatively due to compression of the bronchial lumen. The pores of Kohn form at 3–4 years of age[3] and function as collateral communications between neighboring alveoli; they ensure a more even ventilation/perfusion ratio in the lung, thereby playing a role in preventing atelectasis. At more proximal levels no such collateral communications exist, and occlusion of the bronchial lumen initially leads to air trapping in lung tissue peripheral to the occluded bronchus. The trapped air is gradually absorbed, leading to atelectasis. Causes of obstruction or compression of the bronchial lumen are shown in Box 70.1.

The solubility of the trapped gases determines their absorption rate. The absorption of atmospheric air will take place within hours, whereas oxygen is absorbed within minutes.[4] Atelectasis therefore occurs more rapidly during ventilation with an increased inspired oxygen fraction and especially with 100% oxygen, compared with breathing normal air. This may partly explain the increased risk of atelectasis during anesthesia.[4] The ventilation/perfusion ratio of the atelectatic tissue is regulated through the increased vascular resistance resulting from hypoxic vasoconstriction of the pulmonary vessels secondary to occlusion of the bronchial lumen.[5]

Atelectasis may be caused by any process or procedure that occludes the bronchial lumen. Foreign bodies in the lower respiratory tract may lead to partial or complete occlusion of a bronchus, and complete occlusion will cause atelectasis. With an initial incomplete occlusion, the foreign body may cause inflammation of the mucous membranes, with resulting mucosal swelling and increased respiratory secretions causing complete obstruction of the bronchial lumen and the development of atelectasis.

Misplaced endotracheal intubation may cause total collapse of one lung when the distal part of the tracheal tube is located in a main bronchus (most often the right one).

Inflammatory processes within the bronchial tree are among the most common causes of obstruction of the bronchial lumen, including bronchial asthma (often eosinophilic inflammation)[6] and acute bronchiolitis due to respiratory syncytial virus infections.[7] In asthma and bronchiolitis, the right middle lobe and the lingula are the most common locations of atelectasis, so common that this is given the name of middle-lobe syndrome.[6,8] The finding of positive bacterial cultures from the respiratory tract in children with asthma and bronchiolitis with atelectasis and middle-lobe syndrome has led to a suggested role for bacterial infection in long-standing atelectasis of asthma and bronchiolitis.[7,9]

Airway inflammation due to asthma, bronchiolitis, and other respiratory infections may cause increased bronchial secretions, mucosal edema, bronchial smooth muscle contraction, and destruction of bronchial epithelium with reduced ciliary function, leading to the retention of mucus within the bronchial lumen. Destruction of the bronchial epithelium may alter the airway surface liquid, with an effect on surfactant function; it may thus enhance the tendency for bronchial collapse. In both bronchopulmonary dysplasia and respiratory distress syndrome of prematurity, abnormal surfactant function may contribute to the formation and persistence of atelectasis.[10] Aspiration of meconium, acids, alkali and amniotic fluid also has this effect.

Many diseases increase the susceptibility of the respiratory tract to infection and lead to the accumulation of mucus, which predisposes to the development of atelectasis. These include immunodeficiency, primary ciliary dyskinesia (PCD),[11] and cystic fibrosis.[12]

Bronchial wall processes that narrow the bronchial lumen, including tracheobronchomalacia, vascular rings,[13] tumors such as polyps, papillomas, and (rarely) bronchocentric carcinoma,[14] may cause atelectasis in children. Bronchiectasis, usually caused by recurrent or long-standing airway inflammation, is often complicated by atelectasis.[12]

Extrapulmonary processes may compress normal lung tissue and cause atelectasis without affecting the bronchi, as seen in some patients with congenital heart defects and also with pneumothorax or hemothorax. Rounded atelectasis, seen more often in adults than children, is mostly asymptomatic and associated with chronic pleural disease, lung fibrosis, or pleural effusions. It consists of infolding of atelectatic lung tissue with blood vessels, pleura, and sometimes bronchi.[15]

Atelectasis is common in neuromuscular diseases. Muscular hypotonia impairs ventilation because of reduced movement of respiratory muscles and causes difficulty in clearing bronchial secretions, thus increasing the individual's susceptibility to respiratory infections and atelectasis.[16] Hypoventilation may also contribute to the development of atelectasis that is seen in children during anesthesia.[4]

## Clinical Manifestations

The symptoms and signs of atelectasis will depend on whether single or multiple lobes are involved, the underlying cause, and the age of the patient. In full-term newborn infants with respiratory distress, the presence of atelectasis when accompanied by situs inversus and the need for prolonged supplemental oxygen is highly predictive of a PCD diagnosis (see Chapter 71).[11] In this instance, atelectasis caused by mucous plugging secondary to poor mucociliary clearance is most prevalent in the upper (75%) and middle (25%) lobes. Infants with bronchiolitis who develop lobar atelectasis are more likely to have severe disease and require admission to the intensive care unit,[17] while exhaustion and sudden severe deterioration may indicate the development of massive atelectasis affecting a whole lung. Preterm infants with bronchiolitis are at higher risk of developing atelectasis,[17] and younger children in general are more at risk of developing atelectasis than older children and adults owing to less well developed collateral ventilation effected by the pores of Kohn and the canals of Lambert.[3] In children with asthma, acute deterioration of symptom control may be due to the development of atelectasis affecting the right middle lobe, so-called right-middle-lobe syndrome (Fig. 70.1). Similarly, an exacerbation of symptoms in children with cystic fibrosis or PCD may be due to the development of atelectasis secondary to bacterial infection in the lower airways, causing increased production of mucus and cellular debris with subsequent mucus plugging.[12]

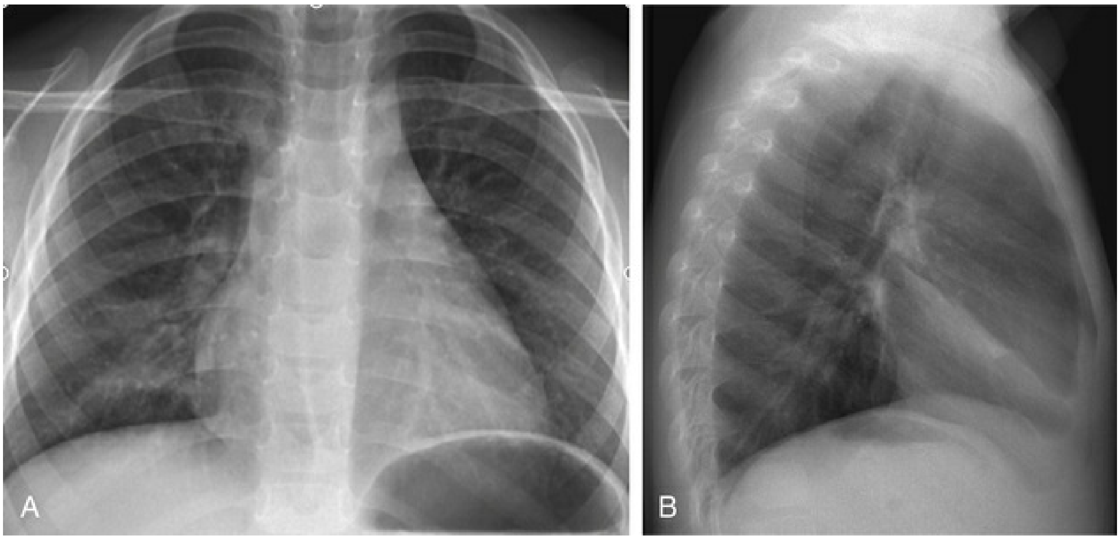

**FIG. 70.1** Three-year-old girl with repeated episodes of atelectasis of the middle lobe. Chest radiograph. (A) Frontal projection shows slight blurring of right heart contour. (B) Lateral projection shows triangular opacity with apex toward the hilum.

An episode of sudden paroxysmal coughing with or without subsequent respiratory distress in a previously healthy young child accompanied by x-ray features of atelectasis may indicate the need for bronchoscopy to exclude an inhaled foreign body. Atelectasis may not cause detectable abnormalities on clinical examination; thus the diagnosis must be made radiologically. But generally clinical signs relate to the size of the atelectasis. There may be impaired oxygen saturation, decreased expansion of the chest on the affected side, dullness to percussion, and diminished or absent breath sounds. If the atelectasis is partial or airway obstruction is not complete, crackles may be heard during inspiration and expiration. In some cases of significant or even whole-lung atelectasis, oxygen saturation may be normal, since alveolar hypoxia can induce reflex vasoconstriction and thus minimize ventilation/perfusion mismatch. Paradoxically, intubation and mechanical ventilation of such patients with supplemental oxygen may cause a temporary deterioration in oxygen saturation due the abolition of the protective vasoconstrictive reflex, thus inducing intrapulmonary shunting and the perfusion of unventilated, atelectatic lung tissue that does not take part in gas exchange.[4] Lung function in patients with atelectasis may be normal if the atelectasis is small or demonstrate a restrictive pattern with a reduced $FEV_1$

and FVC, and a normal $FEV_1/FVC$.

## Diagnosis

The prompt diagnosis of atelectasis in children is important, since early detection and subsequent treatment may lead to an improved outcome.[18] Diagnosis is aided by an understanding of situations in which atelectasis is more likely to occur and the underlying pathophysiologic mechanisms. For example, postoperative atelectasis is not uncommon, particularly in children undergoing cardiac surgery.[19] However, since atelectasis is not always detectable clinically, it may be discovered unexpectedly, for example, during routine chest x-ray in a child with a chronic underlying condition such as asthma or PCD. Flexible bronchoscopy has a role in the diagnosis of atelectasis when there is suspected airway obstruction due to, for example, foreign-body inhalation, mucous plugging, endobronchial tuberculosis, airway malacia, external compression from a vascular ring, enlarged lymph nodes, or an enlarged heart. It may also be therapeutic in cases of intraluminal obstruction.

The most frequently used modality for the diagnosis of atelectasis is *chest radiography*. Frontal projection is always included, but sometimes lateral views are better suited, as in atelectasis of the right middle lobe and the lower lobes. Oblique views may be of particular value in segmental atelectasis. Sometimes *fluoroscopy* is also used to delineate difficult locations of increased opacification. Fluoroscopy may also be used to diagnose air trapping and mediastinal shift when a foreign body is suspected. In older children, however, an x-ray at end-inspiration followed by another at end-expiration will suffice. Because atelectasis results in volume reduction of the affected part of the lung, this may lead to general signs such as elevation of the diaphragm and narrowing of ipsilateral intercostal spaces (Fig. 70.2). Shift of the mediastinum and tracheal contours toward the affected side is quite common, but these general signs may be absent if emphysema develops in the ipsilateral lung or if the atelectasis occurs together with ipsilateral pleural effusion. Atelectasis of the right upper lobe is seen as a combination of increased opacity and volume reduction leading to elevation of the interlobar fissure (Fig. 70.3). A summary of major findings on chest radiography related to extent and location of the atelectasis is presented in Table 70.1.

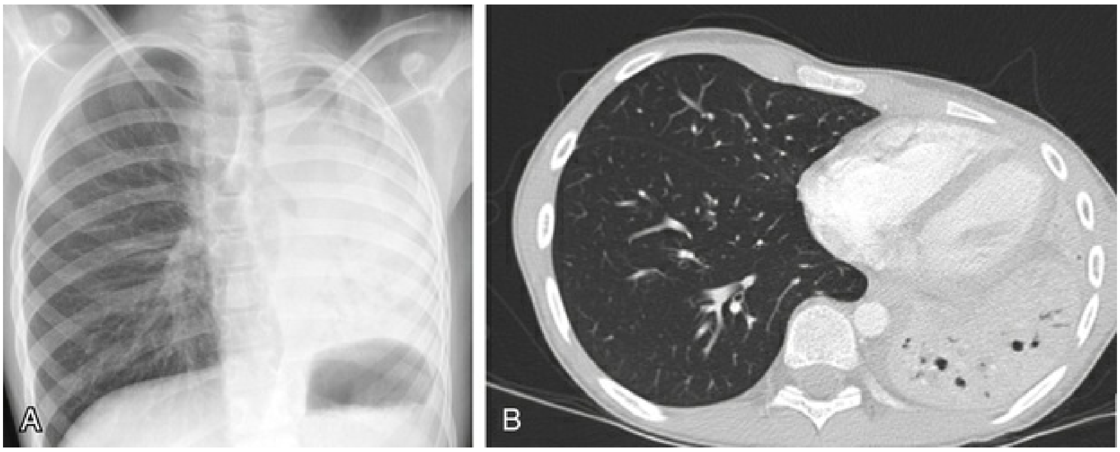

**FIG. 70.2** Eleven-year-old girl with asthma and idiopathic eosinophilic pneumonitis and subtotal atelectasis of the left lung. She had coughed up a bronchial cast. (A) Chest radiograph shows opacification and volume reduction of left hemithorax and shift of trachea/mediastinum toward the affected side, as well as elevation of the contour of the left diaphragm. It also shows reduced left intercostal spaces. (B) Computed tomography shows volume reduction and reduced intercostal spaces on the left side; the heart is shifted to the left, and there is atelectasis of the left lung and some hyperinflation of the right lung (Video 70.1▶).

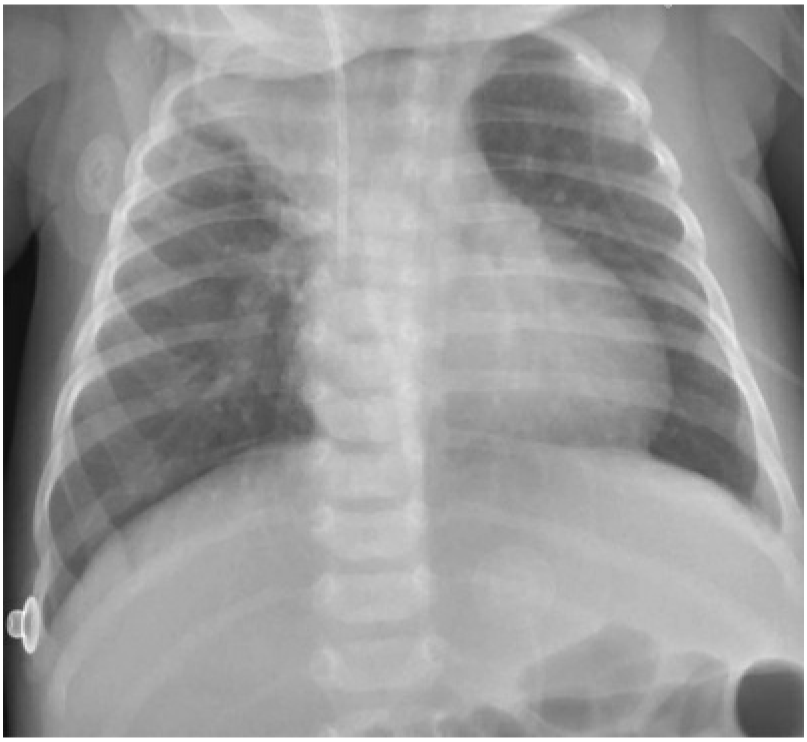

**FIG. 70.3** Two-month-old girl with cystic fibrosis. Chest radiograph shows atelectasis of the right upper lobe and elevation of the interlobar fissure.

---

## Table 70.1

### Chest Radiographic Signs of Atelectasis Related to Location

| Location | Chest Radiographic Signs |
|---|---|
| Complete atelectasis of lung | Opacification of one hemithorax<br>Shift of mediastinum and heart to ipsilateral side<br>Narrowed intercostal spaces<br>On lateral view: blurring of cardiac silhouette, one diaphragmatic contour and one hilum |
| Right upper lobe | Opacification of volume-reduced upper lobe and elevation of interlobar fissure |
| Right middle lobe | Indistinct right cardiac contour<br>On lateral view: triangular density with apex toward hilum |
| Right lower lobe | Visible major fissure shifts downward as lower lobe retracts<br>On lateral view: posterior third of right diaphragm indistinct |
| Left upper lobe | Opacity in upper left hilar region<br>Shift of mediastinal structures to the left; elevation of left diaphragm |
| Left lower lobe | Opacity in retrocardiac space<br>Indistinct vessels in the left lower lobe, visible air bronchogram in lower lobe<br>Left hilum displaced caudally<br>Indistinct medial diaphragmatic contour |
| Segmental atelectasis | Affects parts of a lobe; oblique projections may be helpful |
| Focal atelectasis | Density usually located in the basal lung fields as a thin line |
| Rounded atelectasis | Rounded density adjacent to the pleural surface |

| | |
|---|---|
| Alveolar atelectasis | Decreased aeration, generally bilateral |

*Computed tomography* (CT) and multislice CT with reconstruction may reveal atelectasis not visible on chest x-ray, but the use of general anesthesia, often required in very young children, may induce atelectasis in up to 70% of cases (Fig. 70.4).[20] CT is of particular value with lesions located close to the chest wall or at the periphery of the lung and close to the spine. The use of a controlled ventilation protocol reduces the frequency of atelectasis in these children.[21] Segmental atelectasis affecting a part of a lobe may be more clearly seen with CT (Fig. 70.5).

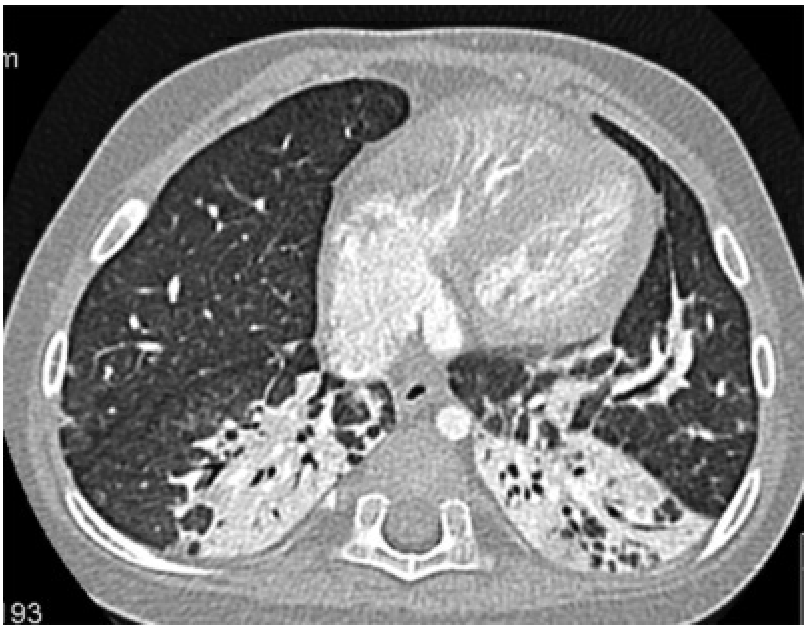

**FIG. 70.4** Two-year-old boy born prematurely. He has bronchopulmonary dysplasia and pulmonary hypertension. Computed tomography after sedation shows extensive dependent atelectases in both lungs (Video 70.2▶).

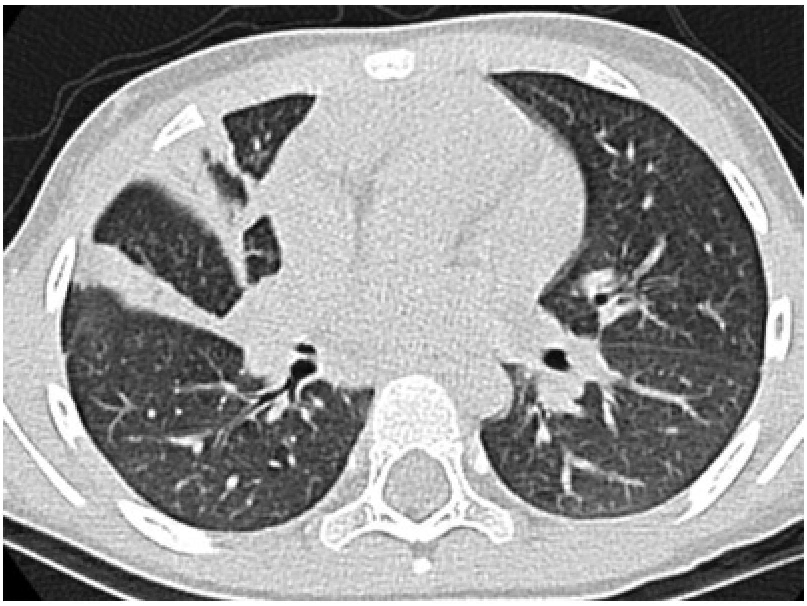

**FIG. 70.5** Four-year-old girl with subsegmental atelectasis in the right lung. Bronchoscopy for suspicion of foreign body was negative.

CT may also offer a better understanding of the whole lesion when atelectasis occurs in combination with bronchiectasis (Fig. 70.6). Rounded atelectasis is also best depicted with CT: a rounded mass at the periphery of the lung adjacent to a pleural thickening and with blurred contours toward the hilum where vessels and bronchi enter the lesion.

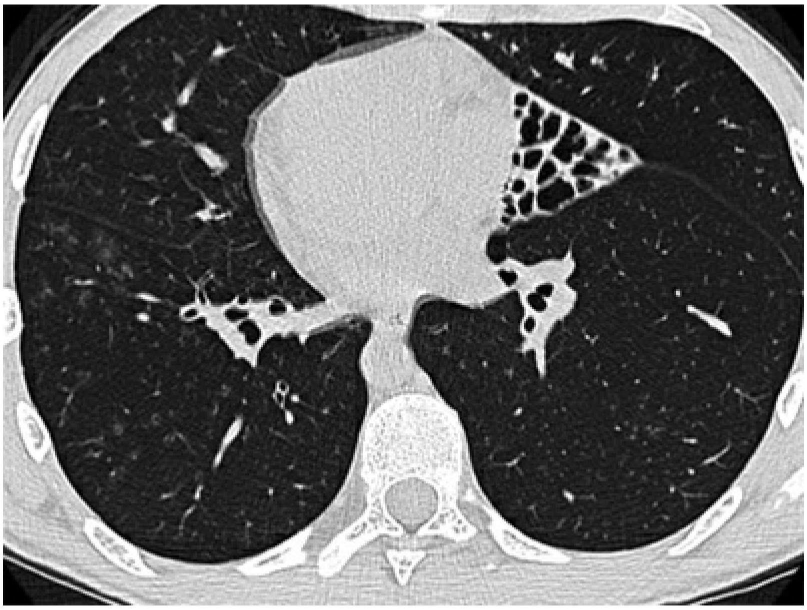

**FIG. 70.6** Sixteen-year-old boy with Kartagener syndrome. Bronchiectasis is most pronounced in the

atelectatic left-sided middle lobe (Video 70.3).

*Magnetic resonance imaging* (MRI) is also very well suited for the diagnosis and follow-up of atelectasis.[22] Because the modality produces pictures of excellent quality in any plane, it is a very good alternative to CT in children who are able to cooperate during the study (Fig. 70.7). For MRI studies, smaller children will often need general anesthesia, and fast multislice CT with an unsedated child may be a better option.

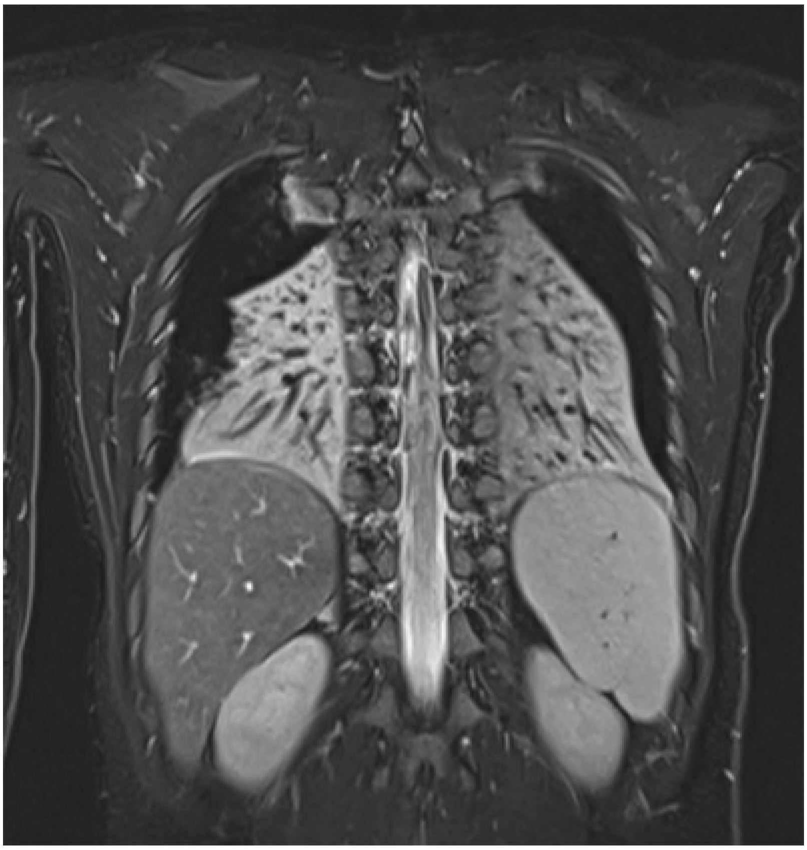

**FIG. 70.7** Ten-year-old girl who underwent heart transplantation at 9 years of age. Magnetic resonance imaging shows extensive atelectasis of both lower lobes (Video 70.4).

When the atelectasis is located near the thoracic cage, and especially when it is combined with pleural effusion (as is often the case after cardiac surgery or pleural empyema), *ultrasonography* is a quick and reliable bedside method.[21] The collapsed lung is easily differentiated from surrounding pleural effusion (Fig. 70.8).

Ultrasonography and MRI can both be used without considering the burden of ionizing radiation.

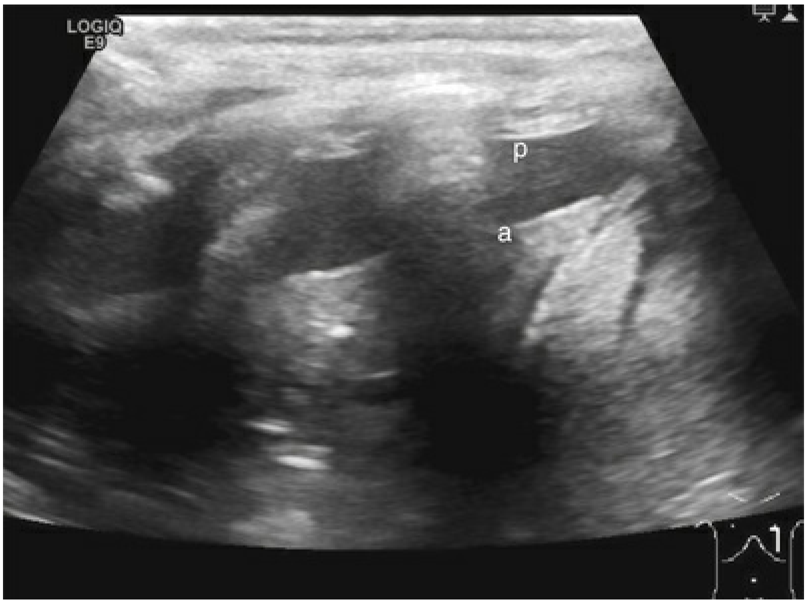

**FIG. 70.8** Two-year-old girl treated with extracorporeal membranous oxygenation because of pneumonia. Ultrasound shows atelectasis of the left lung (a), which is clearly seen next to pleural effusion (p) (Video 70.5 ▶).

*Bronchography* is rarely used but may be combined with diagnostic and therapeutic bronchoscopy in selected cases to show short segments of localized stenosis or bronchomalacia. Difficult postoperative situations with repeated episodes of atelectasis may be better understood when bronchography is combined with monitoring of ventilation pressure (Fig. 70.9).

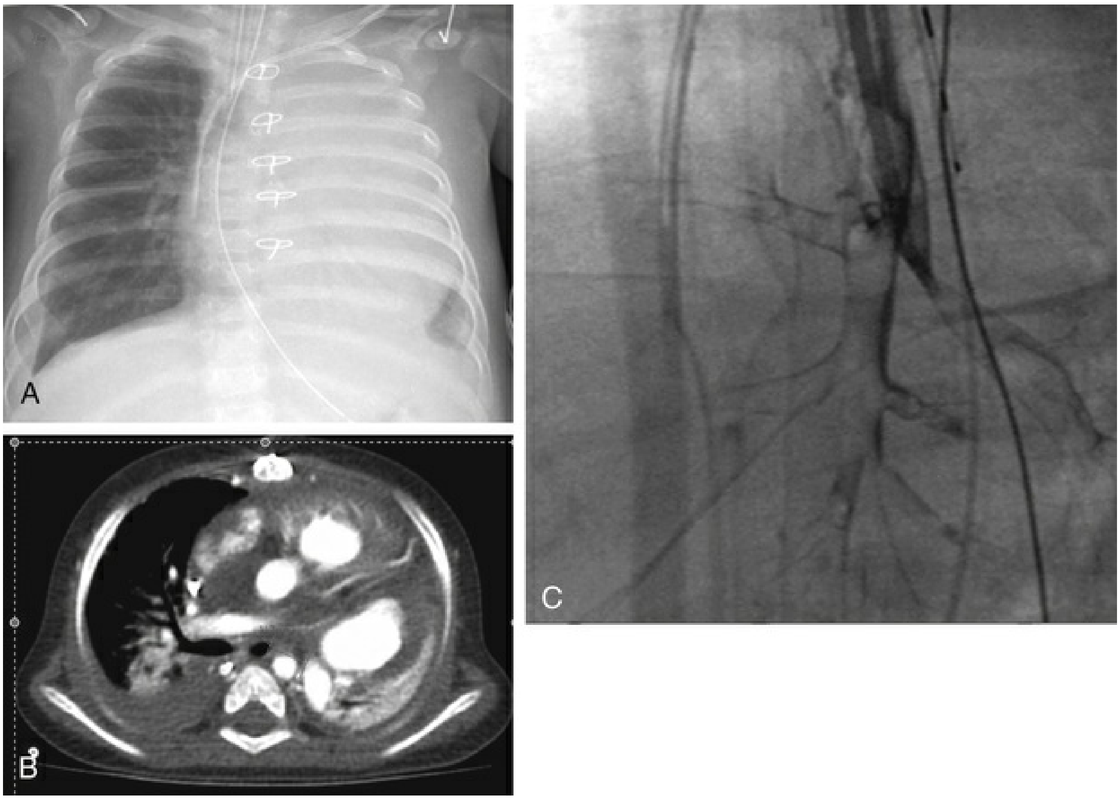

**FIG. 70.9** Seven-month-old boy with complex congenital heart disease. Repeated episodes of atelectasis of the left lung occurred after corrective surgery. (A) Chest radiograph shows atelectasis of the left lung and air bronchogram. (B) Computed tomography shows a compressed left main bronchus 12 mm in length between the enlarged heart and the left pulmonary artery anteriorly and the descending aorta posteriorly. (C) Bronchography performed with monitoring of ventilation pressure shows constant collapse of the left main bronchus at pressures less than 5 cm $H_2O$, partly opening between 5 and 10 cm $H_2O$, and no collapse above 10 cm $H_2O$ (Video 70.6).

## Treatment and Management

The cause of the atelectasis and the presence of any preexisting condition will determine the type of treatment and the need for future prophylactic measures. Schindler in 2005 asked "Treatment of atelectasis: Where is the evidence?"[23] Today it remains elusive. Chest physiotherapy is often used as a first-line approach, but proof of its efficacy is not firmly established. In a prospective controlled study of 46 mechanically ventilated preschool children with atelectasis, children who were randomized to intrapulmonary percussive ventilation comprising ventilation at 180–220 cycles per minute at pressures of 15–30 cm $H_2O$ for 10–15 minutes 4 times daily following instillation of 0.9% saline had clinically important and significant improvement in their atelectasis scores, while children receiving conventional physiotherapy in the form of clapping and vibration showed no improvement.[24] Transient atelectasis, often affecting the right upper lobe, is frequently observed in children hospitalized for acute bronchiolitis and is associated with more severe illness.[17] In the only prospective but uncontrolled study of prognostic factors relating to right-middle-lobe atelectasis in children with acute asthma admitted to hospital, atelectasis resolved in 13 of 27 children after 6 days, at which point chest physiotherapy was initiated. Children who were using controller medications at the time of admission had a higher rate of resolution of atelectasis at 14 days,[6] suggesting a therapeutic advantage of antiinflammatory treatment with inhaled or oral steroids.

Bacterial colonization and infection is common in children with atelectasis[7] and long-standing right middle-lobe syndrome[9]; thus, in tandem with chest physiotherapy and optimization of asthma control, treatment with broad-spectrum antibiotics should be started. Administration of dornase alfa (Pulmozyme), either via nebulizer or direct instillation in intubated patients, may lead to a rapid improvement in atelectasis in children severely ill with respiratory syncytial virus bronchiolitis[25] and after cardiac surgery.[19] There are anecdotal reports of the successful use of dornase alfa in children with plastic bronchitis causing massive atelectasis,[26] but inhaled tissue plasminogen activator, particularly in children following cardiac palliation with a Fontan operation, may represent a better therapeutic option.[27] Fiberoptic bronchoscopy has a clear role in both the diagnosis and treatment of right-middle-lobe syndrome and may prevent the subsequent development of bronchiectasis.[18] The timing of bronchoscopy will depend on the likely cause and preexisting disease. In children with atelectasis due to suspected inhalation of a foreign body, flexible bronchoscopy to confirm the diagnosis is performed urgently in the case of severe respiratory compromise or electively within the next 24 hours in the majority of cases.[28] Rigid bronchoscopy should be available to retrieve the foreign body if necessary. The absence of an air bronchogram on chest x-ray in lobar atelectasis is suggestive of proximal airway occlusion and, in this case, bronchoalveolar saline lavage or the direct instillation of dornase alfa may be useful. Bronchoscopic insufflation can also be useful in acute total lung atelectasis.[29]

In some patients with atelectasis, operative intervention may be indicated. Diaphragmatic eventration and paralysis can cause lobar collapse that responds to plication of the diaphragm.[30] Lobectomy has been advocated in symptomatic children with persistent right-middle-lobe[31] and left-lower-lobe[32] syndrome that has not responded to intensive medical therapy, but this is controversial and rarely indicated. In children with tracheobronchial obstruction secondary to adjacent vascular structures or an enlarged heart, tumor, lymphadenopathy or severe airway malacia, silicone or wire mesh stents have been used to relieve airway obstruction. However, these approaches have been complicated by stent migration, infection, granulation tissue formation, stent fracture, and catastrophic pulmonary hemorrhage, giving rise to considerable concern over their safety and effectiveness.[33,34] That said, stent placement may be appropriate in carefully selected patients,[35] and new biodegradable stents currently undergoing assessment may offer a safer alternative.[36]

Pulmonary tuberculous lymphadenopathy in children occurs most frequently in the subcarinal lymph nodes. In one large series, this caused airway compression in all patients, with more severe compression in infants.[37] The use of systemic steroid therapy for this indication is controversial,[38] with at least one-third of children requiring surgical decompression of their airway obstruction after 1 month of antituberculous and steroid treatment.[39]

# Prevention of Atelectasis

Based on a systematic review, the use of routine prophylactic airway clearance techniques including incentive spirometry was not recommended in hospitalized noncystic fibrosis patients except for those with neuromuscular illness and weak cough.[40] When cough is weak, cough assist devices may be useful. Children undergoing lung resection may benefit from early postoperative physiotherapy, including intermittent positive end expiratory pressure by mask.[41] Although this study was retrospective, the use of physiotherapy was associated with a significantly lower rate of postoperative atelectasis and bronchoscopic intervention. Ventilation strategies in severely ill children requiring assisted ventilation may play a role in the prevention of atelectasis. In a large study of 691 intubated children with inhalation injury, ventilation with a high tidal volume (15 mL/kg) significantly decreased ventilator days and prevented the development of atelectasis and acute respiratory distress syndrome compared with low tidal volume (9 mL/kg).[42] There was a slightly higher rate of pneumothorax in the high-tidal-volume group, but the authors concluded that the use of a high-volume strategy may interrupt sequences, leading to lung injury in this group of patients. In view of the morbidity associated with atelectasis, there is a clear need for prospective randomized controlled studies of the effectiveness of physiotherapy techniques, including the use of mucolytic agents and ventilation strategies in preventing the development of atelectasis in children hospitalized with bronchiolitis, inhalational injury, pulmonary infection, and postcardiac and pulmonary surgery.

# Primary Ciliary Dyskinesia

*Thomas Ferkol MD, Margaret W. Leigh MD*

## Epidemiology

Eighty years ago, Kartagener described a clinical syndrome characterized by the triad *of situs inversus totalis,* chronic sinusitis, and bronchiectasis[1] that later was defined as Kartagener syndrome. Alfzelius and colleagues later found that individuals with Kartagener syndrome, as well as others with chronic sinusitis and bronchiectasis, have defects in the ultrastructural organization of motor cilia.[2–4] Initially, the term “immotile cilia syndrome” was used to describe this disorder, but subsequent studies showed that cilia are often motile but their beat uncoordinated and ineffective. Thus the name was changed to “primary ciliary dyskinesia” (PCD) to more appropriately describe the spectrum of ciliary dysfunction and to distinguish “primary” or genetic ciliary defects from “secondary” or acquired defects associated with epithelial injury.

PCD is an inherited disorder characterized by impaired motor ciliary function leading to diverse clinical manifestations. The frequency of PCD is approximately between 1 in 12,000 and 20,000 live births, based on the prevalence of *situs inversus totalis* and bronchiectasis in population surveys, but these values likely underestimate its incidence in the general population.[5,6] Although PCD is considered a rare lung disease, its prevalence in children with repeated respiratory infections has been estimated to be as high as 5%.[7]

Our understanding of the epidemiology, genetics, pathophysiology, and clinical manifestations of PCD has rapidly advanced over the four decades since the disease was linked to ultrastructural defects of the ciliary axoneme. Advances in cilia genetics and biology have provided new insights into genotype-phenotype relationships and may yield potential therapeutic targets to restore ciliary structure and function.

# Etiology

PCD is a heterogeneous genetic disorder, usually autosomal recessive, of motile ciliary structure function and biogenesis. A wide spectrum of clinical features may be seen, reflecting the numerous organs where cilia are important for maintaining health. The large airways and contiguous structures, such as the nasopharynx, paranasal sinuses, and middle ear, are lined by a ciliated, pseudostratified columnar epithelium that is important for mucociliary clearance. The cells on the lumenal surface of this epithelium are predominantly ciliated cells with interspersed goblet cells. Other epithelia containing motile ciliated cells are found in the ependyma of the brain and the fallopian tubes. Spermatozoa flagella have a core structure similar to that of cilia with the same fundamental motility characteristics.

## Normal Motile Ciliary Structure and Function

Mature respiratory ciliated cells contain approximately 200 cilia of uniform size, with an average length of 6 μm. Each normal cilium contains an array of longitudinal microtubules, consisting of nine doublets arranged in an outer circle around a central pair (Fig. 71.1). The microtubules are anchored by a basal body in the apical cytoplasm of the cell. Several different proteins contribute to ciliary structure and function. Tubulin, a dimeric molecule with $\alpha$- and $\beta$-subunits, forms long microtubules that extend the entire length of the cilium. These microtubules are arranged in a distinct 9+2 pattern, with 9 microtubule doublets arranged in a circular array around a central pair of microtubules. The protein nexin links the outer microtubular doublets, creating a circumferential network, and radial spokes connect the outer microtubular doublets with a central sheath of protein that surrounds the central tubules. Dynein is attached to the microtubules as distinct inner and outer "arms," recognizable on electron micrographs of axonemal cross-sections, and is thought to participate in the provision of energy for microtubule sliding through adenosine triphosphatase (ATPase) activity. Inner and outer dynein arms are attached to each microtubule doublet at precise, repeated intervals—24 nm for outer dynein arms and 96 nm for inner dynein arms. The outer dynein arms are longer and form a hook, whereas the inner dynein arms are straight and linked to radial spokes. Each dynein arm is a multimer of two or three heavy chains (400–500 kd), two or four intermediate chains (45–110 kd), and at least eight light chains (8–55 kd),[8,9] with each chain protein encoded by a distinct gene. The dynein heavy chains contain the ATPase that provides the energy for ciliary movement.

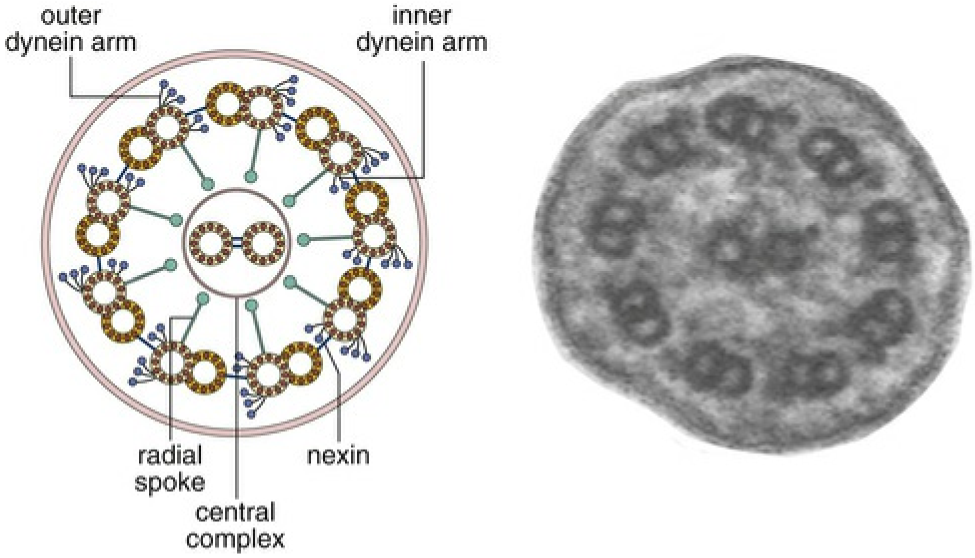

**FIG. 71.1** Schematic diagram *(left)* and transmission electron photomicrograph *(right)* of a normal motor cilium in cross-section showing the ultrastructural features of the ciliary axoneme.

Dynein arms extend from the A tubule and interact with the B tubule of the neighboring outer pair, and the force generated translates to a sliding motion of two neighboring tubules, while the inner dynein arms are central for controlling the rhythmic motion of cilia. The inner dynein arm is also part of a complex referred to as the dynein regulatory complex, a key regulator of motor activity.[10] Located within the nexin link, an elastic element that limits sliding between microtubules. The dynein regulatory complex consists of several closely associated proteins that coordinate the activity of the multiple dyneins. The radial spokes also regulate dynein arm activity, sending signals from the central apparatus to the dynein arms.[11] All these structures work in a coordinated fashion to produce a synchronized ciliary beat and maintain alignment of the doublet microtubules (Fig. 71.2).[12]

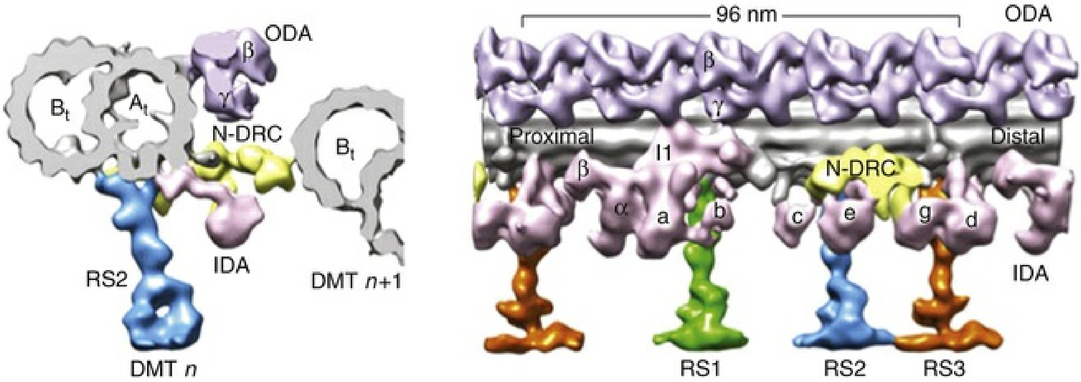

**FIG. 71.2** Isosurface renderings show cross-sectional and longitudinal-front views of the averaged 96-nm repeat in a normal cilium created from axonemal tomograms. *DMT,* Doublet microtubule; *IDA,* inner dynein arm; *N-DRC,* nexin-dynein regulatory complex; *ODA,* outer dynein arm; *RS,* radial spoke. (Adapted from Lin J, Yin W, Smith MC, et al. Cryo-electron tomography reveals ciliary defects underlying human RSPH1 primary ciliary dyskinesia. *Nat Commun*. 2014;5:5727.)

Ciliary motion takes place within an aqueous layer of airway surface liquids and is divided into two phases: an effective stroke phase that sweeps forward; and a recovery phase during which the cilia bend "backward" and extend into the starting position for the stroke phase. Typically, the tips of cilia contact the overlying mucus during the stroke phase to propel mucus forward, but during the recovery phase, cilia lose contact with the mucus. Normal human cilia bend in a rhythmic, wavelike motion within a single plane. The normal beat frequency of human cilia ranges between 8 and 14 Hertz, which can vary with testing conditions.[13] Cila beat quicker in the proximal airways than in more distal airways and faster in young children (13 beats/s) than in adults (11.5 beats/s).[14] In healthy epithelium, cilia are aligned spatially with parallel orientation of the central pair of tubules in adjacent cilia; therefore ciliary motility is maintained in the same general orientation along the length of airways. Normal mucociliary transport rates may be as rapid as 20–30 mm/min. Although the intracellular and intercellular regulation of ciliary actions is complex and not fully understood, several signaling mechanisms including intracellular calcium, cyclic adenosine monophosphate (cAMP), extracellular adenosine triphosphate (ATP), and airway nitric oxide (NO) play key roles in regulating ciliary beat frequency.[15–18] Ciliary motion is synchronized along the respiratory epithelium by calcium signaling through gap junctions. Motile cilia also respond to external stimuli, such as infectious agents and airborne pollutants, suggesting that motile cilia can sense their environment like primary cilia.[19–21]

There are other types of cilia in the body (Fig. 71.3). Nodal cilia exist transiently in the ventral node of the gastrula during embryonic development. The ultrastructure of embryonic nodal cilia has many features of epithelial motile cilia, including the circular array of 9 microtubule doublets with inner and outer dynein arms; however, there is no central pair of microtubules, hence a 9+0 array. This structure allows the organelle to rotate in a whirling motion that generates unidirectional flow of fluid critical for directing left-right asymmetry in the developing embryo.[22] The node includes two populations of cilia: motile and sensory[23]—the motile nodal cilia generate leftward flow of extracellular fluid across the surface that is detected by peripheral sensory cilia, which activates a cascade of transcription and growth factors to establish body sidedness.[24] In the absence of leftward flow, left-right laterality becomes a random event.

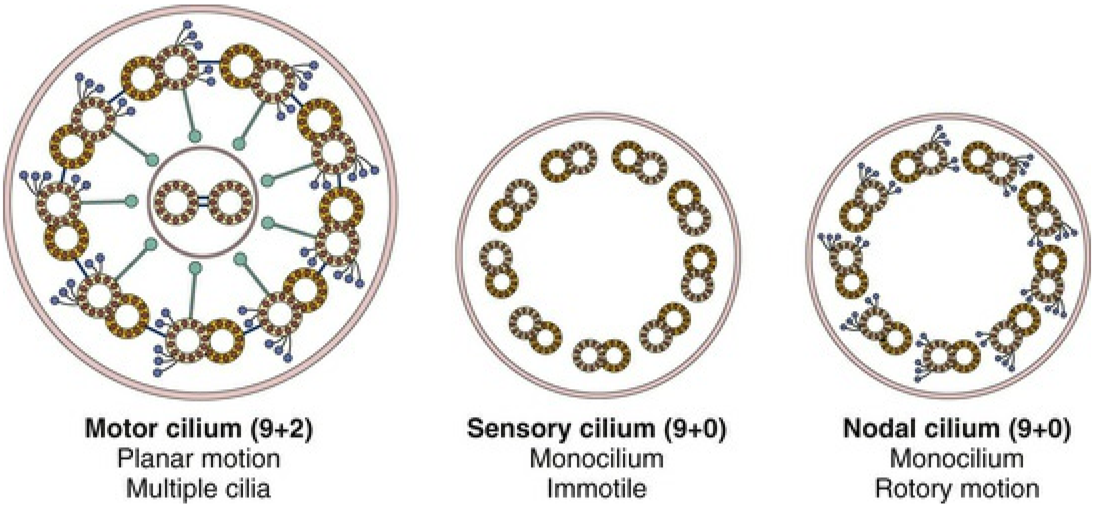

**FIG. 71.3** Schematic diagram showing the structural elements of normal motile "9+2," nonmotile "9+0," and motile "9+0" ciliary axonemes. (Adapted from Ferkol T, Leigh M. Pediatric ciliopathies: the central role of cilia in a spectrum of pediatric disorders. *J Pediatr*. 2012;160:366-371.)

Primary (sensory) cilia are solitary structures present on the surface of many nondividing cells, as well as epithelia-lined sensory organs, biliary ductules, renal tubules, chondrocytes, and astrocytes.[9,25] These structures were long considered vestigial remnants of no physiologic significance but are now recognized as vital signaling organelles that sense the extracellular environment. Primary cilia serve as chemoreceptors, mechanoreceptors, osmoreceptors, and, in specialized cases, changes in light, temperature, and gravity.[26,27] Development, growth, and repair functions are also mediated by primary cilia through surface receptors, and genetic defects are associated with clinically diverse pediatric conditions, collectively known as ciliopathies.[28,29] Primary cilia have a 9+0 structure like nodal cilia but do not have dynein arms and consequently are not motile. Otherwise, primary cilia and motile cilia share many proteins and structures, and there are several lines of evidence that suggest motile cilia have sensory and signaling functions. Defects in the assembly and function of primary cilia have been linked to a wide variety of disorders termed *primary ciliopathies*, including polycystic kidney disease, Bardet-Biedl syndrome, Joubert syndrome, and retinitis pigmintosa (Fig. 71.4).[9,25,30] New insights into the molecular basis for primary ciliopathies has raised interest in potential overlap between sensory and motor ciliopathies.

## Pathology and Pathogenesis

## Genetics

PCD has been reported in diverse ethnic groups without apparent racial or gender predilection. In most families, PCD appears to be transmitted by an autosomal-recessive pattern of inheritance; however, rare instances of autosomal-dominant or X-linked inheritance patterns have been reported.[31,32] Parents of affected children are normal and have no evidence of impaired ciliary structure or function.

Genetic heterogeneity of PCD is suggested by its various ultrastructural phenotypes.[33,34] The conservation of cilia and flagellar structures along the phylogenetic tree, from algae *(Chlamydomonas reinhardtii)* to flies *(Drosophila melanogaster)* to fish *(Danio rerio)* to mammals, has provided insights into the genetics of the human cilium. For instance, *C. reinhardtii,* a biflagellated single-cell organism,[35] has been a widely used as a powerful model to study motile cilia. The entire genome for Chlamydomonas has been sequenced, and genetic analyses in dysmotile mutant strains of *Chlamydomonas* have identified numerous orthologous human genes that are mutated[9] in PCD. Indeed, most of the mammalian genes linked to PCD have *Chlamydomonas* orthologs. The identification of PCD-associated genes has relied on a combination of experimental models, creation of cilia-related transcriptomes and proteomes, and powerful sequencing techniques of candidate genes. Massive parallel sequencing has permitted rapid identification of new mutations in PCD subjects without previous knowledge of candidate genes.[36]

Initial genetic studies focused on genes encoding dynein arm proteins but more recently expanded to include other proteins in ciliated cells. Through a collaborative, international research effort, great progress has been made in identification of PCD genes.[37–40] To date, more than 35 genes have been liked to PCD (Table 71.1), and approximately 70% of all patients tested have biallelic mutations of these genes. As gene discovery continues, that number will continue to rise. Many of the gene mutations have been linked to specific ultrastructural defects and ciliary dysmotility, including genes that encode outer dynein arm components: *DNAH5* (MIM 603335), *DNAI1* (MIM 604366), *DNAL1* (MIM 610062), *DNAI2* (MIM 605483), *TXNDC3* (MIM 607421), and *CCDC114* (MIM 615038);

inner dynein arm, dynein regulatory complex, and nexin components: *CCDC39* (MIM 613798) and *CCDC40* (MIM 613799); or the radial spokes and central apparatus: *RSPH9* (MIM 612648), *RSPH4A* (MIM 612647), and *HYDIN* (MIM 610812). More recently, mutations in genes coding for several cytoplasmic proteins not integral to the cilia axoneme have been reported. These genes encode proteins that presumably have roles in cilia assembly or protein transport, including: *HEATR2* (MIM 614864), *DNAAF1* (MIM 613190), *DNAAF2* (MIM 612517), *DNAAF3* (MIM 614566), *CCDC103* (MIM 614677), *LRRC6* (MIM 614930), *DYX1C1* (MIM 608706), *CCDC114* (MIM 615038), *SPAG1* (MIM 603395), and *ZYMND10* (607070) (Fig. 71.5).[41–62]

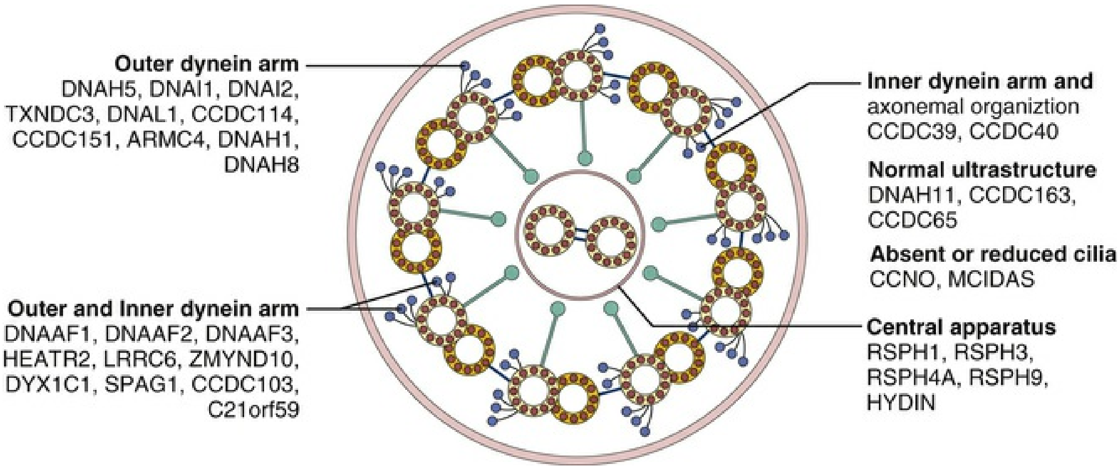
## Table 71.1

## Genes Mutated in Primary Ciliary Dyskinesia

| Human Gene | Encoded Protein | Protein Location | Ultrastructural Defect |
|---|---|---|---|
| *DNAH5* | Dynein heavy chain 5 | ODA-HC | Absent or truncated ODA |
| *DNAH11* | Dynein heavy chain 11 | ODA-HC | Normal ultrastructure |
| *DNAI1* | Dynein Intermediate chain 1 | ODA IC | Absent or truncated ODA |
| *DNAI2* | Dynein intermediate chain 2 | ODA IC | Absent or truncated ODA |
| *DNAL1* | Dynein light chain 1 | ODA-LC | Absent or truncated ODA |
| *TXNDC3* | Thioredoxin domain–containing protein 3 | ODA LC/IC | Absent or truncated ODA |
| *CCDC103* | Coiled-coil domain–containing protein 103 | ODA docking | Absent or truncated ODA |
| *CCDC114* | Coiled-coil domain–containing protein 114 | ODA docking | Absent or truncated ODA |
| *DNAAF1* | Dynein (axonemal) assembly factor 1 | Cytoplasm | Absent ODA and IDA |
| *DNAAF2* | Dynein (axonemal) assembly factor 2 | Cytoplasm | Absent ODA and IDA |
| *DNAAF3* | Dynein (axonemal) assembly factor 3 | Cytoplasm | Absent ODA and IDA |
| *HEATR2* | HEAT repeat–containing protein 2 | Cytoplasm | Absent ODA and IDA |
| *LRRC6* | Leucine-rich repeat–containing protein 6 | Cytoplasm | Absent ODA and IDA |
| *SPAG1* | Sperm-associated antigen-1 | Cytoplasm | Absent ODA and IDA |
| *ZMYND10* | Zinc finger, MYND-type containing 10 | Cytoplasm | Absent ODA and IDA |
| *DYX1C1* | Dyslexia susceptibility 1 candidate 1 | Cytoplasm | Absent ODA and IDA |
| *CCNO* | Cyclin O | Cytoplasm | Reduced numbers of cilia |
| *MICDAS* | Multicilin | Cytoplasm | Reduced numbers of cilia |
| *CCDC39* | Coiled-coil domain–containing protein 39 | DRC | Absent IDA with axonemal disorganization in some cilia |

| | | | |
|---|---|---|---|
| *CCDC40* | Coiled-coil domain–containing protein 40 | DRC | Absent IDA with axonemal disorganization in some cilia |
| *CCDC65* | Coiled-coil domain–containing protein 65 | DRC | Normal ultrastructure |
| *CCDC164* | Coiled-coil domain–containing protein 164 | DRC | Normal ultrastructure |
| *RSPH1* | Radial spoke head protein 1 | RS | Normal ultrastructure |
| *RSPH4A* | Radial spoke head protein 4A | RS | Central apparatus defect |
| *RSPH9* | Radial spoke head protein 9 | RS | Central apparatus defect |
| *HYDIN* | Hydrocephalus-inducing protein homolog | CA | Central apparatus defect |

*CA,* Central apparatus; *DRC,* dynein regulatory complex; *HC,* heavy chain; *IC,* intermediate chain; *IDA,* inner-dynein arm; *LC,* light chain; *ODA,* outer-dynein arm; *RSH,* radial spoke.



**Outer dynein arm**

**FIG. 71.5** Classification of proteins mutated in primary ciliary dyskinesia segregated based on ultrastructural defects of the ciliary axoneme. (Adapted from Horani A, Ferkol TW. Molecular genetics of primary ciliary dyskinesia. *Encyclopedia of Life Sciences* (*eLS*). Chichester, England: John Wiley and Sons Ltd; 2013. http://www.els.net.)

The genetics of PCD has provided unexpected and sometimes surprising insights into ultrastructural phenotypes. For instance, mutations in the dynein axonemal heavy chain 11 *(DNAH11)* gene (MIM 603339) encodes an outer dynein arm protein and, unlike the genes listed previously, is not associated with an ultrastructural defect and cilia have normal (or more rapid) beat frequency. It is likely that an abnormal waveform leads to inefficient mucociliary clearance.[54,63,64] Mutations in *CCDC39* (MIM 613798) and *CCDC40* (MIM 613799), genes that are essential to assembly of the nexin-dynein regulatory complex and inner dynein arms, yield inconsistent ultrastructural abnormalities characterized by absent inner dynein arms in all axonemes and misplaced radial spokes, and microtubular disorganization in only 10%–20% of cilia.[65,66] Investigations have shown that CCDC39 and CCDC40 serve as “rulers” and are critical for the construction of the ciliary scaffold and accurate spacing of the radial spokes along the axoneme.[67]

More recently, several patients who have mutations in genes encoding cyclin O *(CCNO)* and multiciliate differentiation and DNA synthesis–associated cell cycle protein *(MCIDAS)* were found to have symptoms consistent with PCD and markedly reduced motor cilia on the epithelial surface. CCNO is required for centriole production, and mutations cause mislocalization of basal bodies, consistent with defective basal body replication and migration to the cell surface.[68,69] MCIDAS controls centriole replication required for normal ciliated cell formation.[70] Thus, although the absence of epithelial cilia frequently can be sequelae of infectious insults, it may also have a genetic etiology.

Although the genetic testing holds considerable promise as a diagnostic tool for PCD, it has limitations. First, because PCD is an autosomal recessive condition, presence of a single mutation (or single mutations in different genes) is insufficient to make the diagnosis. Whole exome or genome sequencing is a powerful tool that has allowed more rapid identification of sequence variants,[71] but it is not always clear whether these variants are disease causing. Polymorphisms are fairly common, especially in larger PCD-associated genes, like the heavy chain dyneins. Irrespective of the gene affected, nonsense mutations or deletions result in a truncated protein and loss of function and are likely pathogenic. However, rare sequence variants and missense mutations that change a single amino acid are more difficult to link to disease. In addition, it is possible that some biallelic variants may not cause classic PCD but result in mildly reduced cilia function and more subtle clinical manifestations.

## Ultrastructural Ciliary Defects

The ciliated epithelium of patients with PCD may appear normal, but distinct ultrastructural defects of the ciliary axoneme have been identified of cilia using transmission electron microscopy, including abnormalities in the dynein arms, radial spokes, nexin links, and microtubular organization (Fig. 71.6, Table 71.2). These distinct ultrastructural defects are generally apparent in cilia throughout the airways, middle ear, and oviduct, as well as in sperm flagella, demonstrating that PCD is a generalized disorder of genetic origin.

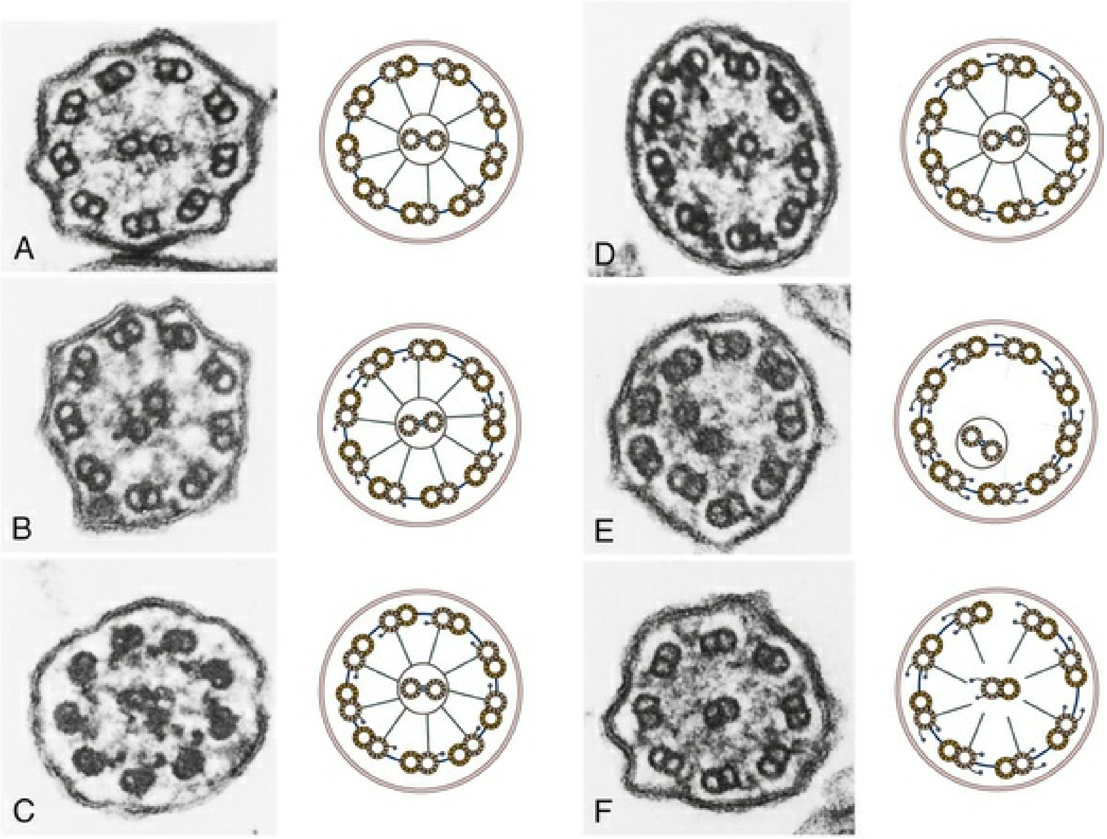

**FIG. 71.6** Specific ciliary defects that cause primary ciliary dyskinesia. Each panel shows transmission photomicrograph of ciliary cross-section *(left)* with corresponding diagrammatic representations *(right).* (A) Dynein arm defect: total absence of outer and inner dynein arms. (B) Dynein arm defect: partial absence of outer and inner dynein arms (~60% of dynein arms are absent). (C) Dynein arm defect: absence of outer dynein arms. (D) Dynein arm defect: absence of inner dynein arms. (E) Radial spoke defect: absence of radial spokes with eccentric central core. (F) Microtubular transposition defect: absence of central tubules with transposition of one doublet to the central axis of the cilium. (A, B, and D, original magnification

×106,000; C, original magnification ×104,000; E, original magnification ×140,000; F, original magnification ×110,000.) (Photomicrographs courtesy of J.M. Sturgess and J.A.P. Turner.)

**Table 71.2**

**Axonemal Ultrastructural Defects That Have Been Associated With Primary Ciliary Dyskinesia**

| **DYNEIN ARM DEFECTS** |

| Absent central pair of tubules with transposition of outer doublet(s) |
| **OTHER** |
| Ciliary aplasia<br>Absence of nexin links<br>Basal body anomalies<br>Central microtubular agenesis<br>Normal ultrastructure but impaired function |

Dynein abnormalities occur in approximately 80% of PCD patients who have ultrastructural defects and include complete absence of both inner and outer dynein arms,[2,72] complete or partial absence of outer dynein arms alone, and in rare cases absence of inner dynein arms alone.[73,74] Outer dynein arms are readily identifiable, but inner dynein arm analyses can be difficult because these structures are often obscured by abundant overlying electron-dense material. Computer-assisted image analysis has been used to improve visualization of inner dynein arms, thereby enhancing the ability to detect inner arm defects.[75,76] Because inner dynein arms abnormalities may be observed in normal subjects with recent respiratory infections or other epithelial insults, the diagnosis of PCD in individuals with only inner dynein arm defects can be challenging and repeat confirmatory testing is recommended.[74,77]

A number of defects in radial spokes have been associated with ciliary dysmotility, including total absence of radial spokes and absence of radial spoke heads.[78] These defects are recognized by an eccentric position of the central pair of microtubules that are normally stabilized in a central position by the radial spokes. Central displacement of one of the outer microtubular doublets may also occur. A characteristic alteration in the 9+2 configuration of axonemal microtubules has been described in some families with PCD. Typically, the central pair of tubules is missing, and one of the outer microtubular doublets is transposed to the center in both cilia and flagellae.[79]

Acquired ultrastructural defects have been described that are likely secondary to epithelial insults, such as viral infections. Indeed, ciliary disorientation was initially described as an ultrastructural phenotype of PCD,[80] but this defect is more likely related to airway injury than a genetic defect.[81] One approach to discern whether defects are acquired or congenital is to examine ciliary ultrastructure in epithelial cell cultures grown at air-liquid interface, which allows cells to polarize and redifferentiate.

It is important to note that approximately 30% of patients who have typical clinical manifestations of PCD and ciliary dysmotility will have normal ciliary ultrastructure, indicating that some defects affect function but not structure.[82] As mentioned previously, some ciliary abnormalities in PCD are not found in every axoneme and the changes are often attributed to an acquired defect, further complicating the use ciliary ultrastructural analyses as a diagnostic tool.

## Functional Ciliary Defects

In contrast to cystic fibrosis, in which abnormal apical channels result in obstruction and persistent infection, the ineffective cilia beat leads to impaired mucociliary clearance and chronic infections in the PCD airway (Fig. 71.7). Advances in high-speed, high-resolution videomicroscopy have led to its development as a diagnostic tool for PCD, mainly in Europe.[83–85] Digital imaging of ciliary motion in multiple planes has permitted comprehensive analysis of abnormal beat patterns. Ciliary motion may be assessed by videomicroscopy of freshly excised ciliated epithelium obtained by scrape or brush biopsy of the inferior surface of the nasal turbinate, or by bronchial brush biopsy. Freshly collected ciliated cells maintain ciliary beating for several hours if placed in appropriate culture media. In PCD the cilia may be immotile or dyskinetic. High-speed videomicroscopy has shown that certain beat patterns are associated with specific ultrastructural defects; specifically, absence of outer dynein arms is associated with immotility or a slightly flickering beat pattern; isolated inner dynein arm defects or radial spoke defects are associated with a slow, stiff motion; and ciliary transposition defects are associated with a circular beat pattern that may have a normal beat frequency but lacks the directional bend.[86] Representative high-speed videomicroscopy videos of ciliary motility (provided by Amelia Shoemark at National Heart & Lung Institute, Imperial College, London, recorded at 500 frames per second and playback at 60 frames per second, magnification 100×, temperature 37°C) are available online for healthy control (Videos 71.1A and 71.1B▶) and individuals with PCD confirmed by genetic mutations in *DNAH5* (Video 71.2▶), and *DNAH11* (Video 71.3▶).

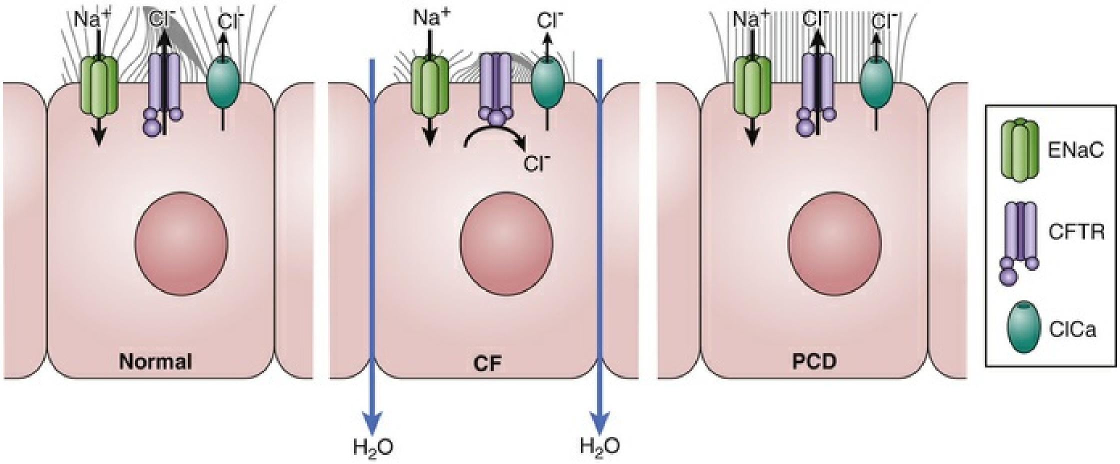

**FIG. 71.7** Schematic diagram showing the pathophysiology of two inherited motor ciliopathies, cystic fibrosis (CF) and primary ciliary dyskinesia (PCD). *CFTR,* Cystic fibrosis transmembrane conductance regulator; *ClCa,* alternative chloride channel; *ENaC,* epithelium sodium channel.

Other disorders, including viral infections and asthma, can cause acquired ciliary dysfuction,[87] which can complicate analyses. To address this limitation, several European sites grow airway epithelial cells in primary culture at an air-liquid interface. The cells redifferentiate and undergo ciliogenesis, and acquired ciliary defects can be reduced.[87] Assessment of ciliary beat pattern and frequency as a diagnostic tool should be performed at specialized PCD centers. This approach requires considerable experience, because some forms of PCD characterized by subtle changes in ciliary waveform can be missed. To address these limitations, investigators are developing computational methods that quantitatively analyze elemental components of ciliary motion that could be refined as a diagnostic tool in the future.[88]

Ciliary beat frequency measurements that use conventional microscopic techniques have been used as a screen, but this method alone is insufficient[84] and will miss cases of PCD. Cilia inspection using standard brightfield light microscopy should not be used to support or exclude the diagnosis.

Other tests have been used to examine ciliary structure and function. Some PCD research centers use fluorescence-labeled antibodies to confirm absence of marker ciliary proteins.[55,56,89–91] Another approach to assess ciliary function is measurement of mucociliary clearance. In the past, clinicians applied saccharin particles to the anterior nares and measured the time interval until the bitter saccharin was tasted (saccharin test).[92] This procedure has limited usefulness in children because the patient must lie still and not sneeze, sniff, or cough for up to 1 hour. In specialized centers, nasal or lung mucociliary clearance is determined by using a gamma counter to measure the rate of removal of inhaled radiolabeled particles.[93,94] When cough is suppressed, patients with PCD have little clearance of isotope from the lung.[93–97] Unlike in cystic fibrosis, cough clearance in PCD is preserved and serves as a compensatory clearance mechanism.[97] This approach is largely used as a research tool, and few centers are using mucociliary clearance as a diagnostic tool for PCD.[98]

## Nasal Nitric Oxide

Nasal nitric oxide (NO) measurement has been adopted by many PCD centers in Europe and North America as a screening or diagnostic tool for PCD. First described more than 2 decades ago, children with PCD produce very little nasal NO.[99] Subsequent studies have demonstrated that nasal NO is extremely low (5%–15% of normal) in most but not all PCD patients.[100–104] NO is formed by the nitric oxide synthase (NOS) enzyme system in the presence of appropriate substrate (L-arginine and oxygen) and cofactors, including tetrahydrobiopterin. Although NOS is localized to the proximal cilia, the actual relationship between motile cilia and NO levels still needs to be defined. Indeed, the mechanism for altered nasal NO production in PCD is still unknown.[105]

In normal adults, production of NO from the nasopharynx and primarily from paranasal sinuses is 10- to 50-fold greater than from the lower airways. Accurate assessment of nasal NO production requires maneuvers for palate closure, breath-holding, or intubation to exclude contaminating gases from the lower airway that have much lower NO concentrations. Preschool children cannot cooperate with palate closure or breath-holding maneuvers, which have limited the use of nasal NO measurement in young children.[104] Interestingly, some patients with cystic fibrosis also have reduced nasal NO but not as low as in PCD.[104] Thus cystic fibrosis must be excluded from consideration as part of the diagnostic evaluation for PCD.[104] In addition, nasal NO levels may be lower in individuals heterozygous with PCD-associated mutations.[103]

# Clinical Features

## Symptoms and Physical Findings

Clinical symptoms in PCD affect the entire respiratory tract and are distinctive from cystic fibrosis (Table 71.3). The majority of respiratory symptoms occur daily and begin soon after birth.[106] Neonatal respiratory distress is a common feature, and infants typically develop symptoms 12–24 hours of life with increased work of breathing, tachypnea, and upper and middle lobe atelectasis on chest radiographs.[107] Often diagnosed with transient tachypnea of the newborn or pneumonia, PCD infants frequently require supplemental oxygen flow for days to weeks and are more likely to have lobar consolidation. When neonatal respiratory distress occurs in infants with situs anomalies, PCD is highly likely.

## Table 71.3

### Comparison of Clinical Features in Cystic Fibrosis and Primary Ciliary Dyskinesia

| Clinical Features | Cystic Fibrosis | Primary Ciliary Dyskinesia |
|---|---|---|
| Bronchitis/bronchiectasis | ++++ | ++++ |
| Neonatal respiratory distress | − | ++++ |
| Chronic sinusitis | ++++ | ++++ |
| Nasal polyposis | ++ | ++ |
| Otitis media | + | ++++ |
| Laterality defects | − | +++ |
| Male infertility | ++++ | ++++ |
| Congenital heart defects | − | ++ |
| Hydrocephalus | − | + |
| Blindness (i.e., retinitis pigmentosa) | − | + |
| Pancreatic insufficiency | ++++ | − |
| Diabetes | ++ | − |
| Biliary cirrhosis | ++ | + |

Prevalence range: ++++, >75%; +++, 31%–74%; ++, 11%–30%; +, 2%–10%; −, <2%.

Children with PCD have a history of chronic and recurrent respiratory infections, beginning early in life, including rhinitis, sinusitis, otitis media, bronchitis, and pneumonia.[103–106,108,109] Daily, year-round productive (wet) cough that begins in infancy is a distinctive feature of PCD.[110] Sputum may be mucoid or purulent that clears with antibiotic therapy, but the cough persists. In many children, exercise tolerance is normal but can become impaired with advancing obstructive airways disease in older children and young adults. Findings on chest examination are variable. Some patients have localized crackles that may or may not clear following forceful cough, and some may have hyperinflation of the chest. Wheezing is relatively uncommon. Digital clubbing may be apparent in the older patients with bronchiectasis. Bacterial cultures of sputum and bronchoalveolar lavage yield a number of organisms, such as nontypable *Haemophilus influenzae, Staphylococcus aureus, Streptococcus pneumoniae,* and *Pseudomonas aeruginosa.*[103] Older patients with long-standing disease may be chronically infected with *P. aeruginosa,* although young children with PCD may be infected with this organism, at least transiently. Nontuberculous mycobacteria, particularly *Mycobacterium avium* complex and *Mycobacterium abscessus* have been recovered in respiratory cultures from older children and adults with PCD.[103]

Early studies identified chest radiographic findings in children with PCD, including lung hyperinflation, bronchial wall thickening, segmental atelectasis/consolidation, situs inversus, and bronchiectasis.[111] Computed x-ray tomography (CT) findings suggest that bronchial wall thickening and mucus plugging are more prevalent than hyperinflation and air-trapping.[112–114] Bronchiectasis can occur in early childhood and becomes more prevalent with age such that close to 100% of adults with PCD have bronchiectasis,[112–115] frequently involving the middle lobe, lingual, and lower lobes. With the exception of situs inversus, these radiographic features may be apparent in other chronic disorders, including cystic fibrosis, immunodeficiency, and chronic aspiration.

Pulmonary function tests may be normal during early childhood but more typically demonstrate obstructive airway disease that becomes more severe in adulthood. Typical findings include reduced forced expiratory flow between 25% and 75% of vital capacity ($FEF_{25\%-75\%}$) and forced expiratory volume in 1 second ($FEV_1$), increased residual volume (RV), and elevated ratio of residual volume to total lung capacity (RV/TLC). Bronchodilator responsiveness is variable. Longitudinal analyses of children with PCD suggest that lung function may remain stable over relatively long periods of time; however, there is a wide variation in course of lung function in PCD.[116–118] Genotype-phenotype relationships are emerging. A cross-sectional study of subjects with ultrastructural defects showed that individuals who had inner dynein arm defects associated with microtubular disorganization, primarily due to biallelic mutations in *CCDC39* or *CCDC40*, had more severe lung disease.[119] Conversely, patients with biallelic mutations in *RSPH1* have milder respiratory phenotypes.[120]

Daily, persistent nasal congestion and rhinitis is a common feature, typically present since early infancy, with little to no seasonal variation.[110] Most patients describe chronic mucopurulent nasal drainage. Typically, sinus radiographs or computed x-ray tomograms demonstrate mucosal thickening and/or opacification of all paranasal sinuses, even in the absence of sinus symptoms. Anosmia, hyponasal speech, and halitosis are more apparent in severely affected patients.

Situs inversus totalis occurs in nearly 50% of patients with PCD.

Typically, all viscera in the chest and abdomen are transposed (i.e., situs inversus totalis). The underlying basis for situs inversus totalis in PCD is attributed to dysfunction of the embryonic nodal cilia that play a key role in directing normal rotation of viscera.[22–24,46,121,122] Without functional nodal cilia, thoracoabdominal laterality becomes random, which has been demonstrated in genetically identical twins with PCD: one with situs solitus and one with situs inversus totalis,[123] as well as in mouse models.[46,121,122,124,125] Studies have demonstrated that heterotaxy (situs ambiguus or organ laterality defects other than situs inversus totalis) occurs in at least 6%–12% of individuals with PCD.[126,127] Heterotaxia is often associated with complex congenital heart disease and includes a wide array of laterality defects such as abdominal situs inversus, polysplenia (left isomerism), and asplenia (right isomerism and Ivemark) syndromes.[128] More than 100 genes have been linked to laterality defects, including PCD genes, which has led to greater focus on the overlap between PCD and the full spectrum of laterality defects between situs solitus and situs inversus totalis.[129] Respiratory ciliary dysfunction is frequently found in patients with heterotaxy and congenital heart disease, which demonstrates the importance of cilia function in normal cardiac development.[130] Indeed, these findings have led to searches for ciliary anomalies in children with congenital heart disease to uncover the genetic cause of these defects.[131] Mutations in some PCD genes, such as those encoding radial spoke proteins, CCNO and MCICAS, do not alter nodal cilia and hence are not associated with laterality defects.[51,68,70,120]

The presence or absence of the clinical manifestations listed previously should assist the clinician in determining whether further testing is needed. They may not be seen in all affected individuals, but most patients with PCD have at least two or three of these features. The combination of these clinical features markedly increases the likelihood of diagnosis (see Table 71.3).[110]

Chronic otitis media of variable severity is present in almost all patients with PCD. At the time of diagnosis, many patients older than 2 years have a history of either chronic tympanic membrane perforations or have had tympanostomies with insertion of ventilation tubes in the tympanic membranes. Many have conductive hearing loss at least intermittently during early childhood, which improves by during adolescence.[132–135] While recurrent or chronic otitis media is not predictive of PCD, middle ear findings may be most helpful in distinguishing PCD from cystic fibrosis or other causes of chronic lung disease.

Male infertility is common and attributable to impaired sperm motility. The ultrastructural and functional defects in cilia are mirrored in sperm flagellae in some but not all PCD patients.[72,136–138] The occurrence of ultrastructural ciliary defects in ciliated cells lining fallopian tubes[139–141] has led to speculation that subfertility and ectopic pregnancies could be increased in women with primary ciliary defects, but this association has not been examined systematically.

Although common in mouse models, hydrocephalus is rare in PCD.[142–145] Ultrastructural and functional defects in ventricular ependymal cilia provide a theoretical basis for this association. Defective leukocyte migration has been reported in a few PCD patients, suggesting that the cytoplasmic microtubules of leukocytes may be altered, but specific defects in neutrophil chemotaxis have not been defined.[146,147]

## Overlapping Ciliopathies

Advances in our understanding of the genetics and molecular abnormalities in sensory cilia has helped to define a diverse group of diseases or primary ciliopathies. Primary cilia are found in almost all cells at some time in development and play key roles in sensation and signaling; therefore primary ciliopathies include a wide range of disorders. Some primary ciliopathies are manifested primarily in one organ (e.g., retinitis pigmentosa, polycystic kidney disease, or nephronophthisis), whereas others are manifested as complex syndromes (e.g., Bardet-Biedl syndrome, Joubert syndrome, Leber congenital amaurosis).[148] Rare case reports have demonstrated features of PCD and primary ciliopathies in the same patient, which has heightened interest in potential overlapping ciliopathies. Retinitis pigmentosa leads to progressive blindness due to mutations in the retinitis pigmentosa guanosine triphosphatase (GTPase) regulator gene *(RPGR)*, but these individuals can develop progressive respiratory symptoms due to motile cilia dysfunction.[32,149–153] There are also case reports that suggest respiratory disease secondary to motile cilia dysfunction in Usher syndrome, a rare genetic condition that affects the retinal photoreceptors and cochlear cilia.[154,155] Similarly, a family with mutations in *OFD1* (linked to the primary ciliopathy syndrome, oral-facial-digital syndrome, type 1) had clinical features and functional respiratory ciliary studies consistent with PCD.[156] Finally, adults with autosomal dominant polycystic kidney disease, which is caused by mechanoreceptor polycystin 1 or polycystin 2 mutations, have increased risk of respiratory disease and radiographic evidence of bronchiectasis[157–159] Finally, there are growing associations between ciliary defects (involving motile and sensory cilia) with congenital heart disease, which may provide further insights into pathogenesis of this birth defect.[160] The mechanistic link between sensory and motor functions is largely unknown, and further investigation into the function of motile cilia in primary ciliopathies is needed.

# Diagnosis

The diagnosis of PCD requires clinical phenotypic features in conjunction with diagnostic testing. Definitive diagnosis can be challenging and requires involvement of specialized centers with expertise in clinical features of PCD, as well as the different tests to assess ciliary motility, ciliary ultrastructure, high-speed videomicroscopy, nasal NO measurement, and genetic testing. Suitable samples for examination of ciliary motility and ultrastructure include nasal biopsy obtained by brushing or curettage of the inferior surface of the nasal turbinates, or bronchial brush biopsy. Identification of impaired motility and one of the specific ultrastructural defects in a patient with clinical characteristics, including daily productive cough, nonseasonal rhinosinusitis, left-right laterality defects, or neonatal respiratory distress, provides solid evidence for the diagnosis. Airway insults such as exposure to pollutants and respiratory viral infections may be accompanied by nonspecific ultrastructural changes in cilia that impair motility. Therefore analysis of ciliary ultrastructure should be performed by an electron microscopist who has extensive experience examining ciliated cells. Despite expert review, the ultrastructural analysis may be inconclusive in some cases because of uncertainty in distinguishing primary from secondary ciliary defects; repeat biopsies may be needed before a conclusive diagnosis can be made. Nasal NO measurement has become a useful adjunctive test for PCD in individuals older than 5 years.[100–104] However, few studies in younger children have been reported, and the accuracy of nasal NO measurements in infants has not been established. With recent advances in identification of PCD genes, genetic testing has increasingly become a viable diagnostic tool.

## Management and Treatment

At present, no specific therapies are available to correct ciliary dysfunction, and to date there have not been large randomized controlled trials of any treatment for PCD. Management should include aggressive measures to enhance clearance of mucus, prevent respiratory infections, and treat bacterial superinfections.[106,108]

Approaches to enhance mucus clearance in PCD are similar to those used in the management of cystic fibrosis. Chest percussion and postural drainage facilitate clearance of distal airways. Because cough is an effective clearance mechanism, patients are encouraged to cough and to engage in activities such as vigorous exercise that stimulate cough. All patients and families should be counseled about the importance of cough and instructed to avoid cough suppressants. Bronchodilators such as albuterol may aid mucus clearance in patients who have airway hyperreactivity. As in cystic fibrosis, antiinflammatory agents, deoxyribonuclease, nebulized hypertonic saline, and other measures to facilitate airway clearance may be beneficial; however, specific indications and utility in PCD have not been defined.

A number of measures to prevent respiratory tract infection and irritation should be considered. PCD patients should receive routine immunizations that provide protection against a number of respiratory pathogens, including pertussis, measles, *H. influenzae* type b, S. pneumoniae, and influenza. Preventive counseling should include avoidance of exposure to respiratory pathogens, tobacco smoke, and other pollutants and irritants that may damage airway mucosa and stimulate mucus secretion.

Prompt institution of antibiotic therapy for bacterial superinfections (bronchitis, sinusitis, and otitis media) is crucial for preventing irreversible damage. Sputum Gram stain and culture results may be used to direct appropriate choice of antimicrobial therapy. In some patients, symptoms recur within days to weeks after completing a course of antibiotics. This subgroup may benefit from extended use of a broad-spectrum antibiotic such as trimethoprim-sulfamethoxazole.

Surgical intervention may be indicated for specific complications. Tympanostomy with ventilation tube placement have been used to control chronic serous otitis media that persists despite antibiotic therapy. Tympanostomy placement may improve hearing but is often complicated by offensive otorrhea; therefore there is ongoing debate about indications and utility of this intervention in PCD.[134,135] Sinus drainage may benefit patients with severe sinusitis that does not respond to antibiotic therapy. Lobectomy may be considered in patients with localized bronchiectasis or atelectasis that is thought to be a nidus for chronic infection. However, lobectomy should be approached cautiously, recognizing that removal of any functioning lung tissue in patients with progressive lung disease could have long-term adverse consequences. Lung transplantation (including heart-lung, bilateral lung, and living related bilateral lung transplantation) has been performed successfully in PCD patients with end-stage lung disease, with surgical modifications for patients with situs inversus.

## Prognosis

Chronic lung disease with bronchiectasis and some degree of pulmonary disability has been the usual outcome and has a negative impact on overall quality of life for individuals with PCD. Progression of lung disease is variable, with some individuals experiencing normal or near-normal life span while others develop advanced lung disease progressing to respiratory failure in early adulthood. Several longitudinal studies suggest that aggressive approaches to airway clearance and controlling lung function can slow progression of lung disease.[117,118]

# Chest Wall and Respiratory Muscle Disorders

*Jean-Paul Praud MD, PhD, Gregory J. Redding MD*

## Introduction

Since Lavoisier's stipulation in 1791 that respiration is essentially a phenomenon of oxygen ($O_2$) consumption and carbon dioxide ($CO_2$) production, the chest wall has been recognized as the vital pump responsible for the movement of gases between the atmosphere and the lungs. Today, much is known regarding the adaptability of this vital pump to satisfy the changing metabolic needs under various physiological and pathological conditions (e.g., rest, exercise, and hyperthermia). Patients must overcome adverse conditions affecting chest wall function: conditions ranging from the cartilaginous, pliable rib cage of the preterm infant to the scoliotic thorax of the adolescent, and from the weak chest wall in neuromuscular disease to the stiff rib cage in asphyxiating thoracic dystrophy or obesity. The vital pump also participates in numerous functions, such as singing, talking, wind instrument playing, coughing, sneezing, load lifting, parturition, and hiccupping, all of which can interfere with lung ventilation.

In normal resting conditions, the diaphragm is the principal muscle used for inspiration while the accessory inspiratory muscles mainly stabilize the rib cage. When the inspiratory workload is increased, additional diaphragmatic motor units and accessory inspiratory muscles are recruited, the latter producing an upward motion of the ribs resulting in a more pronounced thoracic expansion. In normal resting conditions, expiratory muscles are inactive. During increased demands for air pumping, the expiratory muscles become activated during the second phase of expiration and decrease the end expiratory volume below functional residual capacity (FRC). Any decrease in the force of the expiratory muscles leads to an increased residual volume and decreased vital capacity.

Sleep is responsible for significant modifications in lung mechanics and respiratory muscle control. Assuming the supine position leads to a decrease in FRC, mainly due to the cephalad movement of the abdominal contents. Sleep also leads to a decrease in tonic activity of intercostal muscles and upper airway muscles, a phenomenon further pronounced in rapid-eye-movement (REM) sleep. These changes are responsible for paradoxical inward rib cage movement during inspiration in infants due to their compliant rib cage and in patients with neuromuscular disorders. Nocturnal hypoventilation with alteration of blood gases is often the first sign of chronic respiratory failure in progressive neuromuscular disorders, such as Duchenne muscular dystrophy. In addition to nocturnal hypoventilation, obstructive and/or central sleep-disordered breathing have been reported in a number of neuromuscular diseases, including Duchenne muscular dystrophy, myotonic dystrophy, congenital myopathies, metabolic myopathies, myasthenia gravis, and spinal muscular atrophy.[1]

## The Chest Wall in the Newborn

The features of the chest wall and respiratory muscles in the newborn period predispose to pump failure during illness (Fig. 72.1). The very compliant chest wall of the premature and to a lesser extent the full-term infant results in chest wall distortion rather than efficient ventilation when inspiratory muscles contract against high mechanical loads, such as during lower respiratory infections. Ossification of the ribs is responsible for stiffening of the chest wall, so that chest wall compliance is up to seven-fold greater than lung compliance at birth, and reduced by half by the age of 3. The ribs are aligned perpendicular to the spine, rendering intercostal muscles unable to add volume with the “bucket handle” motion present in adults. This spine-rib angle approaches adult values by 2–3 years of age. The insertion of the diaphragm to the rib cage is also more perpendicular, which favors inward displacement of the lower ribs with any forceful diaphragmatic contraction. Therefore excessive diaphragm contraction has to be used to produce an adequate tidal volume. In addition, respiratory muscle mass and the proportion of fatigue-resistant fibers in the diaphragm are lower, resulting in less resistance to fatigue. This can be further amplified by nutritional difficulties and hypoglycemia, hypocalcemia, hypophosphatemia, or acidosis. To cope with all of this, the newborn in resting conditions breathes rapidly, with limited excursion of the diaphragm. In disease conditions, rather than increasing the depth of each breath, the newborn further increases the respiratory rate, thereby preventing diaphragmatic fatigue by decreasing the duration of inspiratory contraction. Functional residual capacity is actively maintained in the newborn by increasing the respiratory rate, hence decreasing the time devoted to lung deflation, or by breaking the expiratory flow through active glottal closure. Extremely prematurely born infants are particularly at risk of respiratory pump failure. Respiratory muscle fatigue is more often the cause of respiratory failure in the newborn than at any other time in life.

**FIG. 72.1** Peculiar features of the chest wall in the newborn. The features of the rib cage predisposes the newborn to diaphragmatic fatigue and respiratory failure: (1) the rib cage is very compliant due to nonossification of the ribs; (2) intercostal muscles are unable to add volume with the "bucket handle" motion present later in life, due to the perpendicular alignment of the ribs to the spine; (3) the insertion of the diaphragm to the rib cage is perpendicular, which favors inward displacement of the lower ribs with any forceful diaphragmatic contraction. (From Taussig, Landau, Pediatric Respiratory Medicine, 2nd edition, 2008, Mosby, Elsevier.)

## Respiratory Muscle Disorders—General

## Considerations

Diaphragm dysfunction can be due to a wide variety of disorders. Disorders of the diaphragm produce abnormalities in its position within the chest, excursion with inspiratory efforts, weakness and fatigability. These features often coexist. Hyperinflation due to intrathoracic airway obstruction flattens the diaphragm contour and reduces the surface area of the zone of apposition of the diaphragm, and hence inspiratory force. The higher the lung volume above FRC, the greater the reduction in maximal inspiratory force. Muscle weakness due to phrenic nerve injury leads to an elevated diaphragm on the affected side. Distortion of the diaphragm, as occurs with scoliosis, also causes a reduction in inspiratory force generation and excursion.[2] Primary inspiratory muscle weakness predisposes these muscles to fatigue in the presence of mechanical loads due to disease processes.

Disorders that alter functional properties of the diaphragm and the other respiratory muscles include neuropathic processes, such as quadriplegia, or myopathic processes (e.g., muscular dystrophies). In addition, conditions producing primary respiratory disease can also affect the respiratory muscles secondarily. Examples include hyperinflation in asthma, cystic fibrosis, and bronchopulmonary dysplasia, as well as malnutrition, as observed with cystic fibrosis. Conditions that reduce blood flow to the diaphragm, such as heart failure and sepsis, predispose to diaphragm fatigue, as a less nutrient substrate is delivered to the respiratory muscles. Hypoxemia, as experienced at high altitude, reduces endurance time among healthy individuals breathing against large inspiratory resistive loads. Acute hypercapnia also produces inspiratory muscle fatigue in healthy adults breathing against increased mechanical loads.

In addition, certain therapies can lead to respiratory muscle dysfunction as a result of injury and atrophy. The use of paralytics, corticosteroids, and controlled mechanical ventilation leads to muscle atrophy remarkably quickly. Ventilator-induced diaphragm dysfunction can occur as quickly as 18 hours in patients without respiratory efforts receiving controlled mechanical ventilation. Diaphragmatic atrophy develops in proportion to the degree of muscle inactivity during controlled ventilator support, and the duration of that support. Promoting patient-initiated breaths while administering ventilator support prevents this effect. Aside from ventilator-induced diaphragmatic dysfunction, sepsis appears to result in very early onset muscle injury and loss of contractility before the occurrence of atrophy (i.e., independently of mechanical ventilation).[3]

Clinically, these conditions can be present concurrently, such as controlled ventilation for paralyzed septic patients. Similarly, babies with bronchopulmonary dysplasia who are poorly nourished and who receive corticosteroids to treat acute viral lower respiratory tract infections have multiple etiologies for respiratory muscle dysfunction and failure. The relative importance of each factor when their combined risks occur clinically is unclear, although all etiologies for respiratory muscle dysfunction should be addressed.

## Respiratory Muscle Fatigue

Respiratory muscle fatigue develops when there is a reduction in the force-generating capacity of the neuromuscular respiratory apparatus. This occurs when the energy supply to the respiratory muscles is reduced in the presence of increased work demands. It is also present when respiratory work requirements exceed the work capacity of normal respiratory muscles. In normal adults, inspiratory work that is less than 40% of maximal inspiratory force can be maintained indefinitely. The closer the workload approaches 100% of maximal inspiratory force, the faster respiratory muscle fatigue develops.

When a superimposed inspiratory mechanical load occurs, several mechanisms are called into play to meet muscle work requirements. There is an increase in respiratory drive and phrenic nerve output, which leads to the recruitment of diaphragm motor units. There is an increased recruitment of fast-twitch muscle fibers, which are more capable of generating force than slow-twitch (fatigue-resistant) fibers. There is also recruitment of accessory respiratory muscles of the chest wall and neck and a change in respiratory patterns to reduce the inspiratory time per breath. Despite these responses, mechanical loads imposed on the respiratory system can be of sufficient degree and duration to produce respiratory muscle fatigue and lead to hypoventilation and hypercapnia. Clinical features of impending acute respiratory failure are listed in Box 72.1.

**Box 72.1**

## Clinical Signs of Impeding Acute Respiratory Muscle Failure

### Inability to Perform Nonventilatory Functions

- Inability to eat/drink/cry
- Reluctance to pause breathing voluntarily

### Major Use of Accessory Muscles

- Sternocleidomastoid muscles, pectoral

### Increase in Respiratory Rate to Critical Level

- Adolescents: 55 breaths/min
- Children, 4–10 years: 70–75 breaths/min
- Infants, 1–3 years: 90 breaths/min
- Neonates: 120 breaths/min

### Signs Reflecting Options Taken to Relieve Fatigue

- Shallow breathing
- Deep breaths with a brief pause to rest the muscles
- Respiratory alternans

### Signs Indicating Pending Respiratory Arrest

- Cyanotic spells

- Cyanosis with brief cough or brief pause
- Recurrent apnea
- Sustained paradoxical thoracic/abdominal movement
- Drooling in absence of airway obstruction (cannot pause to swallow)
- Central nervous system signs (confusion)

Chronic respiratory muscle fatigue is less easily identifiable, and respiratory symptoms may not correlate well with the degree of respiratory muscle fatigue. General fatigue and dyspnea on exertion can be the first symptoms of chronic respiratory pump impairment. Additional manifestations of chronic respiratory muscle impairment include sleep hypoventilation, nocturnal parasomnias, enuresis, increased sweating, and daytime symptoms, such as morning headaches, hypersomnolence, chronic fatigue, and decreased attention span. New onset of unexplained symptoms of right heart failure due to unsuspected pulmonary hypertension may also reflect chronic sleep-related hypoxemia and hypoventilation. Serial assessment of chest wall function is necessary to predict or recognize the first signs of chronic respiratory muscle fatigue in patients with neuromuscular disorders (Box 72.2).

**Box 72.2**

## Assessment of Chest Wall Function

### Clinical Evaluation

- Chest wall configuration (e.g., scoliosis, overdistention)
- Pattern of spontaneous breathing
    - Thoracic and/or abdominal breathing
    - Paradoxical thoracoabdominal movements: inspiratory rib cage retraction, paradoxical inspiratory abdominal retraction (unilateral or bilateral)
- Specific maneuvers:

    - Maximal variation in thoracic circumference
    - Maximal excursion of diaphragm (inspection and percussion)
    - Cough strength?

### Laboratory Evaluation

- Roentgenograms:
    - Cinefluoroscopic studies of diaphragmatic movements
    - Plain roentgenograms in full expiration and inspiration
- Real-time ultrasonography of the diaphragm
- Pulmonary function tests:
    - Pressures: maximal inspiratory pressure (PI max) at mouth, sniff inspiratory pressure, maximal expiratory pressure (PE max) at mouth (transdiaphragmatic pressure)
    - Peak cough flow
    - Lung volumes, forced spirometry
    - Variations/coordination of rib cage and abdominal diameter (respiratory inductance plethysmography)
- Electromyographic studies of respiratory muscles (magnetic stimulation of phrenic nerve)

## Etiologies

Chest wall movements should be envisioned as the result of a chain of effectors that successively transmit the drive to breathe from the respiratory centers to the upper motor neurons of the central nervous system, the lower motor neurons, and finally the respiratory muscle fibers. The central drive to breathe is transformed into a mechanical force resulting from contractions of respiratory muscles, which move the chest wall and generate inspiratory and expiratory pressures responsible for air movement into and out of the lungs. Table 72.1 illustrates the systemic conditions that cause disturbances at these various levels. *Neurological diseases* at the level of the central nervous system (upper motor neurons) or at the level of peripheral innervation of the chest wall (lower motor neurons) may lead to secondary dysfunction of the muscular components of the chest wall. The best examples of these entities are hemiplegia, quadriplegia, infantile spinal muscular atrophies, and polyradiculitis (Guillain-Barré syndrome). *Myopathies* from various types of muscular dystrophy or from metabolic origin, as well as disorders of the neuromuscular junction, result in failure of the respiratory muscles to produce an adequate contraction. In addition, systemic diseases associated with severe malnutrition may lead to a loss in respiratory muscle mass and force. *Disorders involving the bony structures of the chest wall*, such as scoliosis and asphyxiating thoracic dystrophy, are responsible for restrictive lung disease and impair the transformation of respiratory muscle contraction into adequate pressure, due to the malposition of these muscles. Finally, *obesity* causes an additional mechanical load on both the thoracic and abdominal components of the chest wall and limits its performance capacity.

## Table 72.1

## Classification of Disorders Responsible for Chest Wall Dysfunction

| Site of Defect | Causes |
|---|---|
| Central drive of breathing | Congenital or acquired |
| Upper motor neuron | Hemiplegia |
| | Cerebral palsy |
| | Quadriplegia |
| Lower motor neuron | Poliomyelitis |
| | Spinal muscular atrophies |
| | Guillain-Barré syndrome |
| | Tetanus |
| | Traumatic nerve lesions |
| | Phrenic nerve paralysis |
| Neuromuscular junction | Myasthenia gravis |
| | Congenital myasthenic syndromes |
| | Botulism |
| | Drugs |
| Respiratory muscles | Muscular dystrophies |
| | Congenital myopathies |
| | Metabolic myopathies |
| | Steroid myopathy |
| | Connective tissue disease |
| | Diaphragmatic malformation |
| Nonmuscular, chest wall structures | Scoliosis |
| | Congenital rib cage abnormality |

| | |
|---|---|
| | Overinflated rib cage in chronic obstructive pulmonary disease |
| | Connective tissue disease |
| | Thoracic burns |
| | Obesity |
| | Giant exomphalos, Prune-belly syndrome |

Despite their differences in pathogenesis, the various entities that cause chest wall dysfunction share some clinical and physiological features. Chest wall dysfunction leads to restrictive pulmonary disease with reduced lung volume, reduced absolute flow rate values, normal forced expiratory volume in 1 second/forced vital capacity ($FEV_1/FVC$) ratio, reduced strength of respiratory muscles and decreased ventilatory performance in response to exercise. Residual volume can be normal or augmented, depending on normal or decreased strength of the expiratory muscles, respectively. With respiratory muscle strength at less than 50% predicted, the decrease in vital capacity is generally greater than expected, due to the decreased compliance of the lung (atelectasis) and the rib cage (costovertebral and costosternal joint ankylosis). Hypercapnia is usually present during wakefulness when respiratory muscle strength is less than 25% predicted, but it can occur when weakness is less profound in the presence of coexisting mechanical loads due to additional respiratory disorders. With less severe disease, hypercapnia may be present during sleep, and patients are at risk of ventilatory failure during critical periods of their lives, such as in the neonatal period, during respiratory infections, following general anesthesia, and during the last trimester of pregnancy.

# Pathogenesis

## Diaphragm Paralysis

Diaphragm paralysis generally results from injury to the phrenic nerve during thoracic or neck surgery. Tumors of the mediastinum, peripheral neuropathy, and agenesis of the phrenic nerve are less likely causes. In the newborn, stretching of the root C3–C5 during breech delivery is a frequent cause, most often in association with brachial plexus injuries (Erb's paralysis). Most diaphragm paralyses are on the right side, with bilateral paralysis occurring in only 10% of cases. Bilateral diaphragm paralysis can be responsible for a severe restrictive syndrome, with total lung capacity often below 50% of predicted value. Elevation of the paralyzed diaphragm is greater in the supine position, due to pressure from the abdominal content, and can be responsible for orthopnea.

## Spinal Muscular Atrophies

Childhood spinal muscular atrophies (SMA) are a group of autosomal recessive neurodegenerative disorders with onset from birth to adulthood. Spinal muscular atrophies are due to a deficient survival motor neuron (SMN) protein, which is encoded by two adjacent and nearly homologous genes, *SMN1* and *SMN2,* located on chromosome 5. *SMN1* is the only gene able to produce the full-length SMN protein that is essential to the survival of motor neurons. Although the *SMN2* gene differs by only a few nucleotides from the *SMN1* gene, it mainly produces a truncated, rapidly degraded SMN protein. Spinal muscular atrophies are due to a mutation of the *SMN1* gene, which results in the degeneration of the anterior horn cells of the spinal cord and often of the bulbar motor nuclei, leading, in turn, to skeletal muscle weakness and atrophy.

## Neuromuscular Junction Diseases

### Myasthenia Gravis

#### Juvenile Myasthenia Gravis.

Similar to the adult form, juvenile myasthenia gravis is an acquired autoimmune disorder of neuromuscular transmission associated with circulating autoantibodies against acetylcholine receptors (AChR) in 80%–90% of cases. The juvenile form accounts for 10% of all cases of myasthenia gravis.

#### Neonatal Myasthenia Gravis.

Neonatal myasthenia is a transient disorder, which affects 10%–30% of infants born to mothers with autoimmune myasthenia gravis. It results, at least partly, from passively transmitted maternal AChR autoantibodies, even if the mother has shown no clinical symptoms.

### Congenital Myasthenic Syndromes

Congenital myasthenic syndromes refer to a group of various inherited disorders resulting from mutations of genes crucial for neuromuscular transmission. At least 24 different genes are known to cause congenital myasthenic syndromes.[4]

## Myopathies

### Duchenne Muscular Dystrophy

Duchenne muscular dystrophy (DMD) is the most common and severe form of muscular dystrophy afflicting humans. Inherited as an X-linked recessive trait, it has an incidence of approximately 1 : 3500 male births. Almost one-third of cases result from new mutations. The gene responsible has been localized within the dystrophin gene located on the short arm of the X chromosome (Xp21). Dystrophin links the normal contractile apparatus to the sarcolemma in skeletal muscle. Dystrophin gene mutations result in either a lack of dystrophin (usually DMD) or the expression of mutant forms of dystrophin (usually Becker muscular dystrophy).

### Other Myopathies

Aside from DMD, myotonic dystrophy is the other muscular dystrophy which commonly leads to respiratory failure before adulthood. Myotonic dystrophy type I (Steinert disease) is a multisystem disease, which includes anomalies of the skeletal and smooth muscle as well as of the eye, central nervous system, heart, and endocrine system. Myotonic dystrophy type I follows a pattern of autosomal dominant inheritance and has a worldwide prevalence of 1 : 8000. The culprit mutation is an expansion of the cytosine-thymine-guanine (CTG) trinucleotide in the nontranslating region of the dystrophia myotonica protein kinase *(DMPK)* gene on chromosome 19. The highly variable phenotype, with an age of onset spanning from the prenatal period to adulthood, is closely related to the size of the CTG expansion, so that a longer expansion is responsible for a more severe phenotype.[5]

In addition, pulmonary function abnormalities and respiratory failure have been reported in metabolic myopathies as well as in the childhood form of limb girdle muscle dystrophy, facioscapulohumeral dystrophy, and Emery-Dreifuss syndrome.

## Disorders Involving the Bony Structure of the Chest Wall

### Pectus Excavatum

Pectus excavatum is characterized by a symmetric or asymmetric depression of the sternum and anterior chest deemed to be due to defects in the sternum cartilage or overgrowth of the costal cartilage of the ribs. It is accompanied by an abnormally shallow chest in the anterior-posterior dimension in 60% of cases, described as a pectus gracilis.[6] Severity of the pectus excavatum is directly correlated with the severity of the pectus gracilis, raising the question as to whether the pectus excavatum is a thoracic as well as a sternal deformity. It occurs predominantly in white males, with an estimated incidence of 1 in every 300–400 live births and represents more than 90% of all congenital chest wall abnormalities. Its etiology remains unclear, although a genetic base is suggested by the observation that about one-fourth of patients have an affected family member. Pectus excavatum appears to be polygenetic, following various patterns of inheritance.[7] It is frequently associated with idiopathic scoliosis, and is a component of a number of connective tissue disorders, especially Marfan syndrome. Severe pectus excavatum can induce mild restrictive syndrome and can be associated with limitation in exercise tolerance.

### Kyphoscoliosis

Scoliosis is the result of underlying pathological processes leading to lateral displacement in the coronal plane of the spine. Kyphosis describes the curvature of the spine in the sagittal plane, which curves the spine forward. There are children with major scoliosis and minor kyphosis and children with major kyphosis and minor scoliosis. Kyphoscoliosis is also associated with rotation of the spine, which contributes to spine deformity and distorts the thoracic cage. Kyphoscoliosis distorts the ribs, sternum, and respiratory muscles, as well as intrathoracic organ orientation.

### Classification of Kyphoscoliosis.

The age of onset and etiology are most often used to classify kyphoscoliosis in children. The most common form of scoliosis has its onset at the time of adolescence in otherwise healthy children. Less than 10% of spine deformities are those first diagnosed before 10 years of age, known as early onset scoliosis. The specific ages of different idiopathic scoliosis and the categories of etiologies that are nonidiopathic are listed in Box 72.3.

**Box 72.3**

## Classification of Scoliosis

### Idiopathic (85% of All Scoliosis)

- Infantile (<3 years old)
- Juvenile (3–9 years old)
- Adolescent (10 years old to skeletal maturity)

### Congenital (5% of All Scoliosis)

- Failure of formation (hemivertebra(e))
- Failure of segmentation
- Mixed

### Neuromuscular (5% of All Scoliosis)

- Neuropathic
- Lower motor neuron (e.g., poliomyelitis)
- Upper motor neuron (e.g., cerebral palsy)
- Other (e.g., syringomyelia)

- Myopathic
- Progressive (e.g., muscular dystrophy)
- Static (e.g., amyotonia)
- Others (e.g., Friedreich's ataxia)

### Associated With Neurofibromatosis (Von Recklinghausen Disease)

Mesenchymal

- Congenital (e.g., Marfan syndrome)
- Acquired (e.g., rheumatoid disease)
- Others (e.g., juvenile apophysitis)

Traumatic

- Vertebral (e.g., fracture, radiation, surgery)
- Extravertebral (e.g., burns, thoracoplasty)
- Secondary to irritative phenomenon (e.g., spinal cord tumor)

### Idiopathic Kyphoscoliosis.

Idiopathic kyphoscoliosis is defined as a spine deformity without any overt malformations of the vertebral bodies or predisposing conditions leading to secondary spine deformity. Autosomal dominant, X-linked and multifactorial patterns of inheritance have been reported to account for the hereditary factors of the disease. Idiopathic scoliosis, which accounts for 80%–85% of cases, is further categorized into infantile, juvenile, and adolescent idiopathic scoliosis, depending on the age of onset.

### Congenital Scoliosis.

Congenital scoliosis is due to the presence of vertebral anomalies with or without associated rib deformities. Common malformations include single or multiple hemivertebrae and segmentation defects, which produce block vertebrae of variable length. Congenital scoliosis can be present at birth with associated pulmonary hypoplasia, or can be mild and diagnosed later in childhood.

Congenital scoliosis is often accompanied by other congenital anomalies and represents one component of a multiorgan syndrome (e.g., VACTERL syndrome).

## Respiratory Effects of Kyphoscoliosis.

The respiratory effects of kyphoscoliosis vary with age of onset, initial severity, and progression of deformity over time. The degree of respiratory impairment is primarily due to the constraint of the lung by a relatively rigid thoracic cage related to the severity of the three-dimensional deformity of the spine. In addition, kyphoscoliosis can be responsible for a decrease in inspiratory muscle strength, as well as impaired lung growth.

The consequences of scoliosis on lung growth remain unclear. Postmortem quantitative studies among adolescents who died of severe kyphoscoliosis suggest that alveolar number and complexity are decreased in congenital or infantile scoliosis, whereas the alveoli may not enlarge normally in idiopathic juvenile or adolescent scoliosis. The number of pulmonary vessels in scoliotic children is also reduced in proportion to alveolar hypoplasia. Lung function studies have demonstrated a greater reduction in vital capacity for the same Cobb angle among children with early onset scoliosis compared to adolescent onset, raising the question of associated pulmonary hypoplasia in those with early onset spine disease. Pulmonary hypoplasia has recently been produced in rabbits that undergo iatrogenic scoliosis with postnatal rib tethering.[8] Pulmonary hypertension and cor pulmonale have been described in a small minority of children with spine and chest deformities, and this number may be even less when sleep-related breathing abnormalities are treated with oxygen or noninvasive positive pressure ventilation.

The term *"thoracic insufficiency syndrome"* has been used to identify those children with spine and chest wall disorders that impair lung function, or postnatal lung growth with skeletal immaturity and future bone growth.[9] The syndrome includes children with early onset scoliosis, regardless of etiology, which is sufficiently severe to impair lung function. Early onset scoliosis may become thoracic insufficiency syndrome as it progresses and as respiratory function becomes compromised over time. Clinical and/or objective measurements of lung function are needed to make this diagnosis.

## Hypoplastic Thorax Syndromes

A variety of syndromes are associated with small thoraces leading to secondary respiratory failure in the first year of life and high mortality rates. These conditions represent a separate category of thoracic insufficiency syndrome. Hypoplasia can occur due to a reduced circumference or due to reduced thoracic vertebral height. There is a continuum of hypoplasia in most of these syndromes, so some patients live to adulthood without respiratory support.

### Asphyxiating Thoracic Dystrophy.

The most common hypoplastic thorax syndrome is asphyxiating thoracic dystrophy, also known as Jeune syndrome or thoracic-pelvic-phalangeal dystrophy. This autosomal recessive disorder is part of the ciliary chondrodysplasias, a group of inherited conditions resulting from cilia malfunction affecting skeletal development in mammals.[10] It is characterized by a narrow, hypoplastic rib cage, and generalized chondrodystrophy with short limb dwarfism. Pelvic and phalangeal abnormalities, polydactyly, renal, and hepatic disorders, thrombocytopenia as well as Shwachman syndrome have also been reported in conjunction with asphyxiating thoracic dystrophy, with renal disease emerging later in life as a serious concern. Estimates suggest that up to 600 patients per year are born with this disease worldwide.

### Jarcho-Levin Syndrome.

An alternative type of chest wall hypoplasia is illustrated by patients with Jarcho-Levin syndrome. This syndrome includes two distinct genetic disorders, spondylocostal dysostosis and spondylothoracic dysplasia, which present with multiple vertebral and costal anomalies. The vertebral anomalies result in a shortened spinal height and increased anterior–posterior dimension albeit with a reduced intrathoracic volume.

*Spondylocostal dysostosis* is associated with mutations in the *DLL3* (delta-like canonical Notch ligand 3) gene, which is involved with the Notch pathway in separating future vertebrae from one another during early development (somite segmentation). It has both autosomal dominant and recessive inheritance patterns. *Spondylothoracic dysplasia* is associated with mutations in the *MESP2* (mesoderm posterior bHLH transcription factor 2) gene, which is of Puerto Rican heritage and controls activity of genes in the Notch pathway. It is inherited in an autosomal recessive manner.

# Clinical Features

## Diaphragm Paralysis

Unilateral diaphragm paralysis is usually asymptomatic, but can lead to exercise limitation in some patients. When bilateral, the prominent clinical features include unexplained tachypnea, hypoxia, or respiratory distress, which usually worsen in the supine position. Respiratory failure or difficult weaning from ventilatory support after surgery can occur, especially in the neonate or when underlying pulmonary disease is present. In chronic cases, respiratory insufficiency, recurrent atelectasis and infections can be observed, as well as failure to thrive.

## Spinal Muscular Atrophies

While there is no clear delineation of SMA subtypes, the clinical classification by age of onset and maximum function achieved is useful for prognosis and management.[11]

### Spinal Muscular Atrophy Type I

In infants with SMA I (incidence ~1 : 10,000 live births), poor muscle tone and muscle weakness begin at age 0–6 months and are associated with a lack of motor development and an inability to sit without support. There is minimal or absent facial weakness, but fasciculation of the tongue is observed in most children. Tendon reflexes are absent. There is no sensory loss and cerebral function is normal, including intellect. A prenatal subtype with overt manifestations at birth occurs. Infants with prenatal SMA and SMA I have impaired head control, with a weak cry and cough. Intercostal muscle weakness is responsible for paradoxical inward rib cage movement with each inspiration, the diaphragm being relatively spared. Chest x-rays show a reduced intrathoracic volume and a bell-shaped thorax. Affected patients suffer from swallowing disorders and aspiration, and are at risk of recurrent respiratory failure with viral respiratory infections. The prognosis is poor, with 95% of infants dying from respiratory failure by the age of 18 months without intensive respiratory intervention.

## Spinal Muscular Atrophy Type II

In children with SMA II, muscle weakness usually begins after the age of 6 months. The child can sit independently when placed in a sitting position, but cannot walk. Low muscle tone is present and tendon reflexes are absent in about two-thirds of children. They have average intellectual skills during the formative years and above average by adolescence. Swallowing disorders, gastric reflux, recurrent atelectasis, and respiratory infections vary in their degree of severity and carry the risk of respiratory failure. In the majority of older children, thoracic and thoracolumbar scoliosis further aggravates respiratory function. Even after the spine is fused and stabilized, the chest wall can continue to collapse, producing the appearance of a closing parasol (Fig. 72.2). Typically, recurrent pulmonary infections precede nocturnal hypoxemia, nocturnal hypoventilation, and then daytime hypoventilation. With adequate respiratory management tailored to respiratory involvement, including noninvasive ventilation, mechanical in-exsufflation, and the prevention of respiratory infections, a good quality of life and lifespan into adulthood is expected for most patients.[11]

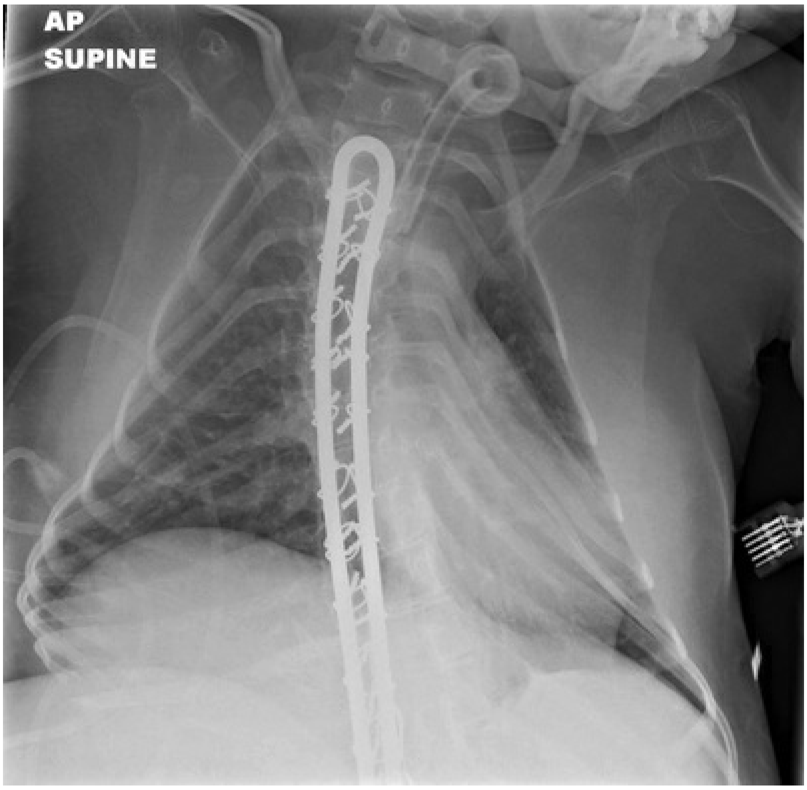

**FIG. 72.2** "Closing parasol" appearance of the thorax in an SMA 2 patient with continuing chest wall collapse despite spinal surgery.

### Spinal Muscular Atrophy Type III

Patients with SMA III usually present with proximal limb weakness after the age of 10 months. The legs are more severely affected than the arms; they are able to walk at least 25 meters, but frequently fall or have trouble walking up and down stairs at the age of 2–3 years. Respiratory involvement is usually minimal, and a normal lifespan is expected.

## Neuromuscular Junction Diseases

Pediatric myasthenia is a group of rare disorders due to anomalies of the neuromuscular junction. Three subtypes are generally recognized: juvenile myasthenia gravis, congenital myasthenia gravis, and congenital myasthenic syndromes.[12]

### Juvenile Myasthenia Gravis

Juvenile myasthenia gravis (JMG) may present at any age during childhood, even as early as 6 months. It is characterized by fatigable muscle weakness, which improves with rest. While ocular JMG mainly presents with ptosis, ophthalmoplegia or diplopia, JMG can present with swallowing difficulties and dysphonia, or as a more generalized form consisting of generalized progressive weakness in all muscles, and abnormal fatigability on exertion, which improves with rest. Severe generalized disease can cause a progressive decrease in respiratory muscle strength, leading to a restrictive lung pattern. Myasthenia gravis crisis with life-threatening respiratory involvement can also be triggered by infections, stress, or certain drugs.

### Neonatal Myasthenia Gravis

Neonatal myasthenia gravis usually presents within hours of birth with feeding and respiratory difficulties, hypotonia, weak cry, facial weakness, and ptosis. Respiratory difficulties are related to feeding problems causing aspiration pneumonia, upper airway obstruction due to the inability to handle pharyngeal secretions, plus respiratory muscle weakness and fatigability.

### Congenital Myasthenic Syndromes

Congenital myasthenic syndromes are characterized by a wide spectrum in terms of age of onset. With early neonatal onset, clinical features can mimic neonatal myasthenia gravis and lead to respiratory failure with sudden apnea, or patients may present with bilateral vocal cord paralysis. Other types beginning after the neonatal period are characterized not only by usually mild symptoms but also by sudden exacerbations of muscle weakness and respiratory failure, which can be triggered by infections or stress. Some cases have been reported to mimic congenital myopathies, muscular dystrophies, or metabolic myopathies.

## Myopathies

### Duchenne Muscular Dystrophy

DMD presents in boys with proximal muscle weakness at 2–4 years of age. The progression is fairly rapid, with the patient becoming confined to a wheelchair at around 10–12 years of age, requiring spine fusion for scoliosis in early adolescence. In the early phases of the disease, when the gait is still preserved, respiratory function is essentially normal, although a loss in the strength of the respiratory muscles can be readily shown. Impairment of respiratory function is accelerated by the loss of ambulation. Every patient with DMD experiences a maximum plateau in absolute vital capacity between the ages of 10 and 12 years, and a progressive decrease thereafter. Patients with DMD present a restrictive syndrome due to muscle weakness and contractures, spinal deformity, vertebro-costal joint ankylosis, and frequent obesity. The first sign of chronic respiratory failure is nocturnal hypoventilation, which can be aggravated by obstructive sleep-disordered breathing, a frequent occurrence in patients with DMD, even in the first decade.[13] Premature death has been reported at a median age of 19 years or a mean age of 17.7 years (range 11.6–27.5) in patients without ventilatory support. The use of ventilatory support, together with early, aggressive management of respiratory infections, has been shown to prolong life. A median age of 27.0 years and a mean age of 27.9 years (range 23–38.6) for death have been reported in patients with ventilator support.[14,15] Given that prolonged survival to adult age in patients with DMD is mainly due to better respiratory care, pediatric pulmonologists must be aware of how quality of life is affected by this chronic disease. While there is agreement on decreased physical aspects of health-related quality of life, conclusions of recent studies are conflicting with regard to psychosocial areas, ranging from preservation[16] and satisfaction with overall quality of life[17] to poor health-related and global quality of life.[18] Cultural differences may explain part of this discrepancy. However, the fact that patients with DMD are heterogeneous in relation to neuropsychosocial and neurobehavioral functioning, due to the lack of dystrophin normally present in a number of brain areas,[19] likely explains part of the literature discrepancy on quality of life.

## Myotonic Dystrophy

Myotonia and muscle weakness are the prominent clinical features of myotonic dystrophy, although a number of other organ systems can be affected (cataracts, cardiac dysrhythmias, sleep disorders and hypersomnia, cognitive deficit, frontal balding and endocrine disorders). Involvement of the respiratory system contributes substantially to morbidity and mortality.

### Congenital Myotonic Dystrophy.

Congenital myotonic dystrophy has a prevalence of ~1/47,000.[5] Newborns with this severe phenotype typically present with generalized hypotonia and immobility, contractures, bilateral talipes, facial dysmorphia, and weak cry, along with respiratory and feeding difficulties. Myotonia is absent. Thin ribs and right diaphragmatic elevation can be observed on chest x-ray. Diagnostic suspicion is increased by examining the mother, who often presents mild weakness of eyelid closure and more or less overt grip myotonia. Genetic testing confirms the diagnosis. Polyhydramnios, prematurity, hydrops fetalis with pleural effusions and pulmonary hypoplasia can increase respiratory difficulties due to diaphragmatic weakness at birth. Important respiratory difficulties with a need for ventilatory support are present in 50% of cases and are responsible for neonatal death in approximately 30% of patients. The condition usually improves in early childhood, although features of the classic disease gradually appear in late childhood or adolescence. If ventilatory support is needed beyond 4 weeks of life in the neonatal period, the prognosis is poor, with the risk of sudden death in survivors, even without apparent respiratory exacerbation.

### Childhood-Onset Myotonic Dystrophy.

Childhood-onset myotonic dystrophy begins between ages of 1 and 10 years and mainly affects cognition, muscle strength, and respiratory, central nervous, and gastrointestinal systems. *Juvenile myotonic dystrophy type I* begins between 10 and 20 years.[5] Although expiratory muscle weakness has been shown in children and adolescents, a true restrictive syndrome is commonly reported in adult patients only and chronic respiratory failure is rare before late adulthood. However, weakness of the respiratory and swallowing muscle renders patients with myotonic dystrophy type I prone to repeated aspiration pneumonias and pulmonary infections as well as postanesthetic failure. Sleep disorders often represent a significant issue, with 50% of children and adolescents complaining of excessive daytime sleepiness. The latter has been blamed on sleep fragmentation secondary to central hypoventilation and/or obstructive apneas that have been reported in 30% of children with myotonic dystrophy type I, and can occur concurrently with periodic leg movement disorder and REM sleep dysregulation.[15] Obesity or adenotonsillar hypertrophy can act as aggravating factors.

## Respiratory Function Testing in Neuromuscular Diseases

Respiratory function must be assessed annually in children with neuromuscular disorders. Routine measurements of lung function usually include spirometry, static lung volumes, maximal inspiratory pressure (or sniff inspiratory pressure) and maximal expiratory pressure, peak cough flow, and gas exchange. Although advocated by some teams, the measurement of esophageal pressure is not commonly used in clinical practice. When below 80% in the sitting position, vital capacity should also be measured in the supine position, to investigate for diaphragm weakness (defined by a decrease in vital capacity >20% from the sitting position). Peak cough flow values under 160–200 L/min in adolescents and adults indicate that cough is ineffective and could place patients at risk of recurrent respiratory infections and respiratory failure. Corresponding reference values in younger children are now available.[20,21]

Overnight polysomnography or combined pulse oximetry and transcutaneous/end tidal arterial pressure of carbon dioxide ($PCO_2$) should be performed annually in children, especially when vital capacity is less than 60%. The relevance of performing polysomnography, when available, stems from the recognition that sleep-disordered breathing is frequent, even before the loss of ambulation, and includes not only diaphragm weakness-related alveolar hypoventilation but also obstructive apneas.[13,22–24] In DMD patients, an inspiratory vital capacity of less than 60% or 40% has been found to be both sensitive and specific for sleep-disordered breathing and nocturnal hypoventilation, respectively.[13]

# Disorders Involving the Bony Structure of the Chest Wall

## Pectus Excavatum

Most patients with pectus excavatum (PEx) do not present any symptoms at rest. Although they frequently complain of a limited ability to exercise due to dyspnea or chest pain, studies on the association between pulmonary function and PEx have yielded conflicting results. A multicenter study of 310 patients aged between 6 and 21 years reported that pulmonary function was related to the depth of the depression, so that patients with severe PEx with a Haller score (ratio of the transverse to the anteroposterior diameter of the thorax measured on a computed tomography [CT] scan) greater than 5 were more likely to display a mild restrictive defect on lung function.[25] In addition, severe PEx is responsible for causing compression and displacement of the heart, resulting in distortion of normal cardiac geometry, which, in turn, restricts right ventricular filling during diastole. Some patients with PEx also demonstrate reduced systolic contractility, which can be segmental or global.[26] Although there is a lack of definitive evidence that the mild impairments in lung and cardiac function reported in PEx patients are responsible for the frequent complaint of exercise limitation, a recent communication has reported decreased cardiopulmonary adaptation to exercise, which was proportional to the severity of PEx.[27]

## Kyphoscoliosis

Although the natural history of scoliosis is one of curve progression, cardiopulmonary impairment, back pain, cosmetic deformity, poor balance, and neurological compromise, the condition varies greatly, depending on specific etiology, the age of onset, the genetic background, and the curve pattern. Adults whose scoliosis is first diagnosed before 8 years of age have a higher mortality rate than the general population after the age of 40 years.

Radiographic measurements of the structural severity of spine curves include the angle of displacement on an anterior–posterior spine radiograph, known as the Cobb angle, and the degree of kyphosis and lordosis of the spine in the lateral projection. Each curve can vary according to the site of the curve's apex (cervical, high thoracic, thoracic, thoracolumbar, lumbar) and the number of curves (single or double) as well as the number of vertebrae involved. In addition, the spine rotates with the angle of rotation greatest at the apex of the Cobb angle. Given that kyphoscoliosis is a three-dimensional deformity, two-dimensional structural descriptors, such as the Cobb angle, do not correlate well with respiratory functional measurements at any age.[28]

### Adolescent Idiopathic Scoliosis.

In the general school population, the prevalence of adolescent idiopathic scoliosis with a curve greater than 10 degrees is 2%–3%, dropping to 0.5% and 0.2% for curves greater than 20 degrees and 30 degrees, respectively. Untreated adolescents with severe idiopathic scoliosis followed over a 50-year period have been shown to have a mortality rate 2.2 times greater than controls. These deaths generally occur in the fourth or fifth decade of life, due to cardiopulmonary insufficiency. Most of the survivors show significant physical disability characterized by dyspnea, back pain, and exercise limitation.

### Infantile Idiopathic Scoliosis.

Infantile idiopathic scoliosis in untreated children followed to maturity may progress to become a severe and crippling deformity, with a Cobb angle that can exceed 70 degrees. Spontaneous regression of idiopathic scoliosis is uncommon, although progression does not always occur. The greatest risks for progression occur during rapid somatic growth (e.g., the adolescent growth spurt).

### Congenital Scoliosis.

Congenital scoliosis is usually progressive and, if untreated, results in severe spinal deformity. The ultimate severity of the curve depends on both the type of anomaly and the site at which it occurs. The most progressive of all anomalies is a unilateral unsegmented bar combined with single or multiple convex hemivertebrae on the contralateral side with or without associated fused ribs. At an early stage of the disease, scoliosis is generally painless and asymptomatic. While restrictive lung disease is detectable when the Cobb angle is greater than 50–60 degrees, a Cobb angle greater than 90 degrees greatly predisposes the patient to cardiorespiratory failure.

### Respiratory Function Testing in Kyphoscoliosis.

The degree of restrictive lung disease in a child with kyphoscoliosis is related to the severity of the three-dimensional deformity of the spine. In adolescent idiopathic scoliosis, multiple structural features of the spine, when used in combination, account for 14%–18% of the variation in lung function in populations of affected children.[29] Reduction in chest wall compliance, and thus, lack of chest wall excursion, impaired lung growth, and decreased inspiratory muscle strength due to chest deformity, also account for reductions in vital capacity and other lung volumes. In addition, most imaging is static and does not measure motion over time. Dynamic magnetic resonance imaging (MRI) methods are currently being developed for motion imaging.

FVC is most sensitive to reductions in both thoracic cage size and chest wall compliance as well as inspiratory and expiratory respiratory muscle dysfunction. Residual volume (RV) is reduced less (as a percent of predicted value) than vital capacity. This may explain the elevated residual volume (RV)/total lung capacity (TLC) ratio reported in patients with scoliosis. Airway resistance may be normal or slightly increased, due to main stem bronchial distortion associated with chest deformity. This occurs in up to 10% of patients with adolescent idiopathic scoliosis and up to 30% of children with early onset scoliosis.[30] In children with obstructive lung disease and scoliosis, more common etiologies for airway obstruction (e.g., asthma) should be investigated. Absolute values of spirometric lung functions are normalized as a percentage of predicted values based on arm spans or length of specific bones (e.g., ulnar length), since height is directly influenced by spine curvature. Nutritional values, such as body mass index, must also be corrected using these surrogates for height. Ventilation and lung perfusion scans demonstrate right–left lung functional imbalance in up to 50% of children with early onset scoliosis (EOS). However, the side that is least functional cannot be determined by an anteroposterior chest film. Ventilation and perfusion usually match well in the absence of additional pulmonary diseases. There is seldom significant alteration of blood gases in patients with kyphoscoliosis and a Cobb angle of less than 60 degrees. Nocturnal alveolar hypoventilation has been observed in patients with a Cobb angle greater than 60 degrees, and cardiorespiratory failure can be present in the most severe patients with a Cobb angle greater than 90 degrees. The Apnea-Hypopnea Index is usually increased in children with EOS irrespective of $CO_2$ elevation due to recurrent oxyhemoglobin desaturation associated with hypopneas.[28] Apnea *per se* is a rare event and should signal other etiologies (e.g., tonsillar and adenoidal enlargement) in children with spine and chest wall deformities. Patients with moderate to severe scoliosis, and obesity or neuromuscular weakness in particular, should therefore be evaluated with nocturnal polysomnography or, if not available, at least with oximetry and $PCO_2$ recorded during sleep.

## Hypoplastic Thorax Syndromes

### Asphyxiating Thoracic Dystrophy.

Asphyxiating thoracic dystrophy is usually diagnosed immediately after birth when the thoracic circumference is found to be less than 75% of head circumference and the infant is tachypneic. If untreated, most infants with asphyxiating thoracic dystrophy die within the first year of life due to respiratory failure. Less severe variants have been reported with clinical courses that vary from respiratory failure in infancy to few or no respiratory symptoms at all. In those patients who survive the neonatal period, respiratory failure may occur later during infancy and childhood because of chest constriction, impaired lung growth, and superimposed pneumonia. Improvement in bone abnormalities may occur with age, thereby justifying life-support procedures in early life, such as long-term mechanical ventilation.

### Jarcho-Levin Syndrome.

Clinical features of both spondylocostal dysostosis and spondylothoracic dysplasia include a shortened thoracic height due to vertebral anomalies; however, congenital scoliosis is present (in spondylocostal dysostosis only). Spondylothoracic dysplasia is more severe and can present with respiratory distress in the neonatal period, with up to one-third of children dying of respiratory failure in the first year of life.[31] Lung function in adults with either form of Jarcho-Levin syndrome reflects severe restrictive changes, including tachypnea and a vital capacity of less than 30% predicted values.

# Diagnosis

## Diaphragm Paralysis

On chest x-ray, unilateral paralysis of the right hemidiaphragm should be suspected if it is more than two rib spaces higher than the left hemidiaphragm; on the left side, it results in an elevation of the hemidiaphragm of at least one rib space above the right hemidiaphragm. Contralateral mediastinal shift also can be observed in severe cases. Fluoroscopy with a sniff test and ultrasonography in a spontaneously breathing patient show a paradoxical inspiratory upward motion of the paralyzed hemidiaphragm compared to the contralateral side. Electromyography in association with percutaneous stimulation of the phrenic nerve can confirm the paralysis. *Repeated* evaluations by fluoroscopy, ultrasonography, or electromyography can aid in assessing diaphragmatic function.

## Spinal Muscular Atrophies

The diagnosis of SMA is established in children with motor difficulties, physical signs of motor unit disease and mutations in the *SMN1* gene.[11]

In addition to the clinical classification of SMA subtypes, the diagnosis of SMA is based on molecular genetic testing. About 95%–98% of individuals with SMA are homozygous for a deletion (lack of exon 7 in both copies of *SMN1* genes) or gene conversion of *SMN1* to *SMN2.* A number of *SMN2* copies of three or more is associated with a milder phenotype.

If molecular genetic testing of *SMN1* does not identify mutations, additional tests can be used. Electromyography reveals denervation and diminished motor action potential amplitude. Motor and sensory nerve conduction velocities are normal. Muscle biopsy reveals group atrophy of type 1 and type 2 muscle fibers.

# Neuromuscular Junction Diseases

## Juvenile Myasthenia Gravis

Diagnosis of JMG relies on the following: clinical symptoms, a transient improvement upon administration of the anticholinesterase medication edrophonium chloride (Tensilon), abnormal electrophysiological studies (including an abnormal response to repetitive stimulation during nerve conduction study), anomalies of single fiber electromyography, and a positive test for circulating AChR autoantibodies.

## Neonatal Myasthenia Gravis

The diagnosis of neonatal myasthenia gravis is made on the presence of myasthenia gravis in the mother, a transient improvement in clinical symptoms after the administration of edrophonium chloride or neostigmine, and the presence of circulating antibodies against acetylcholine receptors.

## Congenital Myasthenic Syndromes

Diagnosis relies on family history, clinical myasthenic findings, the absence of circulating AChR antibodies, the stimulation single fiber electromyography, and a positive response to pyridostigmine or the detection of one of the known mutations.

# Myopathies

## Duchenne Muscular Dystrophy

The frequent findings of delayed muscle function, speech delay, and elevated serum CK concentration (most often 50–100 times the reference range) in a young boy are highly suggestive of DMD. Molecular genetic testing from peripheral blood samples can establish the diagnosis of dystrophinopathy in nearly all individuals with DMD or Becker muscular dystrophy. The correct genetic diagnosis is crucial for DMD patients in order to provide both the optimal care to the patient and genetic counseling to the family, according to published guidelines.[32] In addition, with mutation-specific therapies under development for DMD, a specific genetic diagnosis is also important for assessing whether patients are eligible for treatments.

A stepwise approach for genetic analysis is currently recommended, searching first for large deletions and duplications in the *DMD* gene, which are present in ~70% of the patients; the multiplex ligation-dependent probe amplification technique is the most reliable method for this purpose. If a whole exon mutation or deletion is not found, the next step is to perform exon sequencing to search for a smaller mutation on 1 of the 79 exons of the *DMD* gene (~20% of cases). Lastly, if no mutations are found, next-generation sequencing approaches, such as whole exome sequencing, are needed to complete the genetic testing. Finally, in the exceptional cases where genetic testing is negative, dystrophin protein analysis may be necessary to make the diagnosis from muscle biopsy.

### Myotonic Dystrophy

The diagnosis is established by identification of a heterozygous pathogenic variant in the *DMPK* gene on chromosome 19, using a targeted analysis for an expansion of the CTG trinucleotide repeat in *DMPK.*

## Disorders Involving the Bony Structure of the Chest Wall

### Kyphoscoliosis

Kyphoscoliosis is diagnosed initially by physical features of a posterior rib hump, uneven shoulder height, or abnormal posture. Delineation of the type of scoliosis and the vertebrae and ribs involved requires imaging, initially with an anterior-posterior and lateral view of the entire spine. Further imaging, such as a MRI, of the spine is needed to detect spinal cord and canal disorders, such as syringomyelia and tethered spinal cord. A CT scan of the spine and thorax with three-dimensional reconstruction may help to develop surgical strategies. Of note, diagnosing the structural deformity does not describe respiratory function. Functional severity of kyphoscoliosis should be performed in concert with the structural assessment.

## Hypoplastic Thorax Syndromes

Hypoplastic thoraces may be obvious or subtle at birth. Severe abnormalities are apparent on physical examination. Imaging of the chest wall will reveal abnormal contours. The heart may look abnormally large in a small chest. Lung volumes may be low due to pulmonary hypoplasia. CT imaging of the spine and thorax is helpful where primary vertebral and costo-vertebral abnormalities (i.e., Jarcho-Levin syndrome) are suspected. Abnormal rib structure, including fused ribs, is also identified with CT scanning and three-dimensional image reconstruction. Recently, gender-specific correlations between pelvic dimensions, spine height, and chest wall dimensions have been made, and norms have been published.[33]

### Asphyxiating Thoracic Dystrophy.

Characteristic chest x-ray findings reveal a narrow chest cage, with high-positioned clavicles, short horizontal ribs, and flaring of the costochondral junctions (Fig. 72.3A). The CT scan is characteristic with a four-leaf clover appearance due to foreshortened ribs (see Fig. 72.3B). The lungs are constrained by the chest and are elongated in the process.

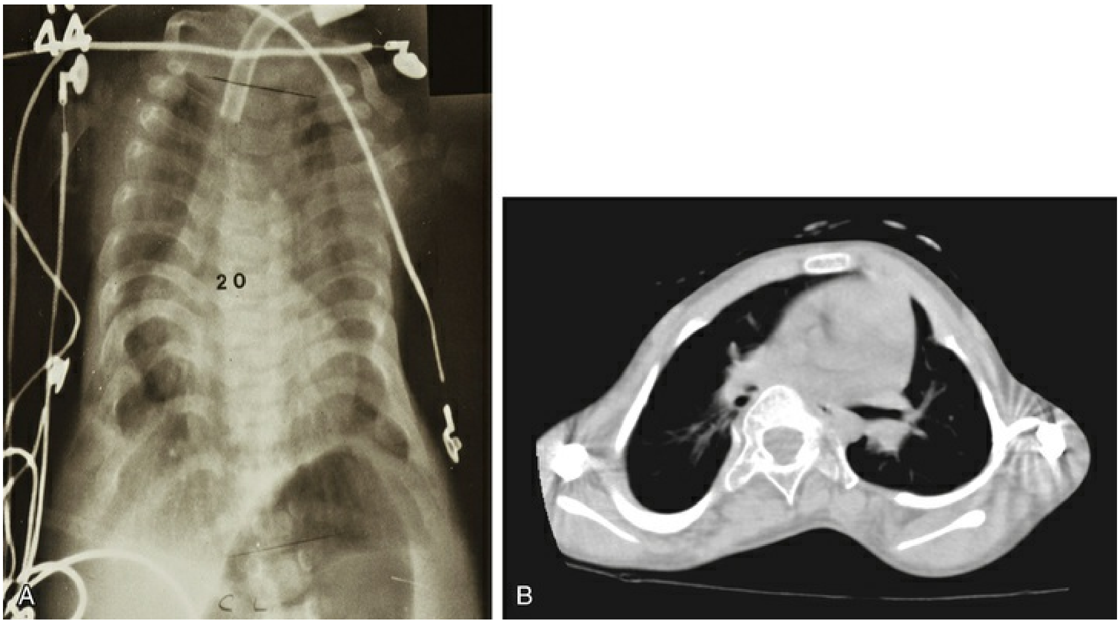

**FIG. 72.3** Imaging features of asphyxiating thoracic dystrophy. (A) Chest radiograph of an intubated infant with asphyxiating thoracic dystrophy showing the narrow chest cage with high-positioned-clavicles, short horizontal ribs and flaring of the costochondral junctions. (B) Features of shortened ribs that curve inward toward the cardiac borders in a “four-leaf clover” appearance on computerized tomography of a child with asphyxiating thoracic dystrophy.

### Jarcho-Levin Syndrome.

The diagnosis is made from characteristic spine and rib abnormalities on spine films and CT scan of the thorax. In spondylocostal dysostosis, broadening, bifurcation, and fusion of the ribs, as well as congenital scoliosis, are seen (Fig. 72.4). In spondylothoracic dysplasia, ribs are symmetrically fused bilaterally at the costo-vertebral junctions, producing a crablike appearance to the thoracic skeleton (see Fig. 72.5).[34]

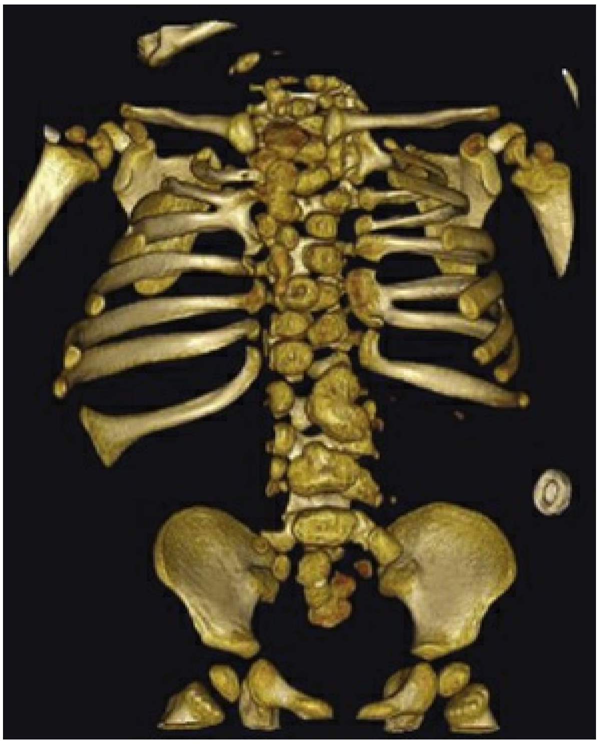

**FIG. 72.4** Reconstructive computed tomography scan of a child with Jarcho-Levin syndrome—subset spondylocostal dysostosis. Vertebral and asymmetric rib anomalies are seen. The thorax is foreshortened with few normal thoracic vertebrae.

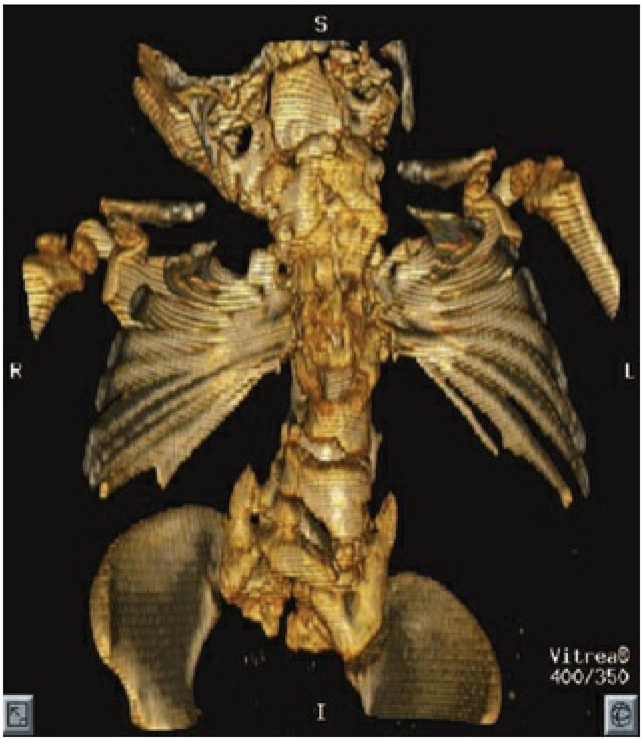

**FIG. 72.5** Reconstructive computed tomography scan of a 2-year-old patient with spondylothoracic dysplasia —subset spondylothoracic dysplasia. Note the symmetrically fused ribs at the costo-vertebral angle, producing the characteristic “fan” or “crab” appearance. (Reproduced with permission from Cornier AS, Ramirez N, Carlo S, et al. Controversies surrounding Jarcho-Levin syndrome. *Curr Opin Pediatr.* 2003;15:614–620.)

# Management

## General Management of Children With Chest Wall Dysfunction

Adequate nutrition is essential for ensuring adequate functioning of the respiratory muscles. Patients with a chronic condition, such as severe DMD, are commonly malnourished, a state that can lead to muscle atrophy and loss of respiratory muscle capacity to perform the work of breathing. An adequate $O_2$ supply and the correction of electrolytic imbalance (hypophosphatemia, hypocalcemia, hypokalemia, acidosis) are also needed for muscles to perform their work.

Associated nonrelated respiratory problems, such as asthma, allergic rhinitis, enlarged adenoids, and tonsils causing sleep-disordered breathing, must be carefully investigated and treated. Prevention of respiratory infections must be implemented by ensuring an optimal environment (e.g., avoidance of passive smoking and large daycare centers) and by providing pneumococcal and annual flu vaccination.

Respiratory muscle training is clearly beneficial in specific conditions where respiratory muscles are intact, such as in quadriplegic patients, following spinal cord injury. However, it must be used with caution in myopathies in order to avoid further muscle injury; in such cases, swimming and aquatic sports can be recommended without reaching fatigue threshold, as long as it is physically possible.

The daily use of assisted cough with lung recruitment techniques, either manually or through the use of an insufflation-exsufflation device, is of paramount importance in the management of patients with severe neuromuscular problems, especially during respiratory infections. In addition, ventilatory support has become an essential tool for increasing quality of life and prolonging life in severely affected patients with neuromuscular disorders by resting weakened respiratory muscles.[35] The development of noninvasive intermittent positive pressure using BiPAP ventilation *via* nasal mask during nocturnal sleep has been especially instrumental in this regard. Current consensus suggests that noninvasive nocturnal ventilatory support is indicated for patients with alveolar hypoventilation,[36] and should be discussed in the presence of failure to thrive or recurrent chest infections (more than three per year). In addition, nocturnal ventilatory support can be indicated in the presence of obstructive sleep-disordered breathing.[13] While most experts state that noninvasive mask ventilation is generally preferred, tracheostomy for ventilatory support should be considered in patients with bulbar involvement and severe retention of secretions despite assisted cough techniques, and those with extreme ventilator dependency or ineffective noninvasive ventilation.[36] Of note, however, the use of tracheostomy poses ethical dilemmas in patients with very severe disease and short life expectancy, as in SMA type I, where treatment burden must not outweigh the benefits.[37]

## Diaphragm Paralysis

Treatment of diaphragmatic paralysis caused by phrenic nerve impairment primarily depends on the presence of respiratory symptoms. Asymptomatic diaphragmatic paralysis does not require any therapy. Treatment for symptomatic cases first consists of ventilatory support, when needed. Surgical plication is generally indicated in the presence of persistent or recurrent respiratory symptoms, and is more often needed in infants than in older children. The optimal timing for surgery in the neonate or child with diaphragmatic paralysis is controversial. Waiting for spontaneous recovery in symptomatic patients can be associated with significant morbidity, especially in high-risk patients on ventilatory support. Recommendations for such patients vary from immediate repair to waiting 2–4 weeks for signs of spontaneous recovery. The use of video-assisted thoracoscopic surgery for diaphragm plication decreases the morbidity associated with traditional open thoracotomy. Long-term intermittent positive pressure ventilation, usually using BiPAP via a nasal mask, is useful in the most severe cases of bilateral diaphragmatic paralysis.

# Spinal Muscular Atrophies

## Spinal Muscular Atrophy Type I

Respiratory management for patients with SMA I raises important and unresolved ethical concerns and varies between countries and institutions. Any therapeutic intervention must aim at increasing the quality of life of the child and must be preceded by information to the family on both the burden of treatment and the grim prognosis. According to the Consensus Statement for Standard of Care in SMA,[11] palliative care or proactive respiratory interventions, which include noninvasive ventilation and insufflation-exsufflation, are usually offered and determined by parental choice in North America. Infants treated by noninvasive ventilation have been shown to survive longer (over half were alive at 4 years of age), albeit at the expense of hospitalizations and a burden of respiratory care that increases with time.[38] A growing number of publications, especially from Europe, defend that it is usually more in the interest of the child to include him/her in a palliative care program that includes aspiration of secretions, nasogastric feeding, nasal oxygen, and morphine/sedation to alleviate dyspnea, without noninvasive ventilation, aside from transient ventilation if needed to facilitate extubation.[39,40] If proactive respiratory support is offered, most experts will recommend noninvasive ventilation over tracheotomy in patients with SMA I, due to the complete loss of spontaneous breathing capability and the impossibility of language development usually associated with tracheotomy. Importantly, a written care plan must be decided in advance with the parents with regard to resuscitation and intubation/ventilation in case of a reversible acute event, such as a respiratory infection.

### Spinal Muscular Atrophy Type II

Spinal muscular atrophy type II requires adequate respiratory management tailored to respiratory involvement, including noninvasive ventilation, mechanical in-exsufflation, and prevention of respiratory infections. A good quality of life and lifespan into adulthood is expected for most patients.[11]

### Spinal Muscular Atrophy Type III

Patients with SMA III usually have minimal respiratory involvement, which does not require ventilatory support, or only in adult life.

### Perspectives for Drug Therapy in Patients With Spinal Muscular Atrophy

The availability of new animal models of SMA (particularly mouse models) has significantly contributed to our understanding of the basic mechanisms, which has translated into several phase 1 and 2 clinical trials. While all patients with SMA have a mutated, unproductive *SMN1* gene, they also retain one to four copies of the *SMN2* gene, which mainly encodes a truncated SMN protein that cannot ensure motor neuron survival. Two promising strategies are currently being tested in clinical trials, aiming at SMN upregulation through either gene therapy or the modulation of SMN2 preRNA splicing. With regard to gene therapy, adeno-associated virus serotype 9 *(AAV9)*-mediated *SMN* gene delivery to motor neurons via systemic injection is currently being tested in a phase 1 clinical trial in patients with SMA I. Modulation of SMN2 splicing is obtained by using antisense oligonucleotides designed to allow the expression of the normally silenced exon 7 in *SMN2*. Two phase 3, randomized, double-blind studies are currently under way to assess efficacy and safety of intrathecal injection of an antisense oligonucleotide in infants with early onset, as well as in children with later-onset, SMA. In addition, further phase 1 clinical trials are currently using small molecules to modify SMN2 splicing.[41]

## Management of Neuromuscular Junction

# Diseases

## Juvenile Myasthenia Gravis

The management of JMG is primarily based on anticholinesterase medication (pyridostigmine bromide). However, improvement with such medication is usually incomplete and most patients require further therapeutic measures, such as prednisone and consideration of thymectomy. During acute exacerbations of the disease, or in the course of respiratory complications, respiratory support may be required for various lengths of time (a few days to several weeks), in association with short-term immunotherapy, including intravenous immunoglobulins and plasmapheresis.

## Neonatal Myasthenia Gravis

Management relies on pyridostigmine as well as adequate feeding and respiratory support until spontaneous remittance of muscle weakness occurs. Total and definitive resolution occurs within 2–8 weeks.

## Congenital Myasthenic Syndromes

Depending on the subtype, treatment for congenital myasthenic syndromes includes cholinesterase inhibitors, such as pyridostigmine, the potassium channel blocker 3,4-DAP, AChR open channel blockers (fluoxetine or quinidine) and beta-2-adrenergic receptor agonists (ephedrine and salbutamol). Importantly, salbutamol or ephedrine, alone or combined with other drugs, is increasingly reported as beneficial for many subtypes of congenital myasthenic syndromes.[4]

# Management of Myopathies

## Duchenne Muscular Dystrophy

The natural history of DMD has been profoundly altered by treatment, particularly respiratory care, and more recently by the use of corticosteroids.

### Long-Term Management of Respiratory Disability.

Given that death is most often related to respiratory insufficiency, a key component of the management of patients with DMD is directed at slowing down the progression of respiratory insufficiency, while ensuring good quality of life. In the first decade, prevention of respiratory infections, undertaking regular submaximal exercise, and the treatment of any associated respiratory problems (e.g., asthma or obstructive sleep apnea due to adenotonsillar hypertrophy) are mandatory and sufficient. Loss of ambulation coincides with the onset of progressively increasing respiratory problems. At some time during the second decade, loss of respiratory muscle strength will lead to recommending the use of lung volume recruitment maneuvers (either by a self-inflating bag or mechanical in-exsufflation)[42] and "respiratory aids," namely assisted cough techniques (either manually or by mechanical in-exsufflation) and noninvasive ventilation. Consensus recommendations on when to use these techniques in patients with DMD are detailed in Box 72.4. While nasal mask ventilation with BiPAP is most often used for nocturnal ventilation, an oral interface with a volume-cycled ventilator is usually the most appropriate device for providing, on demand, daytime assisted ventilation. Many patients with DMD are successfully managed with noninvasive ventilation 24 hours a day.[43] Most experts now reserve tracheostomy for patients who cannot use noninvasive ventilation successfully or prefer tracheostomy, when noninvasive cough assistance techniques are not able to avoid lung aspiration of secretions with repeated $SaO_2$ drops $< 95\%$, or those with multiple failed attempts at extubation after acute respiratory failure despite "optimal" use of mechanical in-exsufflation and noninvasive ventilation.[36] However, of note, a recent retrospective study by one team using hourly mechanical in-exsufflation reported successful extubation to noninvasive ventilation in 97/98 neuromuscular patients who were deemed unweanable by other teams.[44]

### Box 72.4

## Consensus on Respiratory Care in Duchenne Muscular Dystrophy

## Step 1: Volume Recruitment/Deep Lung Inflation Technique

- Volume recruitment/deep lung inflation technique (by self-inflating manual ventilation bag or mechanical in-/ex-sufflation) when FVC < 40% predicted

## Step 2: Manual and Mechanically Assisted Cough Techniques

Necessary when:

- Respiratory infection present and baseline peak cough flow <270 lpm[a]
- Baseline peak cough flow <160 lpm or max expiratory pressure <40 cm water
- Baseline FVC < 40% predicted OR < 1.25 L in older teen/adult

## Step 3: Nocturnal Ventilation[b]

Nocturnal ventilation[c] is indicated in patients who have any of the following:

- Signs or symptoms of hypoventilation (patients with FVC < 30% predicted are at especially high risk)
- A baseline $SpO_2 < 95\%$ and/or blood or end-tidal $pCO_2 > 45$ mm Hg while awake
- An apnea-hypnea index >10/h on polysomnography OR four or more episodes of $SpO_2 < 92\%$ OR drops in $SpO_2$ of at least 4%/h of sleep

## Step 4: Daytime Ventilation

In patients already using nocturnally assisted ventilation, daytime ventilation[d] is indicated for:

- Self-extension of nocturnal ventilation into waking hours
- Abnormal deglutition due to dyspnea, which is relieved by

ventilatory assistance

- Inability to speak a full sentence without breathlessness, and/or
- Symptoms of hypoventilation with baseline $SpO_2 < 95\%$ and/or blood or end-tidal $pCO_2 > 45$ mm Hg while awake.

Continuous noninvasive assisted ventilation (along with mechanically assisted cough) can facilitate endotracheal extubation for patients who were intubated during acute illness or during anesthesia, followed by weaning to nocturnal noninvasive assisted ventilation, if applicable

### Step 5: Tracheostomy

Indications for tracheostomy include:

- Patient and clinician preference[e]
- Patient cannot successfully use noninvasive ventilation
- Inability of the local medical infrastructure to support noninvasive ventilation
- Three failures to achieve extubation during critical illness despite optimal use of noninvasive ventilation and mechanically assisted cough
- The failure of noninvasive methods of cough assistance to prevent aspiration of secretions into the lung and drops in oxygen saturation below 95% or the patient's baseline, necessitating frequent direct tracheal suctioning via tracheostomy

---

[a] All specified threshold values of peak cough flow and maximum expiratory pressure apply to older teenage and adult parents.

[b] Note: Optimally, use of lung volume recruitment and assisted cough techniques should always precede initiation of noninvasive ventilation.

[c] Recommended for nocturnal use: noninvasive ventilation with pressure cycled bi-level devices or volume cycled ventilators or combination volume pressure ventilators. In bi-level or pressure support modes of ventilation, add a back-up rate of breathing. Recommended interfaces include: a nasal mask or a nasal pillow. Other interfaces can be used and each has its own potential benefits.

[d] Recommended for day use: noninvasive ventilation with portable volume cycled or

volume-pressure ventilators; bi-level devices are an alternative. A mouthpiece interface is strongly recommended during day use of portable volume-cycled or volume-pressure ventilators, but other ventilator-interface combinations can be used based on clinician preference and patient comfort.

[e] Note, however, that the panel advocates for the long-term use of noninvasive ventilation up to and including 24 h/day in eligible patients.

---

*Birnkrant DJ, Bushby KM, Amin RS, et al. The respiratory management of patients with Duchenne muscular dystrophy: a DMD care considerations working group specialty article.* Pediatr Pulmonol. *2010;45:739-748.*

Early surgical correction of DMD-related scoliosis is considered the treatment of choice, since spinal bracing is not effective in patients with DMD, and may further reduce vital capacity. Surgery has been recommended in patients with DMD with a progressing Cobb angle of 20 degrees and a vital capacity of at least 40% of predicted values, in an attempt to avoid postoperative respiratory failure. However, several reports have shown that scoliosis surgery can be performed successfully in patients with DMD with very severe respiratory disability (FVC < 30% predicted), with careful preoperative and postoperative care.[45] Of note, a recent Cochrane systematic review was unable to find any randomized, clinical trial assessing the effectiveness of scoliosis surgery in patients with DMD; therefore there are no evidence-based results for more accurately guiding clinical practice.[46]

Obesity is frequent in patients with DMD after loss of ambulation, especially when treated with corticosteroids. Obesity in these patients increases the work of breathing, further compromises chest wall function, and favors obstructive sleep apnea-hypopnea syndrome. All obese patients should undergo a controlled weight reduction program. Conversely, patients with end-stage disease may suffer from severe weight loss with muscle wasting and bedsores, secondary to bulbar weakness (mastication and swallowing difficulties) and an inability to feed themselves. Recommendations on specialized dietary management in patients with DMD have recently been published,[47] as well as an algorithm to manage dysphagia.[48] If necessary, the use of gastrostomy for enteral feeding should be discussed with patients and their families.

## Management of Acute Respiratory Deteriorations.

Respiratory infection is a serious complication in patients with DMD, since muscle weakness impairs both the ability to breathe and to clear airway secretions. Affected children should avoid contact with individuals with respiratory infections, and preventive immunization (influenza, pneumococcal pneumonia) should be performed. During respiratory infections, patients with DMD must increase their use of assisted cough techniques and noninvasive ventilatory support to maintain $SaO_2 \geq 95\%$. Oxygen therapy must be used with great caution and only in conjunction with respiratory aids to avoid masking and aggravating alveolar hypoventilation. Early appropriate antibiotic treatment is recommended when a lower respiratory tract infection is diagnosed by culture or with $SaO_2 < 95\%$. The inability to maintain $SaO_2 \geq 95\%$ in room air is an indication for hospitalization. Again, when endotracheal intubation is necessary, extubation to noninvasive ventilation has been reported to be nearly always successful by using an "aggressive" in-exsufflation device.[44] An action plan for respiratory infections should be given to all patients with DMD with significant respiratory involvement.

When using nocturnal and daytime noninvasive respiratory aids, together with early, aggressive, and adapted management of respiratory infections, patients with DMD can often live beyond 30 years, while usually ensuring an appreciable quality of life. However, even despite preventive treatment including angiotensin-converting enzyme inhibitors with β blockers, intractable cardiac insufficiency claims the life of some patients much earlier, sometimes as early as adolescence.

### Corticosteroid Therapy.

Glucocorticoid treatment has been repeatedly shown to improve the course of DMD. While the cellular and molecular mechanisms of action are largely unknown, recent evidence suggests that in addition to their antiinflammatory effect, glucocorticoids may delay the depletion of muscle progenitor cells.[49] A practice guideline on the use of corticosteroids in patients with DMD has recently been updated by the American Academy of Neurology and endorsed by the American Academy of Pediatrics. Prednisone (0.75 mg/kg per day) or deflazacort (0.9 mg/kg per day) improves strength and pulmonary function and should be offered to patients. Both prednisone and deflazacort are effective in improving motor function, decreasing the need for scoliosis surgery, and delaying the onset of cardiomyopathy. Patients and families must be informed of the potential beneficial effects and adverse events from corticosteroid treatment. Among others, adverse events include increased weight gain (especially with prednisone), cataracts (especially with deflazacort), behavioral changes, and fractures. Over a period of 1 year, a weekly dose of prednisone 10 mg/kg has been shown to be as effective as a daily dose of 0.75 mg/kg. Unfortunately, evidence is still lacking with regard to making recommendations on the age to initiate treatment with corticosteroids, as well as on the duration of treatment.[50]

### Future Perspectives on Duchenne Muscular Dystrophy Treatment.

While DMD still remains an untreatable disease in humans, encouraging results have been obtained nevertheless, and several therapeutic approaches are currently being tested. Early phase clinical trials on a drug to upregulate utrophin, a protein analogous to dystrophin, are ongoing. Mutation-specific therapies have been tested in animal models of DMD for several years, with some currently being tested in clinical trials. In 2014, the European Medicines Agency issued a conditional marketing authorization for the drug Ataluren, which is able to read through premature stop-codon mutations. Clinical trials are also ongoing with antisense oligonucleotides being used to skip an exon close to a deleted gene, bringing the genetic code back into frame and allowing the expression of a functional dystrophin. Despite some encouraging results, substantial work remains to be done before these oligonucleotides can be used to effectively treat patients with DMD. Finally, adenoviral-based gene therapy and stem cell therapy are also under investigation.

## Myotonic Dystrophy

Regular surveillance dictates treatment that is mainly supportive, especially with modification of food consistency and physiotherapy to enhance swallowing, as well as respiratory support as needed.

Sleep-disordered breathing, often present in myotonic dystrophy patients, merits appropriate treatment tailored to obstructive apneas/hypopneas (adenotonsillectomy, continuous positive airway pressure [CPAP]) or central hypoventilation (bilevel positive airway pressure [BiPAP]).

# Disorders Involving the Bony Structure of the Chest Wall

## Pectus Excavatum

Surgical repair of PEx is considered in the presence of exercise limitation or poor self-image responsible for adverse psychological symptoms and decreased quality of life. The Ravitch procedure (costochondral osteotomy) and, more recently, the minimally invasive Nuss procedure (retrosternal placement of a curved metal bar via videoscopy without sternal osteotomy or costal resection) are both in use. Recent reviews comparing the two procedures do not favor one over the other.[7,51] A small improvement in exercise tolerance has been reported after PEx repair.[25,26]

## Kyphoscoliosis

Management of scoliosis depends on the age of the child, the degree of scoliosis, the degree of respiratory impairment, the rate of progression of structural deformities, and the underlying condition that led to the scoliosis (e.g., neuromuscular weakness disorders).

### Adolescent Idiopathic Scoliosis.

Management of adolescent scoliosis should start with early detection before onset of the adolescent growth spurt. In skeletally immature patients with curves of less than 25 degrees, the risk of progression is low and close follow-up may be sufficient. In patients with progressive curves greater than 25 degrees and those that progress, bracing is used first to control spinal curve progression. Bracing efficacy is dependent on the number of hours per day of use with greatest effect when used more than 20 hours/day. However, the Charleston brace is used at nighttime only. Brace therapy continues until spine growth stops.

Uncontrolled curve progression despite orthotic treatment and curves with Cobb angles greater than 50 degrees require spinal fusion with pedicle screw instrumentation to correct for the three-dimensional deformation.[52] In younger adolescents with Cobb angles of less than 30 degrees, a new surgical treatment has been proposed using staples between the vertebrae along the convex side of the scoliotic curve at the apex in order to promote unilateral vertebral growth on the concave side and maintain spinal flexibility. In addition, unilateral vertebral tethers are under study as a less invasive means to control curve progression. Postoperative follow-up of lung function using these newer methods has yet to be reported.

### Juvenile Scoliosis.

Children with nonprogressive spinal curves of less than 20 degrees usually require no additional intervention other than close follow-up, especially at the time of the adolescent growth spurt. Children with a progressive spinal curve should be treated with a brace individualized to minimize further respiratory impairment[53] with selective cut-outs. Those whose curve progression has not stopped or who have spinal curves greater than 40 degrees at the time of diagnosis will likely require surgical treatment. Since 2002, a variety of "growth friendly" and "growth modulating" devices have been developed that are expandable over years of spine growth. Recently, these have been classified according to their effect on the spine and are listed in Box 72.5.[54] These techniques have replaced spine fusion in skeletally immature children in order to maximize potential vertebral, and hence thoracic cage, volumetric growth. Patients with nonprogressive juvenile scoliosis should be followed closely until skeletal maturity is attained.

**Box 72.5**

## Classification of Growth-Friendly Spine Implants for Early-Onset Scoliosis

### Distraction-Based Systems

- Vertical expandable prosthetic titanium ribs (VEPTR)
- Growing rods (spine to spine)
- Hybrid growing rods (spine to ribs)

## Compression-Based Systems

- Vertebral staples
- Vertebral tethers

## Growth Guidance Systems

- Shilla device
- Luque trolley

### Congenital and Infantile Scoliosis.

Both congenital and infantile scoliosis are potentially very serious conditions. Most cases of congenital scoliosis are progressive and do not respond to bracing. Although spine fusion was once considered as first-line therapy, long-term follow-up studies on children fused while growing have demonstrated significant restrictive chest wall disease proportional to the length of spine that was fused and the location of the apex prior to surgery.[55] As with juvenile and infantile idiopathic scoliosis, congenital scoliosis is treated with expandable distraction devices to prevent further spine curvature and preserve lung function. In addition, with fused ribs, an expansion thoracoplasty with rib lysis and separation by means of a vertical expandable titanium prosthetic rib has been approved for use on a case-by-case basis for congenital scoliosis (Fig. 72.6).[9] Growth-friendly distraction devices are placed rib to rib, spine to rib, spine to spine, and pelvis to rib or spine, all meant to distract the spine in the cephalad-caudad direction.[56] Expansion of the devices performed operatively every 6 months increases vertebral height significantly more than expansions on an as-needed basis. Recently, a growth-friendly device that can be advanced noninvasively using a magnetically driven mechanism has been approved for clinical use, dramatically reducing the number of operative expansion procedures for each growing child. Ideal noninvasive rod lengthening intervals have yet to be determined. This device has reduced the cumulative complication rate for repeated surgeries as well. Depending on the duration and amount of growth remaining, each of these devices must be replaced with a larger version after several years. Preliminary results obtained a few years after surgery suggest that this procedure promotes continued spine growth even for abnormal vertebrae, with no increase in curve amplitude. Postoperative studies with serial measurements of vital capacity under anesthesia over 3 years demonstrated an improvement in absolute lung volume but no change or slight loss of lung function expressed as a percentage of predicted norms.[57] Another study of 53 older children undergoing vertical expandable prosthetic titanium rib insertion found no change in vital capacity, but a small increase in residual volume, suggesting that the lung had been stretched as the thorax was expanded.[58] The longest follow-up period for children with scoliosis undergoing growth-friendly device implantation and expansion has been 6 years. Over this longer interval, serial measurements of vital capacity fell by 28% of predicted normal values, suggesting that current surgical treatments do not maintain normal lung growth despite some degree of spine curve correction.[59]

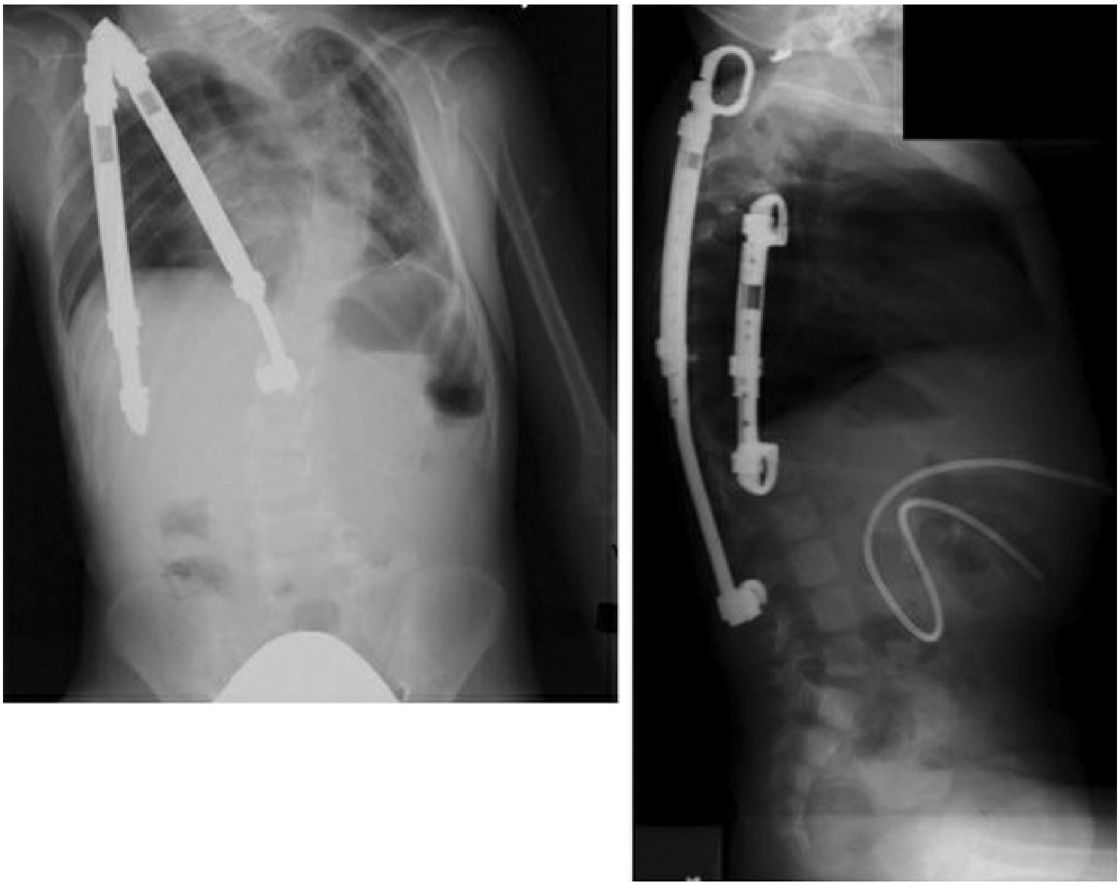

**FIG. 72.6** A pair of vertical expandable titanium prosthetic ribs (VEPTRs) in a child with early onset thoracic scoliosis. The slide mechanism for expansion is located in the middle of each VEPTR. One device is attached from rib to rib (shorter device on the lateral film) and one is attached from ribs to the spine.

Active treatment is mandatory for progressive scoliosis. There is some suggestion that lung function may be better preserved when children undergo nonfusion surgical correction of the scoliosis when they are less than 6 years of age. However, to reduce surgical complications, several spine centers resort to serial casting in children less than 5 years of age, followed by surgical intervention in those who do not improve. The effect of serial casting on pulmonary function over time has not been reported. The surgical strategy for an individual child is developed on a case-by-case basis, and varies among spine centers according to local experience and expertise. Preoperative halo traction has been used to minimize the severity of the spine curvature prior to surgery, particularly when the spine is flexible.

## Spine Deformities in Neuromuscular Diseases.

The issues in patients with neuromuscular diseases are more complex (severity of deformity, pelvic obliquity, associated nutritional, neurological, and cardiopulmonary problems). Although surgery provides significant benefit with regard to quality of life, the consequences on long-term pulmonary function depend on the underlying disease and the nature of the spine deformity. New surgical devices are now being proposed to improve the severe lordosis that occurs in children with spina bifida. Of note, early treatment with corticosteroids largely prevents scoliosis development in patients with DMD.

## Postoperative Pulmonary Function in Scoliosis.

Pulmonary complications are a principal cause of morbidity and mortality in the immediate period following surgery for scoliosis. Therefore preoperative assessment of pulmonary function, including overnight oximetry and the assessment of hypercapnia, should be performed as a guide to prevent and treat postoperative complications. Children with skeletal dysplasia and those with cervical vertebral involvement often have upper airway obstruction and pose intubation challenges at the time of surgery. The most frequent respiratory problems reported in the immediate postoperative course of surgery for scoliosis include atelectasis, pneumonia, pulmonary edema, pulmonary fat emboli, and respiratory failure. Immediate pulmonary complications result from multiple factors such as the surgical procedure itself, the degree of preoperative pulmonary disability, the intraoperative fluid management, the transient limitation of chest wall expansion as a result of pain, and the effects of anesthetics and analgesics. In neuromuscular diseases, respiratory muscle weakness, cough impairment, and swallowing disorders increase the risk of immediate postoperative pulmonary complications. Children with adolescent idiopathic scoliosis whose vital capacities are less than 40% predicted have a three-fold increase in pulmonary complication rate following spine fusion compared to those with better preoperative lung function.[60] Children with underlying neuromuscular weakness who undergo spine fusion have longer postoperative hospitalizations than children with other conditions.

Noninvasive ventilation and mechanical in-exsufflation devices can be of invaluable help in patients with and without neuromuscular weakness in the immediate postoperative period.

Spine fusion reduces the spinal curvature, but improvements in lung volume and arterial oxygenation only become apparent late after surgery. The decrease in vital capacity usually lasts for 6 weeks to 3 months after fusion but can persist for up to 1 year. By 1–2 years after spine fusion, vital capacity returns to preoperative values. Combined anterior fusion and posterior spine fusion is more likely than posterior fusion alone to impair lung function postoperatively for longer periods; the combined fusion approach also reduces the likelihood of further scoliosis postoperatively. Patients with severe scoliosis and marginal lung function who undergo fusion may require outpatient BiPAP support indefinitely following surgery.

## Management of Hypoplastic Thorax Syndromes

The recent development of expandable titanium devices has led to novel interventions with short-term respiratory improvements over several years, although the long-term outlook—even with these new surgical interventions—remains unclear.

### Asphyxiating Thoracic Dystrophy.

Several surgical procedures have been proposed and used clinically to increase thoracic cage size. These include the interposition of adjacent ribs with titanium connectors to make the existing ribs longer. Alternatively, customized curved VEPTR expandable devices have been used in conjunction with osteotomies of the ribs to enlarge the thoracic cavity. The latter can then be regularly expanded to increase the thorax as the child grows. Lung functions have not been reported following these surgical treatments, although mortality has been reduced to 50% in the first year of life in uncontrolled case series.[61]

### Jarcho-Levin Syndrome.

Children with Jarcho-Levin syndrome have received growth-friendly spine distraction devices to further increase thoracic height and width, although lung function following surgical interventions has not been reported.

# Disorders of the Respiratory Tract Caused by Trauma

*Chad M. Thorson MD, MSPH, Matias Bruzoni MD, FACS*

## General Considerations

Traumatic thoracic injury in infants and children is uncommon; it is usually secondary to blunt mechanisms and is often managed nonoperatively. Penetrating injuries, such as stab and gunshot wounds are, fortunately, rare, but they usually require some sort of operative intervention, and result in increased morbidity and mortality.[1–5]

More than 75% of pediatric blunt chest trauma is due to automobile accidents, with the remainder resulting from sports injuries, nonaccidental trauma, and falls from heights.[6] Children involved in automobile accidents tend to be pedestrians rather than occupants of vehicles. The complete spectrum of chest trauma includes pneumothorax, hemothorax, destruction of the integrity of the chest wall and diaphragm, thoracic visceral damage, and combined thoracoabdominal injuries. The mortality rate from thoracic trauma has been reported to be approximately 26%, and can be as high as 33% when penetrating injuries are involved.[3,7,8] Overall, recent literature suggests that the mortality rate for childhood thoracic trauma has decreased.[9] Thoracic trauma is frequently associated with head, abdominal, and spine trauma, making the mortality rate higher in this combined scenario.

Pediatric deaths may occur in the prehospital setting and are usually secondary to hemorrhagic shock or cardiopulmonary arrest related to a tension pneumothorax or cardiac tamponade. The mortality and morbidity rate can be improved if the patient is transferred to a tertiary level pediatric trauma center and managed within “the golden hour” described by the Advanced Trauma Life Support (ATLS) guidelines.

Most blunt thoracic injuries in children can be managed without operative intervention. This often involves significant respiratory support, including analgesia, assisted ventilation, and aggressive physiotherapy. As in adults, the significance of thoracic trauma results from the concomitant pulmonary, cardiac, and systemic dysfunction that follows. In the pediatric age group, because of chest wall plasticity, profound physiologic aberrations can occur in the absence of fractures. Respiratory and circulatory dysfunction secondary to chest injury is frequently complicated by blood loss and hypotension. Hypotension from hemorrhage can usually be managed through volume replacement; algorithmic therapy is monitored and refined by serial determination of blood pressures, hematocrit, central venous pressure, blood gases, and, if necessary, blood volume. Restoration of the normal cardiopulmonary function fundamentally depends on a clean airway, intact chest and diaphragm, and unrestricted cardiopulmonary dynamics. The primary and secondary surveys recommended by the ATLS guidelines are mandatory in pediatric trauma as well. If the patient is hemodynamically stable with a significant mechanism of injury, computed tomography (CT) of the chest should be considered to search for undetected injuries if felt that they would alter the clinical approach. Otherwise, chest radiography is typically adequate and avoids the radiation risk.[10]

The long-term outcome of thoracic trauma in children has not been well studied. A single European study addressed the 5-year outcome of thoracic trauma in children; they concluded that most injuries resolve without significant late sequelae.[11]

# Features of the Pediatric Thorax

The thorax of a child is different from that of an adult from both an anatomic and a physiologic point of view. The pediatric chest is typically more rounded with less developed musculature. This characteristic, together with a more flexible and elastic rib cage, results in a very compliant chest. The ribs and sternum of a child can thus support a significant amount of blunt force without fracture. Deformability is such that the anterior and posterior curvatures of the ribs can contact each other without fracture. Therefore, blunt injury to the chest presents a diagnostic challenge since obvious external signs of injury may be minor, chest radiographs may be normal, and yet the visceral structures may still have sustained serious injury.

Additionally, the mediastinum is relatively mobile and thus less susceptible to the rapid acceleration and deceleration forces commonly experienced in blunt trauma. Increased mediastinal mobility, together with the absence of preexisting vascular disease in children, make injuries to the mediastinum and great vessels less frequent than in adults. On the other hand, conditions such as tension pneumothorax or hemothorax are very poorly tolerated and must be recognized and addressed emergently.

Physiological compensation to trauma is different in children when compared with adults; the cardiovascular and pulmonary reserves are much less in children. Tachycardia may be the only compensatory mechanism in children who present with hypovolemic shock, even with 30% loss of estimated blood volume. Hypotension will only occur in the very late stage, just before cardiac arrest. The pulmonary reserve can be seriously affected by massive gastric distention, a very common finding in pediatric trauma. Prompt insertion of a nasogastric tube is recommended since many children will develop gastric distention due to aerophagia following any type of trauma.

# Sternal Fractures

Fractures of the sternum in infancy and childhood follow high-compression crush injuries and are usually associated with other thoracic and orthopedic injuries. Interestingly, one series has reported sternal fractures as the result of surprisingly minor trauma. The most common injury identified in this report was an isolated anterior cortical fracture.[12]

On physical examination, there is local tenderness, ecchymosis, and sometimes a concavity or paradoxical respiratory movement. The sternal segments are typically well aligned without much displacement. Dyspnea, cyanosis, arrhythmias (most commonly sinus tachycardia), and hypotension may be evidence of an underlying cardiac contusion. Radiographic demonstration of fractures is most commonly by chest x-ray or CT scan, although ultrasound is being used more frequently with high sensitivity/specificity.[13]

Children with traumatic injury of the sternum should be admitted to the intensive care unit given the increased risk for arrhythmias. Cardiac tamponade and blunt myocardial damage must be ruled out by various studies, including serial electrocardiography, echocardiography, and careful monitoring of vital signs. Although cardiac enzymes were once used as a screening tool, their use has been abandoned due to low sensitivity and specificity.[14]

If the bony deformity is minimal, there is no specific treatment indicated. Markedly displaced fragments are reduced under general anesthesia by a closed or open technique in order to prevent a traumatic pectus excavatum. Violent paradoxical respirations can be controlled by assisted mechanical respiration through an endotracheal tube, or rarely by operative fixation of rib fragments.

## Rib Fractures and Flail Chest

Rib fractures are unusual in children because of the extreme flexibility of the osseous and cartilaginous framework of the thorax. The upper ribs are protected by the scapula and related muscles, and the lower ones are quite resilient. As such, rib fractures are present in only about 3% of all children admitted with thoracic injury.[15] Predictably, children with more than one rib fracture are more likely to have sustained multisystem trauma; crush and direct-blow injuries are the usual etiologic factors.[16] Multiple fractures of the middle ribs are almost diagnostic of nonaccidental trauma.

Multiple rib fractures resulting in the destruction of the integrity of the thoracic skeleton can cause the paradoxical motion of the "flail chest" (Fig. 73.1). The unsupported area of the chest moves inward with inspiration and outward with expiration; these paradoxical respiratory excursions inexorably lead to dyspnea (Fig. 73.2). The explosive expiration of coughing is dissipated and made ineffectual by the paradoxical movement and intercostal pain. In effect, the ideal preparation for acute respiratory distress syndrome—airway obstruction, atelectasis, and pneumonia—has been established.

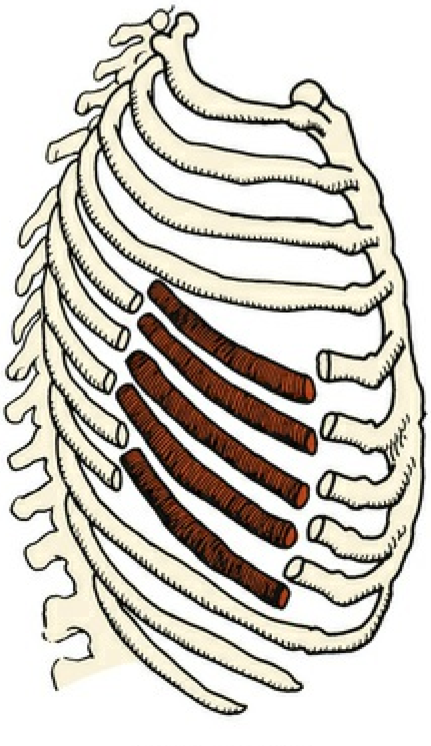

**FIG. 73.1** An illustration of five ribs broken in two places, with loss of chest wall stability and resultant paradoxical or "flail chest" wall.

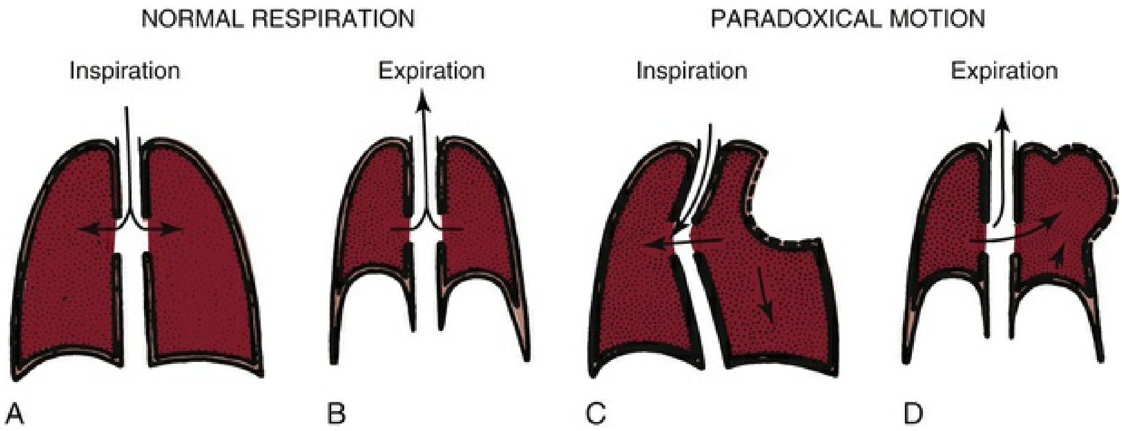

**FIG. 73.2** (A–D) A diagram of the action of a normal chest compared with that of a "flail chest" during phases of the respiratory cycle.

The clinical picture includes local pain that is aggravated by motion. Tenderness is elicited by pressure applied directly over the fracture or elsewhere on the same rib. The fracture site may be edematous and ecchymotic. The clinical manifestations may range from these minimal findings with simple, restricted fractures to severe ventilatory distress with underlying lung injury. Chest radiographs demonstrate the extent and displacement of the fractures and hint at underlying visceral damage.

The treatment of uncomplicated fractures requires pain control to allow unrestricted respiration. With severe fractures, the alleviation of pain and the restoration of cough are important and can be provided by analgesics, physiotherapy, and intermittent positive-pressure breathing. Thoracostomy tubes should be inserted promptly for pneumothorax and hemothorax, and shock should be managed by appropriate resuscitation. There are a few small studies to suggest that surgical fixation results in a reduction in pneumonia, chest deformity, tracheostomy, duration of mechanical ventilation, and length of intensive care unit (ICU) stay.[17]

Paradoxical respiratory excursions with flail chest must be promptly brought under control, sometimes requiring mechanical positive pressure ventilation to help prevent respiratory distress syndrome. In some cases, a thoracic epidural anesthetic may be useful to provide appropriate analgesia and achieve effective ventilation. Although not routinely used, surgical stabilization in severe flail chest has been shown to lower the incidence of pneumonia, shorten the ICU stay, reduce ventilatory requirement, and reduce overall hospital cost.[18,19]

## Tracheostomy in Chest Wall Injury

Controlled mechanical ventilation is an essential component for respiratory insufficiency in the setting of thoracic trauma. Despite vigorous therapy, secretions may be troublesome, and are managed using intermittent tracheal suctioning or bronchoscopy. There is evidence that tracheostomy in children can be avoided by long-term intubation in many cases.[20,21] However, prolonged intubation has become the most important indication for tracheostomy, since it allows an avenue for the control of secretions, diminishes ventilatory dead space, and obtains control of an obstructed airway (Fig. 73.3).

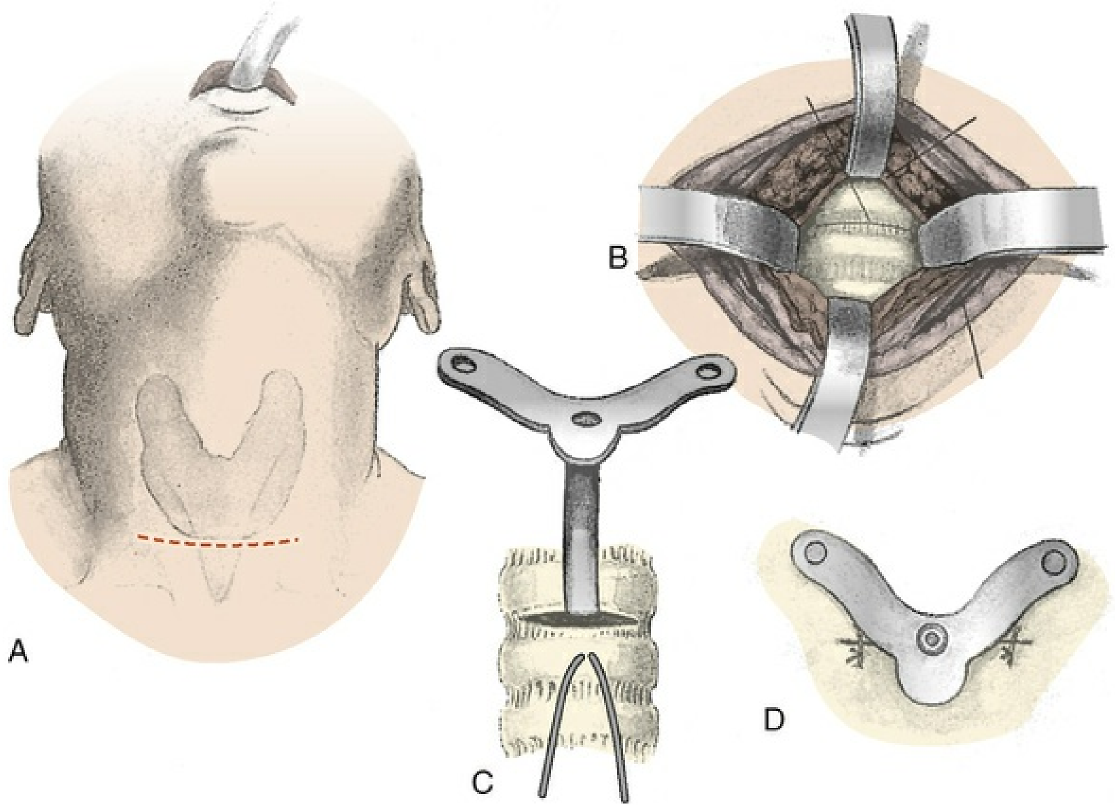

**FIG. 73.3** Techniques of tracheostomy performed over an oral endotracheal tube. Note the transverse skin incision (A) and the suture on the lower tracheal flaps to facilitate subsequent tube changes (C). (B) The anatomy of the area. (D) The tube in place.

During the first year of life, tracheostomy is a particularly morbid operation.[20] Common complications are pneumomediastinum, pneumothorax, tracheal stenosis, and tracheomalacia. Secretions may be difficult to aspirate, as the small tracheostomy tube easily becomes plugged. Distal infection, often with staphylococci, is poorly handled by such young patients. In addition, withdrawal of the tracheostomy tube is a precarious and unpredictable endeavor. Nevertheless, even in this age group, tracheostomy can be lifesaving in specific instances of chest trauma.

The decision for tracheostomy in cases of chest injury can often be made if there is (1) a mechanically obstructed airway that cannot be managed more conservatively, (2) flail chest, or (3) prolonged endotracheal intubation. Unstable, paradoxical chest wall movement can be controlled for long periods by assisted positive pressure respiration through a short, uncuffed Silastic tracheostomy tube.

## Traumatic Pneumothorax

Pneumothorax is one of the most common consequences of thoracic trauma and is identified in approximately 12%–50% of chest trauma patients admitted to hospital.[7] Pneumothorax is potentially fatal and requires specific maneuvers to prevent or reverse a malignant chain of events.

The creation of a tension pneumothorax requires a valvular mechanism through which the amount of air entering the pleural space exceeds the amount escaping it. The positive intrapleural pressure is initially dissipated by a mediastinal shift, which compresses the opposite lung and can result in ipsilateral pulmonary collapse and angulation of the great vessels entering and leaving the heart. Intrapleural tension can be increased by traumatic hemothorax, and respiratory exchange and cardiac output are thus critically diminished.

The etiologic possibilities, in addition to chest wall and lung trauma, include rupture of the esophagus, pulmonary cyst, emphysematous lobe, and postoperative bronchial fistula. These latter sources of tension pneumothorax almost always require thoracotomy for control.

The clinical findings may include external evidence of a wound, tachypnea, dyspnea, cyanosis with hyperresonance, the absence or transmission of breath sounds, and displacement of the trachea and apical cardiac impulse. The hemithoraces may be asymmetric, with the involved side appearing larger and hyperresonant.

A confirmatory radiograph is comforting but often cannot be afforded in this thoracic emergency. Chest tube insertion is indicated for a tension pneumothorax or simple pneumothorax associated with respiratory distress or shock. Prompt relief and pulmonary expansion can be anticipated if the source of the intrapleural air has been controlled. A traumatic valvular defect in the chest wall can be occluded. If the pulmonary air leak persists or recurs, the possibility of tension pneumothorax is circumvented by the insertion of one or more intercostal tubes connected to water-seal drainage with low-pressure suction. Most instances of traumatic tension pneumothorax require tube drainage for permanent decompression, although needle aspiration is indispensable for emergency management. Stubborn bronchopleural fistulas that continue to remain widely patent despite adequate intercostal tube drainage may need thoracotomy and repair or resection of the affected lung segment.

An open pneumothorax (“sucking” chest wound) in which atmospheric air has direct, unimpeded entrance into and exit from the pleural space is a second, equally urgent, thoracic emergency. This pathology is almost always due to a large traumatic wound. Ingress of air during inspiration and egress during expiration produce an extreme degree of paradoxical respiration and mediastinal flutter, which is partially regulated by the size of the chest wall defect in comparison with the circumference of the trachea. If a considerable segment of chest wall is open, more air is exchanged at this site than through the trachea, because the pressures are similar. Inspiration collapses the ipsilateral lung and drives its alveolar air into the opposite side. During expiration, the air returns across the carina. In addition, the mediastinum becomes a widely swinging pendulum compressing the uninjured lung on inspiration and the lung on the injured side during expiration (Fig. 73.4). Obviously, under these circumstances, little effective ventilation is taking place because of the tremendous increase in the pulmonary dead space and the decrease in tidal volumes. A totally ineffective cough completes the clinical picture. The diagnosis is readily made by inspection of the thoracic wound and the peculiar sound of air rushing in and coming out of the wound.

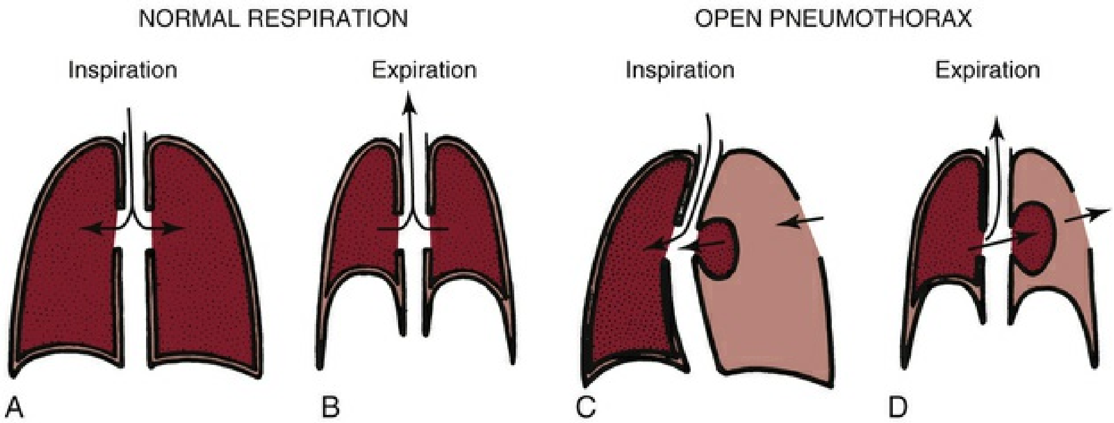

**FIG. 73.4** (A–D) Changes in the normal respiratory pattern brought about by an open, sucking thoracic wall injury.

Emergency management of this critical situation includes prompt occlusion of the chest wall defect by sterile dressings (Fig. 73.5) and measures to prevent conversion of this open pneumothorax into an equally threatening tension pneumothorax, which can occur if the underlying visceral pleura has been injured. Pleural decompression by closed intercostal tube drainage is essential. When immediate chest tube is not available (i.e., in the prehospital setting), closure of the wound with an occlusive dressing sealed on three sides is appropriate. This acts as a one-way valve allowing air to escape from the pleural space on expiration but sealing and preventing further air entry on inspiration. After systemic stabilization, more formal surgical débridement, reconstruction, and closure of the chest wound can be done in the operating room.

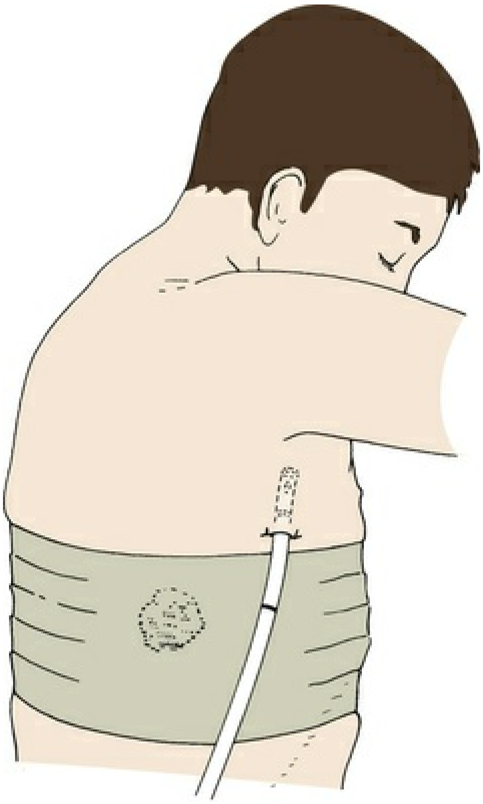

**FIG. 73.5** A temporary occlusive chest wall dressing applied to a sucking wound with underwater intercostal chest tube drainage. Once the period of emergency is over, operative debridement and closure of the chest wound is necessary.

## Hemothorax

Blood in the pleural cavity is perhaps the most common sequel of thoracic trauma, regardless of type. Depending on the speed of the hemorrhage, it can be life threatening. Bleeding sources are abundant, with either systemic (high pressure) or pulmonary (low pressure) sources. Systemic bleeding usually originates in the chest wall from the intercostal vessels. Hemorrhage from pulmonary vessels is usually self-limiting unless major tributaries have been transected. It is important to note that a child can accumulate about 40% of his/her blood volume in the chest.

The immediate findings are those of blood loss compounded by respiratory distress. The trachea and apical impulse may be dislocated, the percussion note is flat, and the breath sounds are indistinct. The actual diagnosis is confirmed by thoracentesis if time allows after adequate radiographic studies.

Management of hemothorax is accomplished by total evacuation of air and blood with a large-bore chest tube. Most often, the evacuation of blood will obliterate the pleural space, and pleural apposition will tamponade parenchymal bleeding. Small-volume hemothorax may be safely observed as long as cardiorespiratory mechanics are not altered.[22] A simple formula to define the need for urgent thoracotomy is a bloody chest tube output of more than 1 mL/kg per minute with associated hemodynamic instability despite rigorous resuscitation. The surgeon's common sense is crucial in this setting, and if one suspects either persistent or voluminous bleeding, an operation should be performed.

Clotting, loculation, and infection may supervene despite vigorous initial therapy. A retained hemothorax can eventually result in empyema. Publications from the adult literature support early thoracoscopy and drainage of the retained hemothorax in order to avoid late infections.[23] As with management of parapneumonic effusions, use of thrombolytics (tissue plasminogen activator [tPA]) is well established to assist with clot dissolution.[24] Unevacuated intrapleural blood eventually clots and can become organized fibrous tissue (fibrothorax). With the development of a fibrothorax, the lung becomes incarcerated and the chest wall is immobilized, chronically altering cardiorespiratory dynamics. Empyema from secondary contamination is always a threat when the pleural space is filled with blood. Patients rarely eventually require thoracotomy and decortication.

## Tracheobronchial Trauma

Rupture of the trachea or bronchus in infants and children is usually preceded by a sharp blow to the anterior part of the neck (clothes-line injury), by penetrating injuries, or severe compression injury of the chest against a closed glottis.[25,26] These injuries represent a diagnostic and therapeutic challenge. Discontinuity of a major airway is characterized by intrathoracic tension phenomena. When the leak is massive, unilateral or even bilateral pneumothorax is present compromising not only the respiratory function, but also cardiac venous return.

Proximal upper airway lesions often present with pneumomediastinum and subcutaneous emphysema, followed by bilateral pneumothorax. This is due to the intramediastinal location of the trachea, directing any air leak to this space, which is in continuity with the neck compartments. When the distal airway is involved, the air leak opens easily into the pleural space causing tension pneumothorax and a persistent air leak. Hemoptysis may also be present.

Conventional chest radiographs may show pneumomediastinum, pneumothorax, and subcutaneous emphysema. Air tracheobronchogram can suggest the diagnosis in the presence of a compatible clinical picture. Spiral CT of the thorax and the neck may allow better visualization of complete or major disruptions, but bronchoscopic demonstration of the rupture is diagnostic.[27–29] The diagnosis may not be suspected in the acute phase of smaller bronchial transections, but becomes obvious when late stricture with distal atelectasis and chronic pneumonitis is related retrospectively to a history of fairly severe chest trauma.

The initial management of bronchial rupture consists of maintenance of a patent airway and decompression of the pleura and mediastinum by thoracostomy tubes connected to closed drainage with suction. Occasionally, multiple tubes may be necessary for control of the associated air leak. Tracheobronchial transection with massive air leak resulting in the inability to ventilate is the rare indication to clamp a thoracostomy tube. This should be followed by emergent, expeditious transport to the operating room for bronchoscopy and immediate repair of the defect, as this maneuver may result in tension pneumothorax. Operative repair requires thoracotomy, usually primary repair, and reinforcement with a pleural or muscular flap.[25]

Surgery remains the mainstay of treatment for posttraumatic lesions of the airway. Small iatrogenic injuries related to placement of an endotracheal tube may heal with conservative management. Additionally, small traumatic injuries confirmed by bronchoscopy without signs of sepsis, evidence of major connection with the mediastinal space, or associated esophageal injuries may be amenable to nonsurgical treatment.[30] Severe lacerations of the trachea can be immeasurably helped by bypassing the glottis with an artificial airway during the acute phase while preparing the patient for emergency tracheal repair. Smaller tears may heal spontaneously with tracheostomy alone; others result in stricture and require selective operative repair.

## Pulmonary Compression Injury (Traumatic Asphyxia)

Explosive blasts compress a child's flexible ribs, sternum, and cartilages against the lungs with a sudden, violent increase in intraalveolar pressure. These injuries are associated not only with pulmonary, but also with hepatic and cardiac contusions.[31] Alveolar disruption, interstitial emphysema, and pneumothorax may follow if the glottis is closed when the compression occurs. Distribution of this force to the great veins of the mediastinum and jugular system leads to venous distention. Extravasation of blood, purplish edema of the head, neck, and upper extremities, and possible central nervous system changes due to intracerebral edema and petechial hemorrhages may also occur with traumatic asphyxia. The pulmonary contusion is represented pathologically by edema, hemorrhage, and atelectasis.

Clinically, there may be dyspnea, cough, chest pain, hemoptysis, hypoxia, hypercarbia, and mental confusion. The face and the neck can be grotesquely swollen, with crepitus and submucosal/subconjunctival hemorrhage. There is no need for evidence of external trauma or fractured ribs in a child, and accordingly, the indication for chest radiograph is merely the possible history of a blast, acceleration (fall), or deceleration (automobile) injury. Pulmonary contusions, hemothorax, pneumothorax, and pneumomediastinum may all be encountered.[32]

There is a high risk of airway compromise associated with these types of injuries; therefore, rapid establishment of a definitive airway is vital. With mild injuries, the subcutaneous emphysema and purplish hue gradually and spontaneously disappear over several days. Patients with more serious blast injuries are initially treated for anoxia and hypotension, and attention is then directed to atelectasis, pulmonary edema, and pleural complications. Rapid progression of the mediastinal and subcutaneous emphysema indicates a serious disruption of the trachea, bronchi, or lungs, and may require intercostal tube drainage or even thoracotomy.[32]

## Posttraumatic Atelectasis

With pulmonary contusion from any source, the production of tracheobronchial secretions is stimulated, but elimination may be simultaneously impeded by airway obstruction, pain, and depression of cough. The addition of hemorrhage to these accumulated secretions produce atelectasis in the damaged lung and inevitable infection—a syndrome aptly called "wet lung."[33] The clinical findings are dyspnea and cyanosis, an incessant, unproductive cough with wheezing and audible rattling, and gross rhonchi or rales. Chest radiographs show varying degrees of unilateral and bilateral atelectasis.

The syndrome demands vigorous treatment—frequent postural changes, insistence on coughing, humidified oxygen, antibiotics, mechanical ventilation, diuretics, and cautious hydration are all useful. If a child with chest trauma will not cough, tracheal suctioning is instituted. Failure of this step should be followed in quick succession by endotracheal tube insertion or tracheostomy.

The adult respiratory distress syndrome (ARDS) that occurs after critical illness with congestion, edema, hemorrhage, pneumonia, and pulmonary fibrosis is rarely encountered in pediatric practice (see Chapter 38). It is often a related sequel to an infectious process and severe hypotension. The mortality rate for pediatric ARDS is between 22% and 35%.[34]

## Cardiac Trauma

Though rare, cardiac wounds should be suspected after penetration of any part of the chest, the lower part of the neck, or the upper part of the abdomen. The possibility of injury to the heart also exists in the presence of blunt trauma to the anterior hemithorax, laceration from fractured sternum or ribs, or severe compression between the sternum and the vertebral column. The most common mechanism is blunt trauma, which is most often sustained by adolescent patients in motor vehicle collisions.[35]

The spectrum of blunt cardiac injury ranges from myocardial contusion to anatomic disruption, such as valve dysfunction or myocardial rupture. The clinical manifestations of a myocardial contusion are arrhythmia, hypotension and, in severe cases, aneurysms from myocardial wall weakness. Blood loss with perforation varies from exsanguination, to cardiac tamponade, to minimal bleeding. Tamponade usually follows trauma to the myocardium when both pleura are intact; the hemopericardium cannot decompress. The resulting increase in intrapericardial pressure constricts the heart and great veins, and venous return and cardiac output are critically impaired. By contrast, delayed diagnosis of myocardial injury may occur in the presence of a left-sided hemothorax, as the blood preferentially decompresses into the left chest without the development of tamponade.[36]

The physical findings with acute tamponade are often archetypal. The veins of the neck and upper extremity may be distended. The heart sounds are distant and perhaps inaudible. The systolic pressure is depressed, the pulse pressure is narrow, and the venous pressure is elevated. However, the classic symptoms of distended neck veins, a raised central venous pressure, and pulsus paradoxus are not often evident in children with tamponade. The diagnosis is confirmed during the Focused Assessment with Sonography in Trauma (FAST) exam or with formal echocardiogram. As stated before in the sternal trauma section, there is no utility in serial cardiac enzyme measurements, although the degree of elevation may indicate increasing severity of the injury.[14,37]

Cardiac tamponade is imminently life threatening and requires emergent intervention. With a suggestive clinical picture, emergency needle aspiration of the pericardial sac through a subxiphoid approach should be performed in addition to systemic resuscitation while the operating room is being prepared. Aspiration of small amounts of blood can restore cardiopulmonary dynamics (Fig. 73.6). If an immediate adjacent operating room is available, a subxiphoid pericardial window can also be diagnostic and therapeutic.[38]

**FIG. 73.6** (A and B) A traumatic cardiac tamponade relieved by an open thoracotomy 5 days following trauma and after two partially relieving pericardiocenteses.

Blunt trauma can produce various degrees of myocardial contusions ranging from a small area of edema to a ruptured chamber. The chest pain and tachycardia may be difficult to evaluate without evidence of cardiac failure. Serial electrocardiograms are recommended to monitor these patients. In cases where persistent arrhythmias or hypotension occur, an echocardiogram should be obtained for further work-up.[39] Physicians attending to an acutely injured child must be prepared to institute prompt external cardiac massage (Fig. 73.7), internal cardiac massage (Figs. 73.8 and 73.9), or cardiac defibrillation (Fig. 73.10).

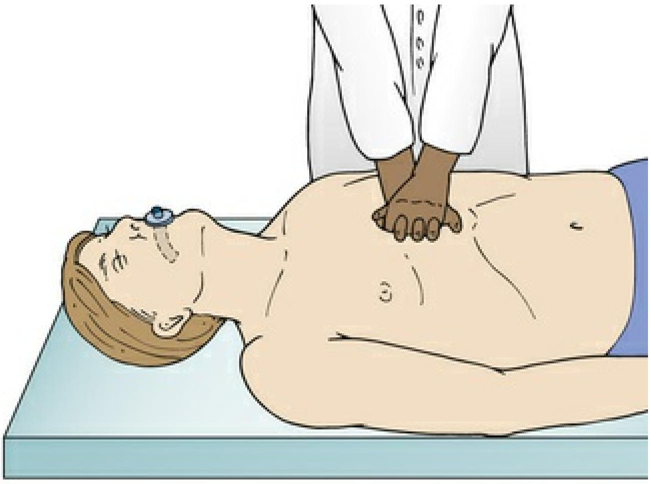

**FIG. 73.7** External cardiac massage: rhythmic compression of the chest and heart in an effort to restore and maintain circulation after cardiac arrest.

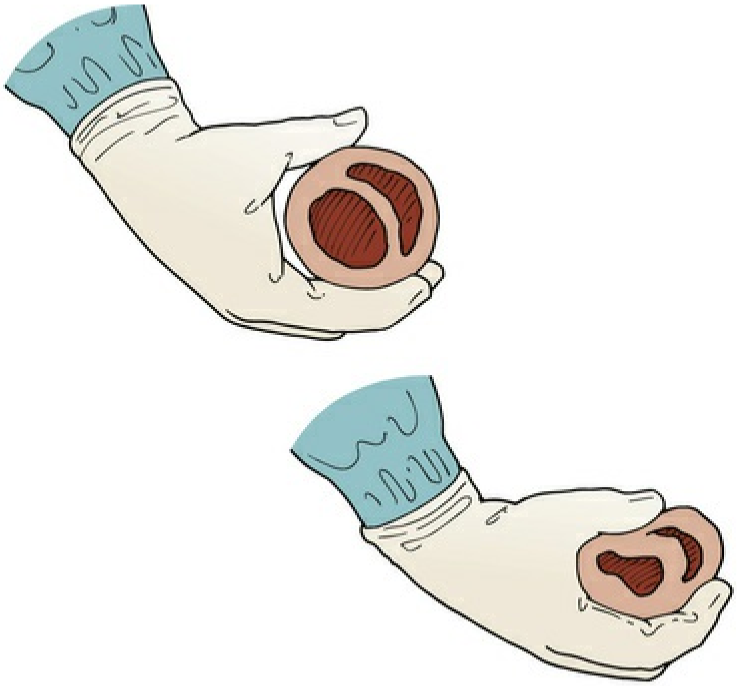

**FIG. 73.8** Internal cardiac massage: one-handed technique for neonates and infants.

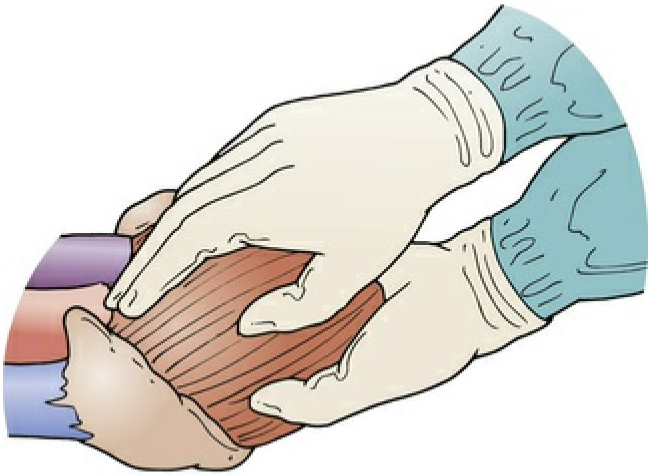

**FIG. 73.9** Internal cardiac massage: bimanual technique for older children and adults.

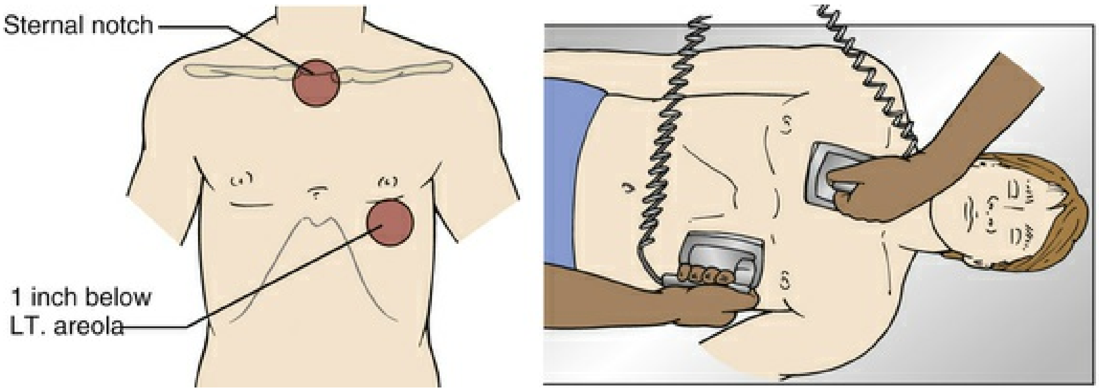

**FIG. 73.10** Electrode application for external cardiac defibrillation.

Penetrating trauma may injure myocardial chambers or coronary arteries, and may require closure of the myocardial chambers or even coronary revascularization. In patients presenting *in extremis,* resuscitative thoracotomy in the emergency department may be lifesaving, with reported results similar to adult literature (survival ~10% in penetrating trauma).[40]

## Traumatic Rupture of the Thoracic Aorta

Thoracic aorta rupture is very uncommon. In a series published at Children's National Medical Center in Washington DC, only 0.14% of the pediatric traumas treated over a period of 6 years presented with thoracic aorta injuries.[41] Aortic transection typically occurs at the level of the ligamentum arteriosum, near the take-off of the left subclavian artery, and usually results from strong deceleration forces. Mediastinal widening on routine chest radiography with a distorted aortic contour is the most significant initial diagnostic study. Even though thoracic aortography is the procedure of choice in hemodynamically stable patients, CT angiogram is becoming widely accepted in many trauma centers as the gold standard.[42] Many injuries of this type are associated with life-threatening injuries in other organs such as the abdomen and head. Treatment consists of aortic repair, usually requiring cardiopulmonary bypass, although endovascular techniques are showing promising results in both the adult and pediatric populations.[43,44] There are case reports and some small series in children with good short-term outcomes.[44–47] Long-term results of this approach are not yet available.

## Injuries to the Esophagus

Esophageal injury is more commonly associated with penetrating trauma. In this scenario, the cervical esophagus is commonly injured, and is usually associated with upper airway or vascular injuries. Blunt abdominal trauma or violent, forceful vomiting, may cause a sudden increase in gastric pressure, and thus create a tear in the wall of the distal esophagus. However, the most common cause of esophageal injury is iatrogenic during instrumentation of the esophagus, such as that seen in dilatations for esophageal strictures, or during endoscopic removal of foreign bodies. Esophageal rupture can also follow the ingestion of caustic agents. Perforation of the esophagus in the pediatric age group can also occur in the delivery room from extreme positive pressure resuscitation or aspiration with a stiff catheter. Finally, spontaneous rupture proximal to an esophageal web has been described.

Clinically, fever, hypotension, and chest and neck pain reflect the presence of mediastinitis. Pneumomediastinum, tension pneumothorax, subcutaneous emphysema, and hematemesis may be encountered.

Plain chest radiographs followed by a contrast esophagram will usually demonstrate the esophageal defect. Sometimes, CT of the chest with a water-soluble, oral contrast study will help in the diagnosis as well as localize the site and size of the leak.

The fundamental principles of management in esophageal perforation include adequate pleural space drainage, intravenous antibiotics, and maintenance of adequate nutrition.[48] The operative therapy varies with the cause, the location of the perforation, and the time interval between the perforation and presentation. Many surgical maneuvers have been described. Given its anatomic location, the mid esophagus is approached via the right chest, whereas the lower esophagus is approached via the left chest. Thoracic esophageal perforation that is recognized early (<48 hours) can be treated with primary repair and muscle or pleural flap reinforcement. If the tissues are very inflamed and cannot hold sutures, resection with proximal diversion and staged reconstruction is recommended. Alternatively, placement of an esophageal T-tube to create a controlled fistula is a viable option and avoids the high morbidity of resection and diversion.[49]

Modern technology and improvements in thoracoscopic and endoscopic techniques have allowed minimally invasive approaches to these lesions. Primary thoracoscopic repair and placement of esophageal stents or endoscopic clipping have been described with good short-term outcomes.[50,51] Cervical perforations can usually be managed with drainage alone since they are more likely to be contained by the surrounding tissues. Stable patients with thoracic esophageal perforations who present several days after the perforation took place can be managed nonoperatively. This includes cessation of oral intake, broad-spectrum antibiotics, and parenteral nutritional support. The overall health status of the patient, the extent of associated injuries, and the underlying esophageal pathologic findings are the critical determinants of successful therapy.

## Traumatic Blunt Rupture of the Diaphragm

Traumatic injury of the diaphragm is often due to penetrating thoracic or abdominal trauma; however, severe thoracic blunt force can also result in rupture. It is much more common on the left (90%). Suggested explanations for this phenomenon include an increased strength of the right hemidiaphragm, the presence of the liver, and a weakness of the left hemidiaphragm at points of embryonic fusion.[52] Most of these injuries are small and will not declare themselves until later during the hospital course. The initial clinical presentation is very nonspecific. Significant cardiorespiratory dysfunction may complicate the early stages. Many significant injuries in other organ systems may confuse the early diagnosis. If the rupture is not initially diagnosed, intestinal obstruction may be the leading symptom at the time of late diagnosis.

The most significant study to arouse suspicion is routine chest radiography, which will frequently show an abnormal diaphragmatic contour (Fig. 73.11). Placement of a nasogastric tube can sometimes show gastric herniation into the chest. Initially, the herniation may not be present or suspected. Serial radiographs are important to determine later herniation. A contrast swallow of Gastrografin or thin barium will help confirm the presence of stomach or intestine in the hemithorax. CT can be helpful in the diagnosis, but the sensitivity and specificity are low for small diaphragmatic injuries.[53,54] While magnetic resonance imaging (MRI) shows exquisite detail of most of the diaphragm, it is not recommended given its impracticality in the acute setting. In those patients with high suspicion for traumatic diaphragmatic rupture, exploratory laparoscopy or thoracoscopy plays an important role and should be strongly considered.[55,56]

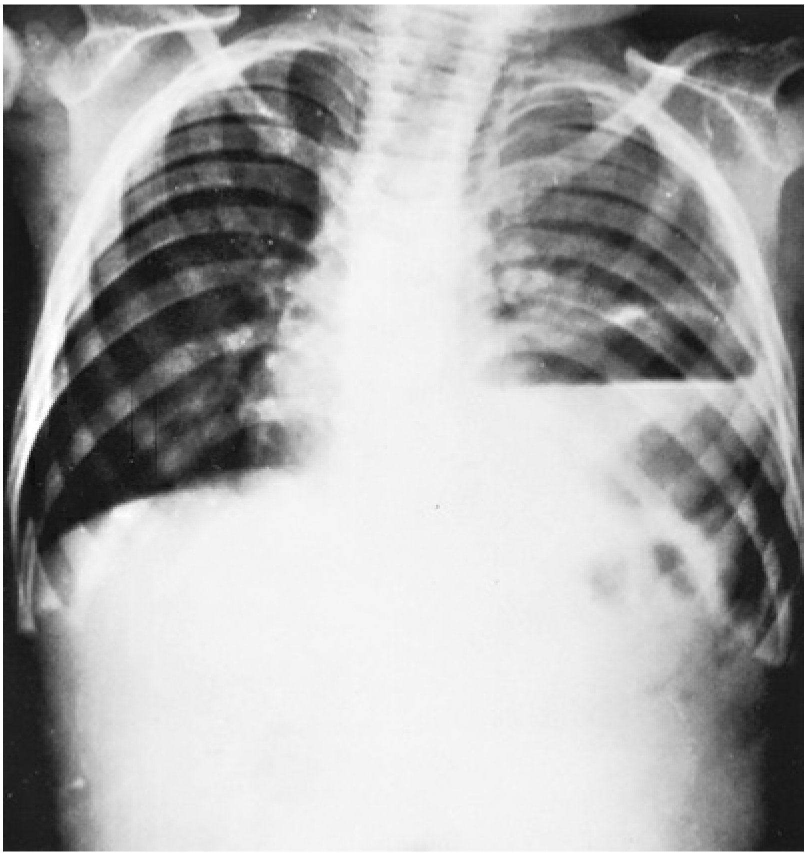

**FIG. 73.11** A blunt traumatic rupture of the left hemidiaphragm that went unrecognized. Death occurred 1 hour later from acute gastric dilation of the intrathoracic stomach (same physiologic effects as

tension pneumothorax).

Acute traumatic diaphragmatic injuries are treated with surgical reduction of the herniated organs and closure of the diaphragmatic defect (Fig. 73.12). It can be approached via either the chest or the abdomen, but given the high rate of associated abdominal injuries, most trauma surgeons recommend the abdominal approach.

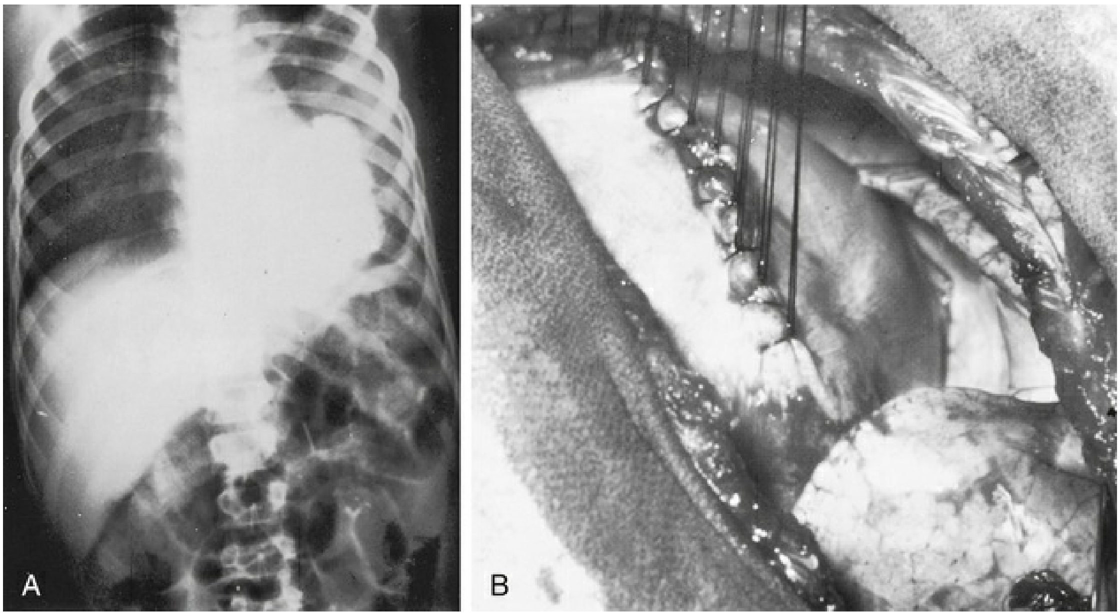

**FIG. 73.12** A blunt traumatic rupture of the left hemidiaphragm, with barium swallow confirmation (A) and final closure at operation (B).

## Thoracoabdominal Injuries

In infants and children, combined injury to the thorax and abdomen, including diaphragm rupture, is usually preceded by a violent traffic accident or other forms of sudden, jolting impact. Splenic and hepatic lacerations commonly occur with minimal external evidence of injury and need not be associated with fractured ribs or soft tissue mutilation.

The clinical signs of upper abdominal tenderness, rigidity, and rebound tenderness almost uniformly accompany lower chest trauma and are explained by the abdominal distribution of the intercostal nerves. Therefore, peritoneal irritation, of itself, is not conclusive evidence of a combined or abdominal injury.

Diaphragm rupture can occur with minimal soft tissue injury, and there may be chest pain, dyspnea, and hypotension. On inspection, the involved chest wall lags during inspiration, and percussion can be dull or hyperresonant. Chest radiographs may not show fractured ribs, but almost invariably demonstrate abnormality or absence of the diaphragmatic shadow on the affected side. There is usually mediastinal shift to the right, because in 90% of cases the posterolateral left leaf of the diaphragm is torn in a radial manner. At times a spontaneous pneumoperitoneum is seen. The presence of blood alone (lacerations of spleen/liver) typically does not result in peritonitis in the absence of hollow viscous injuries (stomach, small bowel, colon).[57] Therefore, careful repeated examinations correlated with laboratory data are necessary for the diagnosis of intraabdominal hemorrhage and perforation in the presence of chest trauma.

The preliminary management of combined thoracoabdominal injuries must provide an adequate airway and circulation, gastric decompression, and evaluation and control of other injuries. Intraabdominal hemorrhage and perforation with thoracic and abdominal soiling is an obvious indication for immediate exploration. Ideally, exploration should be undertaken as soon as systemic stabilization has been achieved.

# Tumors of the Chest

*Jeong S. Hyun MD, Stephanie D. Chao MD*

## Epidemiology

Tumors of the chest in the pediatric population represent many pathologies. They can differ in location from the chest wall, to the mediastinum, to the lung itself. They can be benign or malignant, primary or metastatic. Therefore, depending on the etiology, the incidence and epidemiology differ widely. All forms of primary neoplasms of the lung in the pediatric population are rare. A lung mass in the pediatric population is 10 times more likely to be a benign process than a malignant one.[1] Chest wall tumors account for only 1.8%[2] of all pediatric solid tumors, but tend to be malignant. The most common location of chest tumors is the mediastinum, and mediastinal masses can be further divided by their location into three compartments: anterior, middle, and posterior mediastinum. Mediastinal masses tend to occur early in the pediatric population, with around 40% of mediastinal masses occurring before the age of 2.[3] A case series of 120 patients showed that roughly 30% of these masses occur in the anterior mediastinum, around 25% in the middle mediastinum, and 40% in the posterior mediastinum.[4]

## Etiology

The etiology of tumors of the chest ranges widely, depending on the location of the tumor. In terms of primary pulmonary lesions, tumors can arise from both the tracheobronchial tree and the pulmonary parenchyma itself, and they can accompany a wide variety of subtypes, from benign (inflammatory pseudotumor and hamartomas) to malignant (bronchial adenoma, bronchogenic carcinoma, pleuropulmonary blastoma).[5]

# Benign Primary Pulmonary Lesions

## Plasma Cell Granuloma

Plasma cell granulomas have also been known as inflammatory pseudotumor, histiocytoma, inflammatory myofibroblastic tumor, and fibrohistiocytoma. These lesions are typically seen in patients less than 40 years old, with the majority in the pediatric population occurring in the age group between 8 and 12 years old. They are the most common benign lung tumors in the pediatric population, making up more than 50% of benign lesions and 20% of all primary lung lesions.[6] They usually present as a solitary peripherally based pulmonary nodule, but can also become locally invasive, causing symptoms such as fever, cough, pain, and hemoptysis, which require resection. In a cases series of 28 patients, there was predominance toward male patients, and up to 85% of the diagnosed cases required surgical intervention.[7]

It is unclear whether the underlying etiology is that of a primary inflammatory process or a low-grade malignant process with an inflammatory component. There have been reports that plasma cell granulomas are usually preceded by respiratory infections. Most of these lesions are slow growing, although in some rare cases they can spread quickly, leading to airway compromise.

## Hamartomas

Hamartomas were first described by Eugen Albrecht in 1904.[8] They are benign malformations composed of disorganized components of normal lung tissue, including cartilage, epithelium, fat, and muscle. The lesions are usually located peripherally in the parenchyma of the lung but have also been noted, rarely, to be located centrally, as well as within the chest wall.[9] Hamartomas are the most common benign lesion in the adult population and the second most common benign pulmonary lesion in the pediatric population (18%–23%).[5] Unlike in adults, where they tend to be asymptomatic, hamartomas can grow to be large and symptomatic in children, causing respiratory distress and requiring surgical excision.[1] Popcorn-like calcifications are considered pathognomonic and they can be part of a triad (Carney) consisting of pulmonary hamartomas, extraadrenal paraganglioma, and gastric smooth muscle tumors.

# Malignant Primary Pulmonary Lesions

## Bronchial Adenomas

Bronchial adenomas are tumors that derive from the mucous gland of the bronchi or the cells that line the excretory ducts of these glands. While the name *adenoma* suggests a benign process, bronchial adenomas can become malignant. There are three histologic types of bronchial adenomas: carcinoid, cylindroma, and mucoepidermoid. Around 80%–85% of bronchial adenomas in children are the carcinoid type, and they are similar in resemblance to carcinoid tumors of the small bowel. Bronchial carcinoids are thought to derive from neuroendocrine Kulitchsky cells. They are low-grade tumors, which can metastasize, but most are slow-growing tumors that can grow into the bronchial wall. Carcinoid syndrome itself is rare, although it has been reported in the pediatric population.[10] Cylindromas make up around 10%–15% of bronchial adenomas, and they consist of cuboidal or flattened epithelial cells that derive from the mucous secreting cells of the larynx and tracheobronchial tree. They are also low-grade, slow-growing malignancies, but they are considered the most aggressive of all three histologic types and can metastasize. Mucoepidermoid tumors originate in the larger airways and are the rarest subtype, comprising only 1%–5% of bronchial adenomas.

Bronchial adenomas usually present with vague pulmonary symptoms such as fever, cough, chest pain, recurrent pneumonitis, and hemoptysis as the tumor slowly grows into the airway and causes incomplete obstruction. These symptoms can cause children to be treated for asthma. The rarity of these disorders commonly causes a delay in diagnosis, often for years. The tumors usually involve the right main bronchus and are 5 times more likely to be seen in boys.

Treatment consists primarily of resection of a segment, lobe, or complete lung, according to the degree of involvement, which may be done thoracoscopically or via thoracotomy, depending on the location and extent of the lesion. Luminal excision by bronchoscopy should not be done because it does not permit complete removal of the tumor. Rarely a bronchial adenoma can be removed by bronchial or sleeve resection, followed by airway reconstruction.

## Bronchogenic Carcinoma

Bronchogenic carcinomas are exceedingly rare in the pediatric population, with only 60 reported cases in children,[11] and they represent approximately 20% of primary malignant lung tumors. Most present during adolescence. Most pediatric bronchogenic carcinomas are undifferentiated adenocarcinomas, with squamous cell carcinomas being much less common in the pediatric population, in contrast to the adult population. Usually asymptomatic, the majority of cases present late in the course of the disease leading to a poor prognosis; the mortality is more than 90%, with a mean duration of survival of only 7 months. Localized lesions can be resected with postoperative chemotherapy, but this applies to only a small subset of patients. The presenting symptoms are vague, including cough, hemoptysis, and weight loss. The tumor presents as a central pulmonary mass with endobronchial growth.

## Pleuropulmonary Blastoma

Pleuropulmonary blastomas (PPB) are rare malignant tumors that arise from the primitive interstitial mesenchyme of the lung. These typically occur in younger children prior to the age of 6 years and can behave aggressively with high rates of metastasis. There are three pathologic types of PPBs. Type I is purely cystic and is diagnosed around the age of 10 months, with a survival rate of 80%–85%.[12] Type II is a combination of cystic and solid, and type III is a purely solid lesion. There is evidence that all three types may develop on a continuum, where type II and III types present later, with type II presenting around 34 months and type III around 44 months. There have been reports linking congenital pulmonary airway malformations (CPAM) to PPB. Specifically, type IV CPAMs are highly suspicious for malignancy and may be cystic PPB. With CPAMs, the presence of symptoms, lack of a systemic feeding vessel, and hyperinflated lung lead toward a higher suspicion of possible malignancy.[13] There appears to be a familial component to PPB in up to 25% of cases. The DICER 1 gene has been implicated as an important genetic factor in the development of familial pleuropulmonary blastoma.[14] Often, PPBs occur in the right chest with metastasis to the liver, brain, and spinal cord. Surgical excision of cystic PPBs, with or without adjuvant chemotherapy, offers cure rates exceeding 85%. However, cure rates drop significantly if PPBs present later to care, when they have evolved into mixed cystic/solid or solid phases.[15]

## Chest Wall Tumors

Chest wall tumors are rare, and they encompass a wide variety of disease processes based on tumor types, tissue of origin, and behavior, so it is difficult to characterize them. They can be primary or secondary to invasion from adjacent structures. They are primarily mesenchymal tumors and are divided into benign and malignant disease, with up to 60% being malignant.[16] The majority of chest wall tumors come from skeletal structures (55%), with the remainder originating in the soft tissues of the chest wall (45%).

Chest wall masses often present as seemingly innocuous lumps that are noticed on the chest, which may demonstrate growth. They are typically slow-growing and asymptomatic, but pain can be a presenting symptom that raises the concern for a malignant process. A small percentage of these tumors can have effects on respiratory mechanics, depending on their location and size.

Benign tumors of the chest wall are less common than malignant ones and have a wide variety of etiologies. Lipomas of the chest wall are rare in the pediatric population. The most common soft tissue benign lesion of the chest wall derives from the myofibroblast,[17] including infantile myofibromatosis and desmoid fibromatosis tumor. Infantile myofibromatosis typically presents at birth or early in life and usually undergoes spontaneous regression. In contrast, desmoid fibromatosis can be more challenging to deal with, as they originate as overgrowths of fibrous tissue that can extend through muscle and fascial planes. Full excision can be challenging, and these patients often undergo multiple surgeries.

## Benign Tumors

Mesenchymal hamartomas are benign lesions typically found at birth that may present as a deforming chest mass, or they may be found incidentally on chest radiograph. These lesions tend to grow intrathoracically, causing respiratory symptoms. They have a characteristic appearance on radiograph with large calcifications arising from one or more ribs causing distortion of the osseous thorax. Although this description suggests an aggressive, possibly malignant process, mesenchymal hamartomas are benign, with no reports of malignant degeneration, recurrence, or metastasis after resection. Resection should only be undertaken to relieve respiratory symptoms related to mass effect from the lesion.

The most common benign skeletal neoplasms are osteochondromas, and they account for almost half of all tumors arising from the ribs.[18] These tumors consist of bony and cartilaginous components occurring near the end of long bones. They present during puberty, with an almost 3 : 1 predominance in males. They are frequently asymptomatic, but they can present with pain, can grow into adjacent nerves, may cause pathologic fractures, and can cause physical asymmetry of the chest, which is often cosmetically distressing. There is a characteristic “cartilage cap” seen on plain radiograph, and if the cap is greater than 1 cm, there is concern for the risk of chondrosarcoma.

Chondromas are benign tumors that arise in the costal cartilage and are composed of mature hyaline cartilage, usually at the sternocostal junction. They are typically slow-growing, painless masses that are not aggressive in nature. While benign, they are very similar in clinical course and in terms of imaging features to chondrosarcomas. Therefore they often have to be treated with wide local excision.

## Malignant Tumors

In contrast, chondrosarcomas are rare malignant tumors in the pediatric population, typically peaking in adult males in their thirties. However, given their similar appearance to chondromas, they are important to distinguish. They are slow-growing lesions that can start to cause pain, and they have a risk of late metastasis. The direction of growth appears to be entirely internal, thus stimulating the radiologic appearance of a primary pleural or mediastinal tumor. However, there is usually an externally visible and palpable mass. Chemotherapy and radiotherapy are not effective against chondrosarcomas. Thus they require a wide resection, as there is a high risk for local recurrence.

Of malignant chest wall lesions, primitive neuroectodermal tumors (PNET), often referred to as Ewing's sarcoma or Askin's tumors, are the most common in the pediatric population. They were first described by Askin and colleagues[19] in a series of 20 children. These tumors originate from embryonal neural crest cells and behave aggressively. It should be assumed that there is micrometastasis present at the time of diagnosis. PNETs of the chest typically present in the early teenage years, with a 2 : 1 male to female ratio. Symptoms include the development of a painful mass, dyspnea, weight loss, and, in some cases, Horner syndrome. Radiographs show lytic destruction, with an accompanying pleural effusion. Often computed tomography (CT) scan and magnetic resonance imaging (MRI) are needed to define the extent of the lesion and to determine presence of pulmonary metastasis, which can occur in up to 25% of cases at the time of presentation. Cytogenetic studies have shown that PNETs have a characteristic balanced translocation between chromosome 11 and 22 (t11:22 [q24:q21]). Treatment of PNETs is multimodal including chemotherapy, wide excision, and radiotherapy due to their high local recurrence rate. Prognosis for these tumors can be quite dismal, with 2- and 6-year survival rates being reported at 38% and 14%, respectively.[20]

# Mediastinal Tumors

The mediastinum is the portion of the body that lies between the lungs and contains all the structures within the thoracic cavity except the lung. It is bounded anteriorly by the sternum and posteriorly by the vertebrae and extends superiorly from the suprasternal notch to terminate inferiorly at the diaphragm. Cysts or tumors that arise within the mediastinum may originate from any of the structures contained therein or may be the result of developmental abnormalities.

For ease of definition of sites of disease, the mediastinum may be thought of as divided into three compartments: (1) the anterior mediastinum—the portion of the mediastinum that lies anterior to the anterior plane of the trachea; (2) the middle mediastinum—the portion containing the heart and pericardium, the ascending aorta, the lower segment of the superior vena cava, bifurcation of the pulmonary artery, the trachea, the two main bronchi, and the bronchial lymph nodes; and (3) the posterior mediastinum—the portion that lies posterior to the anterior plane of the trachea.

## Lymphomas

The most common mediastinal masses in children are lymphomas. Any lymph node enlargement in a child should be viewed with suspicion, since lymphatic tumors are one of the more frequently observed malignant growths in childhood. Lymphoma is the third most common malignancy in children overall and represents almost half of all mediastinal malignancies. Hodgkin disease, lymphosarcoma, and reticulum cell sarcoma are found primarily in children older than 3 years of age, with a peak incidence between 8 and 14 years of age. Lymphomas can occur in any of the compartments of the mediastinum, but in children, they most frequently are in the anterior and middle mediastinum. One-third of the lymphomas are Hodgkin lymphoma and two-thirds are non-Hodgkin lymphoma. Non-Hodgkin lymphoma is more likely to occur in younger children, while Hodgkin lymphoma tends to present in adolescent populations.

More than 95% of children with primary lymphatic malignancy have lymph node enlargement as the presenting sign. Tonsillar hypertrophy and adenoidal hyperplasia, pulmonary hilar enlargement, splenomegaly, bone pain, unexplained fever, anemia, infiltrative skin lesions, and rarely central nervous system symptoms may also be present.

The diagnosis should be sought through the study of peripheral blood smears, lymph node biopsy, pleural fluid examination, and bone marrow examination.

If all other diagnostic studies are negative, the mediastinal node can be biopsied. Fine-needle aspiration is usually not satisfactory; thus core needle biopsy (directly or via mediastinoscopy, thoracoscopy, or anterior thoracotomy) is frequently required. Importantly, anesthetic management is complicated if there is greater than 50% tracheal luminal compression or significant preoperative dyspnea. Surgery is rarely required in the treatment of lymphomas, although the diagnosis is often made via surgical biopsy. Biopsy of mediastinal lymph nodes requires careful, multidisciplinary preoperative planning. Often there are palpable cervical or axillary nodes, which may be amenable to biopsy and may pose less risk in establishing the diagnosis.

## Hyperplasia of the Thymus

Hyperplasia of the thymus is the most frequent of the thymic lesions. Because the normal thymus varies greatly in size and with age, *thymic hyperplasia* is a relative term. Steroids, infection, androgens, and irradiation may cause involution; the stimuli that cause hyperplasia are not well understood. As in other ductless glands, variations in size are probably related to patient individuality.

On the chest radiograph of normal infants, a thymic shadow of variable size and shape is typically present during the first month of life. The mediastinal shadow in young infants is proportionally wider than in older children and adults, because of the proportionally larger heart and thymic shadow. The thymic shadow typically disappears by 1 year of age. Among children older than 4 years of age, 2% still have a recognizable thymus on radiographic examination. Cervical extension of the thymus gland is common. If the thymus is in the superior thoracic inlet, its enlargement may cause tracheal compression (Fig. 74.1).

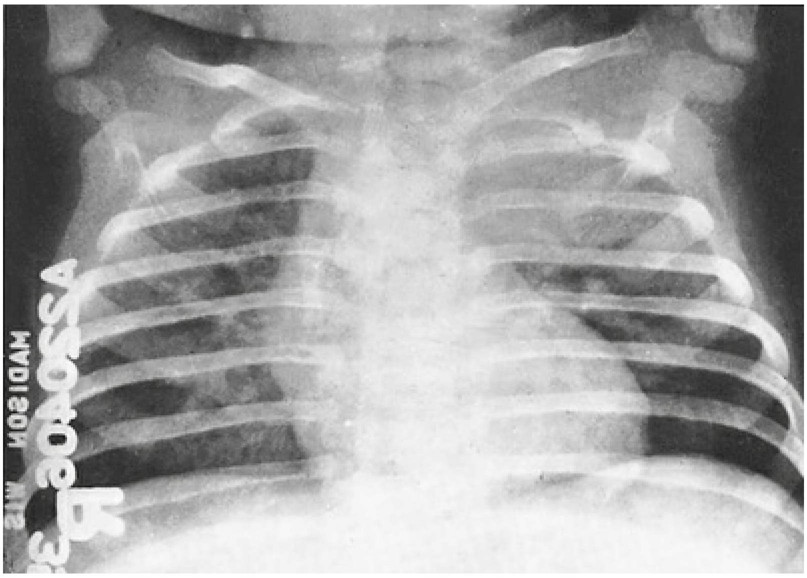

**FIG. 74.1** Mild respiratory distress in an infant with an enlarged thymus. Gradual improvement occurred with age and no specific therapy.

In the unusual situation in which an enlarged thymus causes respiratory obstruction, treatment may be carried out in one of three ways. While the thymus does respond rapidly to small doses of irradiation (70–150 cGy), the concern of a carcinogenic effect has caused this method of treatment to be abandoned. Corticosteroids cause a rapid decrease in the size of the thymus, usually within 5–7 days. However, after cessation of corticosteroid therapy, the gland may reach a size greater than that before treatment was instituted. Such a response may also be used in distinguishing between a physiologic enlargement of the thymus and a neoplasm (Fig. 74.2). Excision may be indicated both for the treatment of respiratory obstruction and for diagnosis.

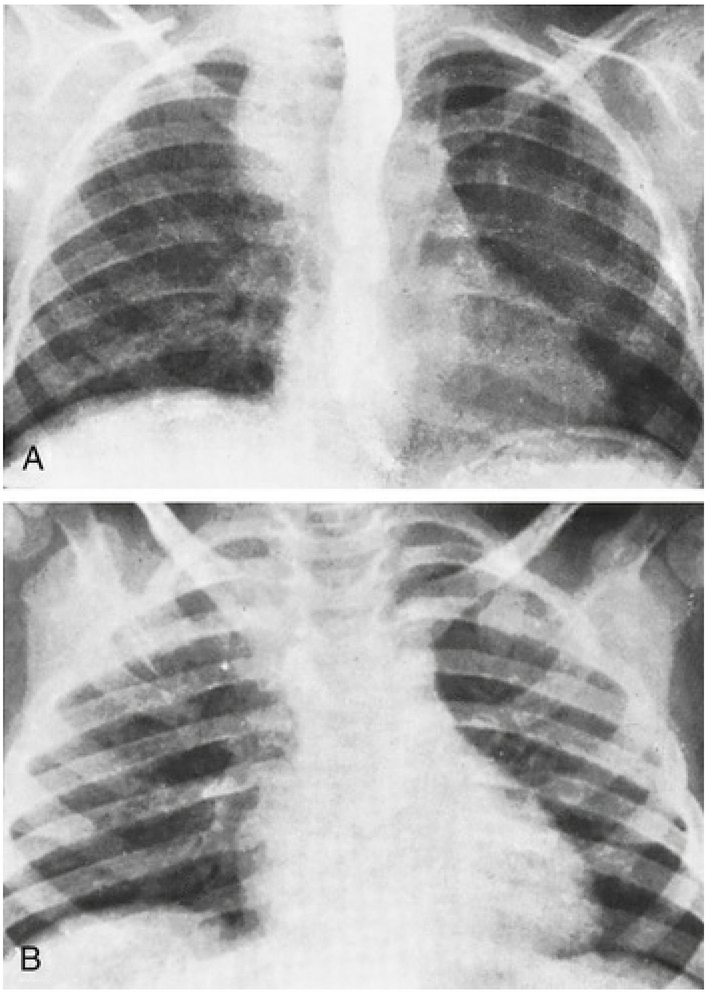

**FIG. 74.2** (A) An enlarged thymus in an infant. (B) A reduction in size can be seen after 7 days of steroid therapy.

## Neoplasms of the Thymus

Malignant thymic tumors in children are quite rare. Lymphosarcoma is more frequent, and primary Hodgkin's disease of the thymus and carcinoma have both been described. In only one 19-year-old patient has there been an associated myasthenia gravis syndrome. An ectopic parathyroid carcinoma located in the thymus has also been documented.[21]

### Benign Thymoma

Rarely benign thymic tumors have been reported in children, accounting for only 1%–2% of mediastinal masses (Fig. 74.3). Roughly one-third of patients with thymomas will have symptoms of local invasion. They are classified as invasive or noninvasive, depending on whether they extend past their fibrous capsule.

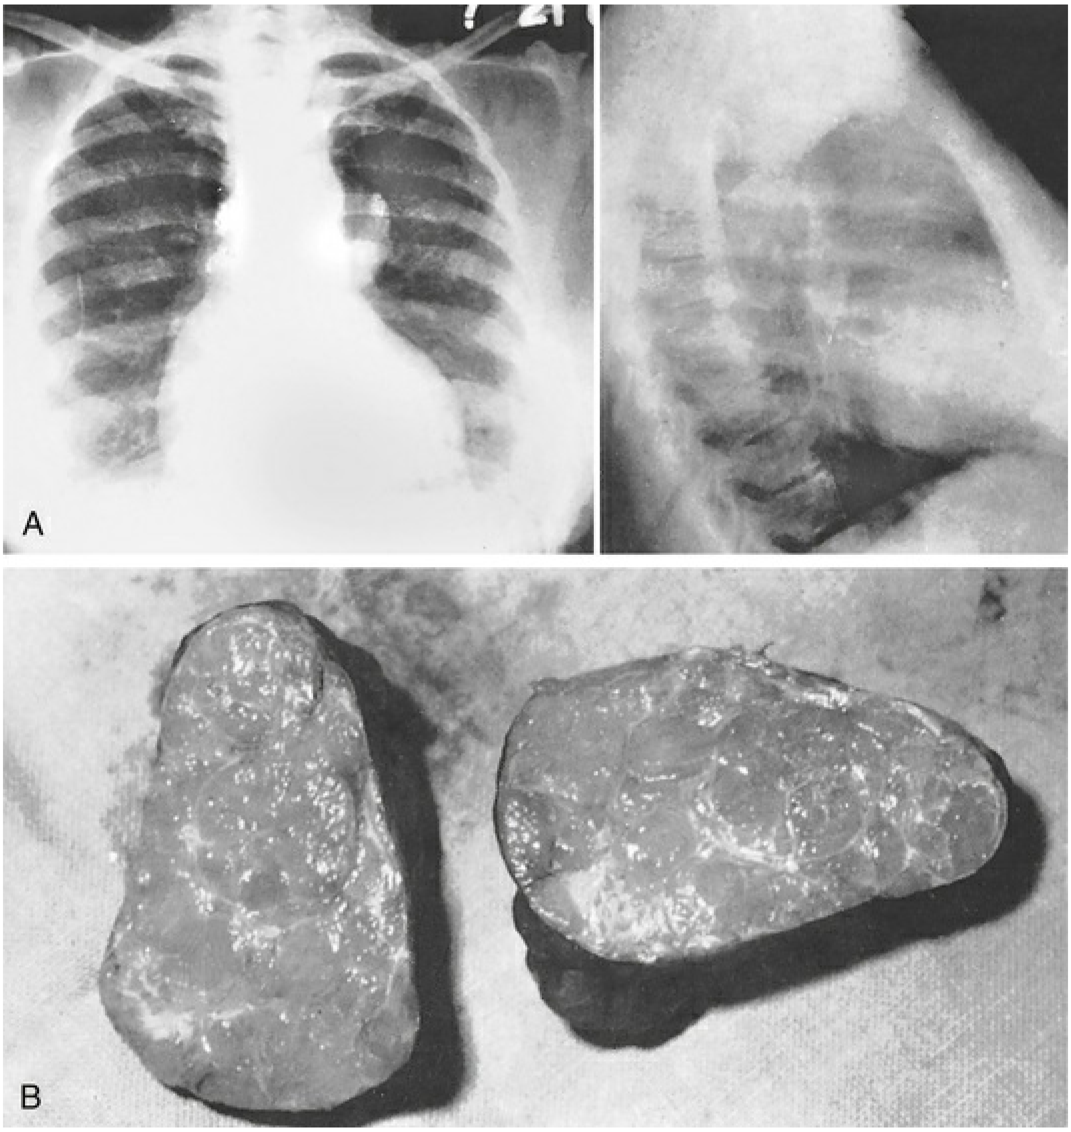

**FIG. 74.3** Benign thymoma located in the anterior superior mediastinum. (A) Posteroanterior and lateral radiographs before surgery. (B) Photograph of thymoma after excision.

## Thymic Cysts

Thymic cysts are rare, cystic remnants of the thymopharyngeal duct. Multiple small cysts of the thymus are frequently observed in necropsy material, but large thymic cysts are rare (Fig. 74.4). While they are typically asymptomatic, manifesting after 2 years of age, there have been reports of cysts causing respiratory failure in infants, as they can be located anywhere between the pyriform sinus and the anterior mediastinum.[22] Techniques and operative approaches are site-specific. Thymic cysts have been resected from a cervical approach (Fig. 74.5).

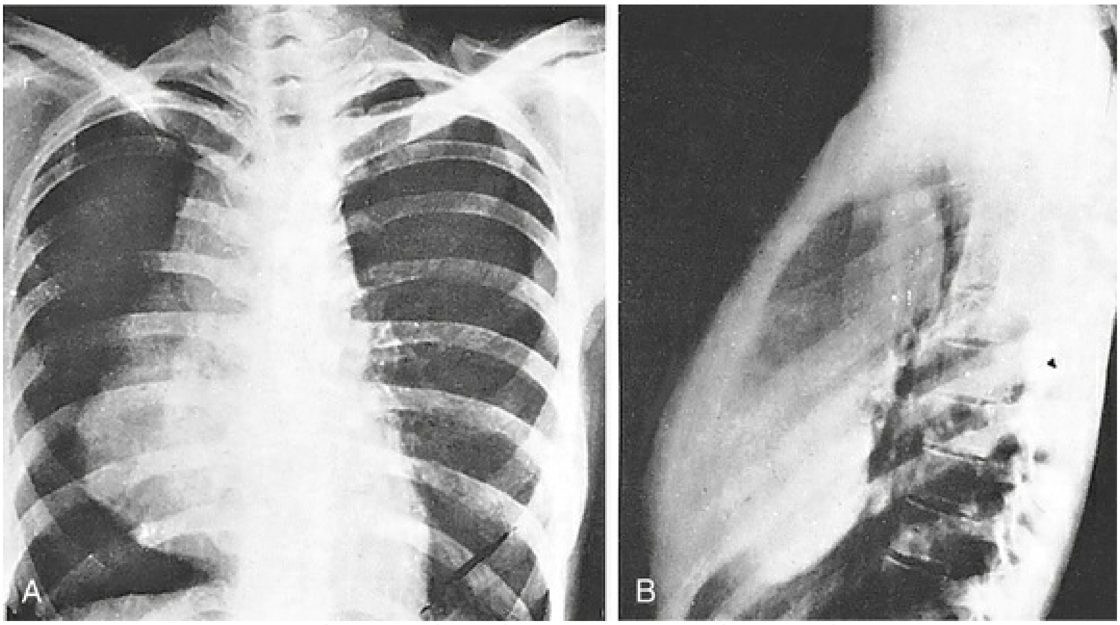

**FIG. 74.4** Large thymic cyst located near the diaphragm in an adult. Posteroanterior (A) and left lateral (B) radiographs.

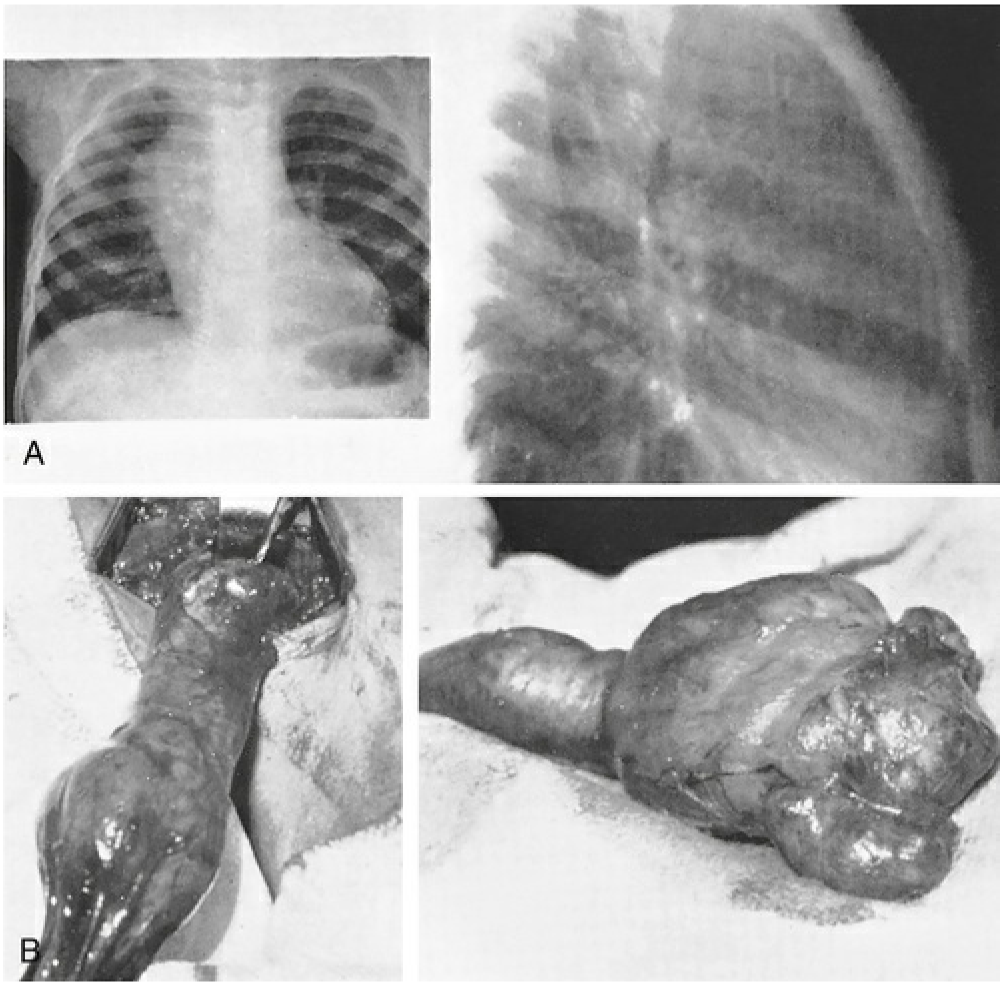

**FIG. 74.5** (A) Large thymic cyst in a 4-year-old boy that was evident as a mass in the right side of the neck clinically as well as on a chest x-ray. Removal required a thoracotomy and a supraclavicular incision. (B) Thymic cyst as seen after a thoracotomy and at the time of removal through a neck incision.

### Teratoma of the Thymus

Several cases of thymic teratoma have been reported. Patients typically have a good prognosis after resection.[23]

## Teratoid Mediastinal Tumors

Teratoid tumors of the mediastinum may be classified as: (1) benign cystic teratomas, (2) benign teratoids (solid), or (3) teratoids (carcinoma). They make up 10%–12% of all teratomas and 20% of all mediastinal pediatric neoplasms.[24]

## Benign Cystic Teratoma

Teratoma of the anterior mediastinum probably results from faulty embryogenesis of the thymus or from local dislocation during embryogenesis. Benign cystic teratomas (mediastinal dermoid cyst) contain such elements of ectodermal tissue as hair, sweat glands, sebaceous cysts, and teeth. Other elements, including mesodermal and endodermal tissue, may also be found when benign cystic teratoid lesions are subjected to comprehensive examination; thus such tumors are more properly classified as teratoid than dermoid cysts.

Cystic teratomas are more common than solid ones. These lesions are predominantly located in the anterior mediastinum and may project into either hemithorax, more commonly the right. In children, females are affected more often than males. Malignant degeneration is less common than in the solid form of teratoid tumor.

These cystic masses usually cause symptoms because of pressure on, or erosion into, the adjacent respiratory structures. Symptoms usually include vague chest discomfort associated with cough, dyspnea, and pneumonitis. Infection may cause a sudden exacerbation of symptoms, and rupture of the mass into the lung may occur with expectoration of hair and other materials; rupture into the pleura or pericardium may also occur.

On radiography, the lesion is well outlined, with sharp borders; definite diagnosis on plain radiograph is not possible unless teeth can be demonstrated in the mass. Calcification, which is not unusual, appears as scattered masses rather than as diffuse stippling. Cystic swelling in the suprasternal notch may be visible.

Benign cystic teratomas should be removed. In cases in which infection, perforation, intracystic hemorrhage, or malignant degeneration has occurred, complete removal may be difficult or impossible, owing to adherence to surrounding vital structures.

## Benign Solid Teratoid Tumors and Malignant Teratoid Tumors

Teratomas are the most common tumor occurring in the anterior mediastinum of infants and children (Fig. 74.6), and the mediastinum is the second most common location for these masses. The solid tumors in the teratoid group are much more complex and have a greater propensity for malignant change (Fig. 74.7). The incidence of malignancy has been reported as 10%–25%. In addition to standard imaging studies, preoperative serum studies should include serum α-fetoprotein, carcinoembryonic antigen, and β-human chorionic gonadotropin, both as diagnostic markers and as baseline values to monitor disease burden.

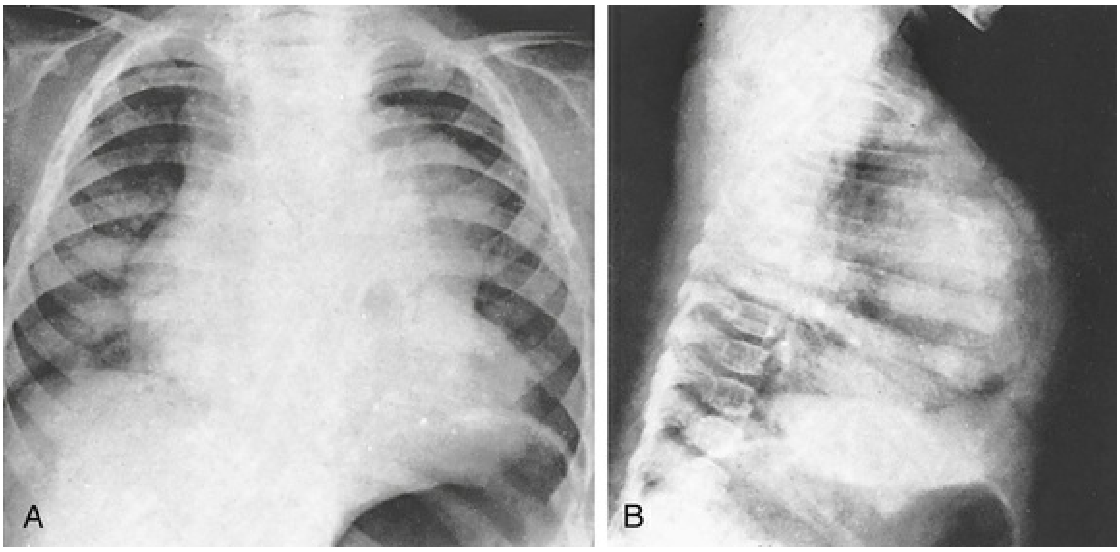

**FIG. 74.6** (A) Large, solid, benign teratoma in an infant. (B) On lateral radiograph, note the anterior mediastinal position and the forward displacement of the sternum.

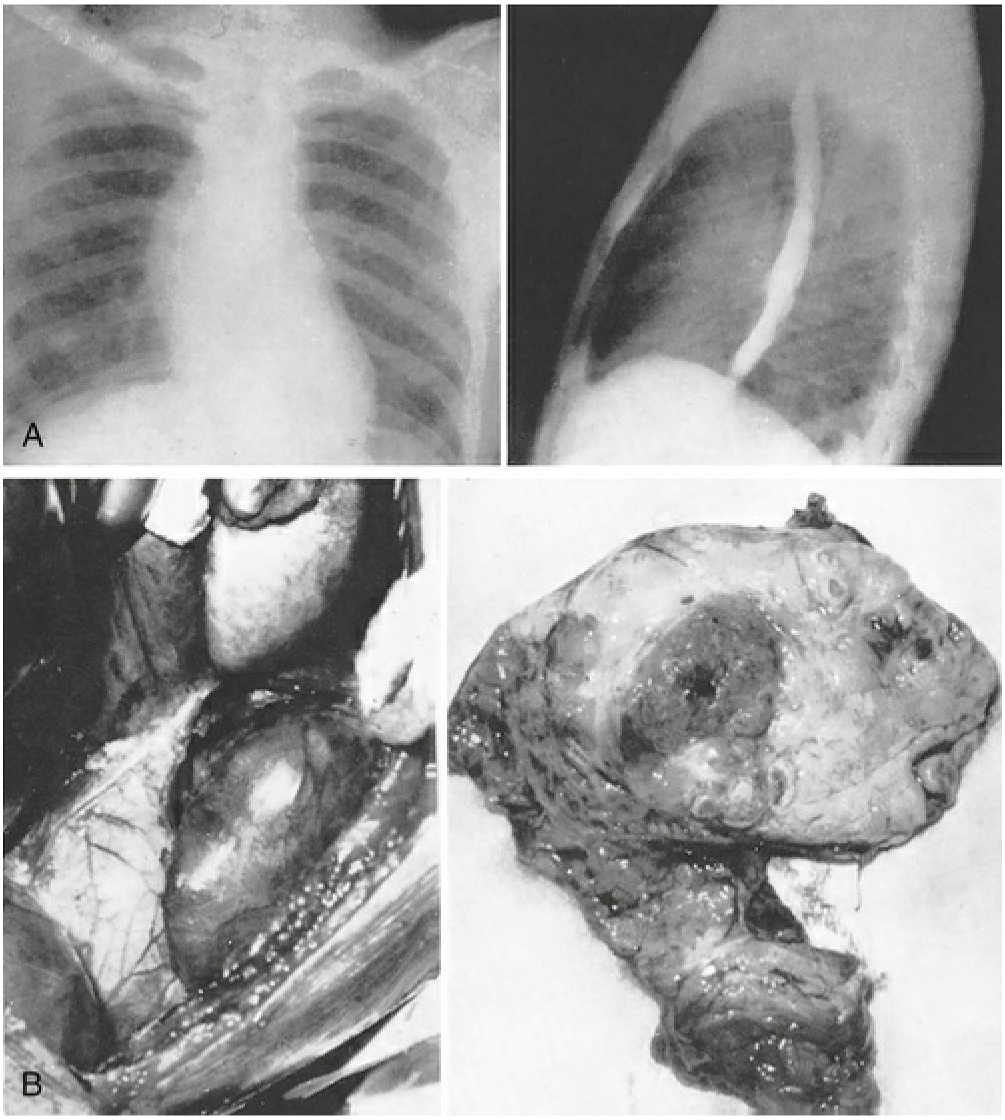

**FIG. 74.7** (A) Posteroanterior and lateral radiographs of an anterior malignant teratoma in an older child. (B) Note the anterior mediastinal position, with the teratoma wedged between the heart and the sternum.

Patients present with chest pain, cough, dyspnea, and rarely hemoptysis.[25] Most mediastinal teratomas are present at birth, and many are now detected prenatally. However, there are multiple reports of large masses discovered only in adulthood.[26]

Benign solid teratoid tumors have well-differentiated structures that are rarely observed in malignant tumors. They contain tissue from one or more of the three germ cell layers. The connective tissue stroma of malignant teratomas is usually poorly arranged, but that of benign teratomas is dense and of the adult type. In the benign type, nerve tissue, skin, and teeth may be found. Skin and its appendages are usually present and remarkably well formed. Hair follicles preserve their normal slightly oblique position relative to the free surface and are always accompanied by well-developed sebaceous glands. Sweat glands, often of the apocrine type, are frequently located near the sebaceous glands. Smooth muscle closely resembling *arrectores pilorum* is occasionally encountered.

Mesodermal derivatives, such as connective tissue, bone, cartilage, and muscle arranged in organoid patterns, are frequently found. When present, hematopoietic tissue is found only in association with cancellous bone. Smooth muscle is most often observed as longitudinal or circular bundles in organoid alimentary structures. Occasionally it is also seen in bronchial walls. Endodermal derivatives representing such structures as intestine and respiratory and pancreatic tissue are also present.

The final diagnosis of malignancy can be determined only after removal and histologic study of the tumor. Malignant degeneration is typically rare and generally only involves one of the cellular components. In general, the outcome is poor with malignant teratomas, chemotherapy and radiotherapy notwithstanding, which usually consists of etoposide, bleomycin, and cisplatin.

### Nonseminomatous Germ Cell Tumors

The nonseminomatous germ cell tumors or embryonal tumors consist of a wide variety of diseases such as seminomas, yolk-sac carcinomas, choriocarcinomas, and embryonal carcinomas. These tumors are all malignant and require multimodal therapy, including resection and chemotherapy. Standard workup should always include cross-sectional imaging, and preoperative serum studies should include serum $\alpha$-fetoprotein, carcinoembryonic antigen, and β-human chorionic gonadotropin.

## Vascular-Lymphatic Abnormalities of the Mediastinum

Vascular-lymphatic abnormalities of the mediastinum may be classified as (1) cavernous hemangioma, (2) hemangiopericytoma, (3) angiosarcoma, or (4) lymphangioma (cystic hygroma).

Vascular tumors isolated to the mediastinum in children are rare, and they may occur at any level in the mediastinum but are more frequent in the upper portion of the thorax and in the anterior mediastinum. They are uniformly rounded in appearance and are moderately dense. There are two major subtypes of hemangiomas: rapidly involuting and nonrapidly involuting. If hemangiomas do not cause respiratory symptoms, they are left untreated as they tend to disappear over time.

Though rare, *isolated* mediastinal lymphangiomas occur more often in infants and children than in adults. These tumors consist of masses of dilated lymphatic channels that contain lymph; they are lined with flat endothelium and are usually multilocular. They may appear to be isolated in the mediastinum (Fig. 74.8) but usually have an associated cervical component. They may be rather large and unilateral, with lateral masses in the superior mediastinum.

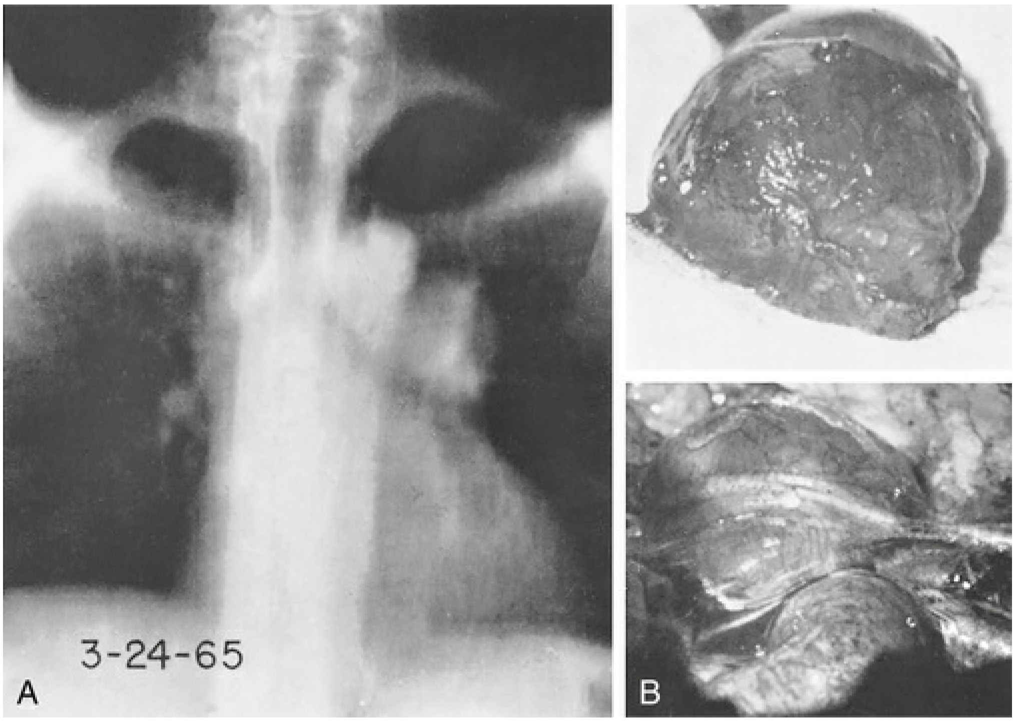

**FIG. 74.8** Large lymphatic cyst in the anterior mediastinum. (A) Posteroanterior radiograph. (B) Photographs.

Diagnosis of a cervicomediastinal lymphangioma is aided by physical examination of cervical swelling and radiographic examination of the chest. Periodic fluctuation in size frequently occurs in the cervical location. Radiographic and fluoroscopic examination may show descent of the mass into the mediastinum on inspiration, with prominence in the neck during expiration.

Cystic hygroma confined to the mediastinum is usually discovered as an unanticipated finding on radiographic examination. The soft and yielding nature of the cysts allows them to attain considerable size without producing symptoms. On radiograph, there is a somewhat lobulated, smoothly outlined mass; however, it is usually not possible to distinguish lymphangiomas from other benign tumors or cysts of the mediastinum by imaging.

When respiratory infections occur, lymphangiomas may become infected. Such infections are usually controlled with antibiotics or drainage. Infection may be followed by local fibrosis and disappearance of the mass. Spontaneous or posttraumatic hemorrhage into a cyst may result in extension of the cyst; this may cause sudden tracheal compression, which is a surgical emergency. Malignant change in lymphangiomas has not been reported.[27]

Surgical excision is the treatment of choice for localized lesions, although it may be challenging due to their tendency to grow around other structures. Incomplete resection ensures almost certain recurrence. Extensive disease remains an unsolved problem; for macrocystic variants, intralesional sclerotherapy has had some utility. Chylothorax may result when there is involvement of the thoracic duct. Antiangiogenesis therapy has shown some promise in treating angiosarcoma, although further investigation is needed.[28] Sclerotherapy has gained favor in complex cervical lymphangiomas; the same principles should apply to thoracic locations.

## Mediastinal Lipoma, Lip Sarcoma, and Lipoblastoma

Intrathoracic lipoma is rare in children. Lipomas of the mediastinum have been divided into three groups according to their location and form: (1) tumors confined within the thoracic cage, (2) intrathoracic lipomas that extend upward into the neck, and (3) intrathoracic lipomas, with an extrathoracic extension forming a dumbbell configuration. Lipomas tend to be soft, so most of these lesions tend to be asymptomatic.

Of the mediastinal lipomas reported in the world literature, 76% were intrathoracic, 10% were cervicomediastinal, and 14% were of the dumbbell type. Only 15 occurred in the pediatric age group, and these were intrathoracic. They may grow to very large size; a mass weighing 7.9 kg has been reported.[29] Seven cases of liposarcoma of the mediastinum in children have been reported.[30] Although these tumors usually do not metastasize, their invasiveness and tendency to recur locally place them in the malignant group.

Lipoblastoma is a rare benign tumor that occurs in children and arises from fetal embryonal fat. Thirty-five cases have been reported in the world literature, only 1 of which was in the mediastinum. Nearly 90% of the tumors are detected in children younger than 3 years of age.[31] At surgery, the lipoblastoma appears as a soft, yellow-gray or white-gray mass that can be easily removed. Histologically they may be confused with liposarcomas.

Complete surgical excision is the procedure of choice. Repeated surgical excisions may serve as a method of extended control, and radiation therapy may be added for palliative purposes.

## Neurogenic Mediastinal Tumors

Neurogenic tumors, by far the most common tumors with posterior mediastinal origin, make up 25%–35% of all mediastinal tumors. More than 50% present before the age of two, and they account for around 10% of pediatric tumors. They have highly variable behavior, sometimes regressing spontaneously, undergoing differentiation, or proliferating to malignant disease. They may be classified as follows:

1. Neurofibroma and neurilemoma
    - Malignant schwannoma
2. Tumors of sympathetic origin
    - Neuroblastoma
    - Ganglioneuroma
    - Ganglioneuroblastoma
    - Pheochromocytoma

3. Chemodectoma

Benign neurofibromas, neurilemomas, and malignant schwannomas are extremely unusual in the pediatric age group, and when present they are most often asymptomatic (Fig. 74.9).

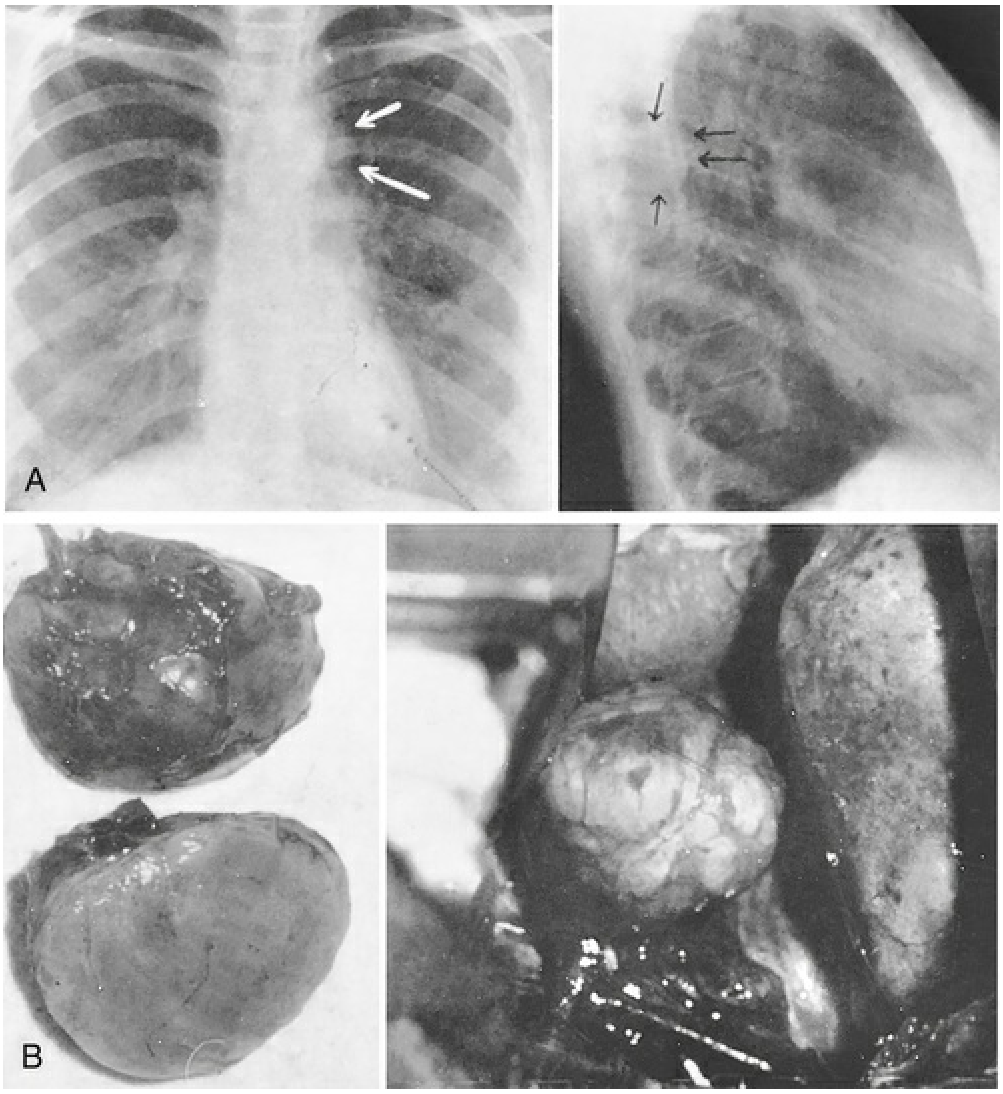

**FIG. 74.9** (A) Neurofibroma seen posteriorly located in posteroanterior and lateral radiographs. (B) Note the solid nature of the lesion, its round smooth outline, and its attachment to the intercostal nerve.

A neuroblastoma is a malignant tumor arising from a neural crest origin; the usual site is the adrenal medulla, but it may occur anywhere along the ganglia of the sympathetic chain from the neck to the pelvis. Although a primary neuroblastoma may cause the first clinical signs or symptoms (such as Horner's syndrome or respiratory distress), metastases in the bone, skin, or lymph nodes can also be the first indication of its presence. While most other childhood cancers have shown marked improvement in survival over the last 3 decades, neuroblastoma has not. Infants younger than 1 year of age do have a better prognosis and respond better to chemotherapy. The International Neuroblastoma Staging System, adopted in 1988, relies on complete surgical resection along with lymph node and distal metastases to dictate treatment.[32] The ganglioneuroma is a benign tumor made up of mature ganglion cells, few or many, in a stroma of nerve fibers. Ganglioneuroblastoma is a tumor composed of various proportions of neuroblastoma and ganglioneuroma.

Ganglioneuroma and ganglioneuroblastoma are more likely to present after 2 years of age. The more malignant forms, such as neuroblastoma, frequently manifest before the age of 2 years. Ganglioneuroma is more common in children than in adults; respiratory symptoms are rare.

Most of these tumors usually occur in the upper two-thirds of the hemithorax and tend to extend locally. They may grow into the lower part of the neck, across the midline through the posterior mediastinum to the opposite hemithorax, descend through the diaphragm into the upper part of the abdomen or into the intercostal spaces posteriorly, and involve one or several of the vertebral foramina.

While some such tumors are discovered incidentally, symptoms such as radicular pain, paraplegia, motor disturbances, and Horner syndrome may be the presenting complaint. Upper respiratory tract infections, dyspnea, fever, and weight loss may occur. Neurogenic tumors of the neuroblastoma group usually occur in younger children, and respiratory symptoms, thoracic pain, and fever are more common (Fig. 74.10).

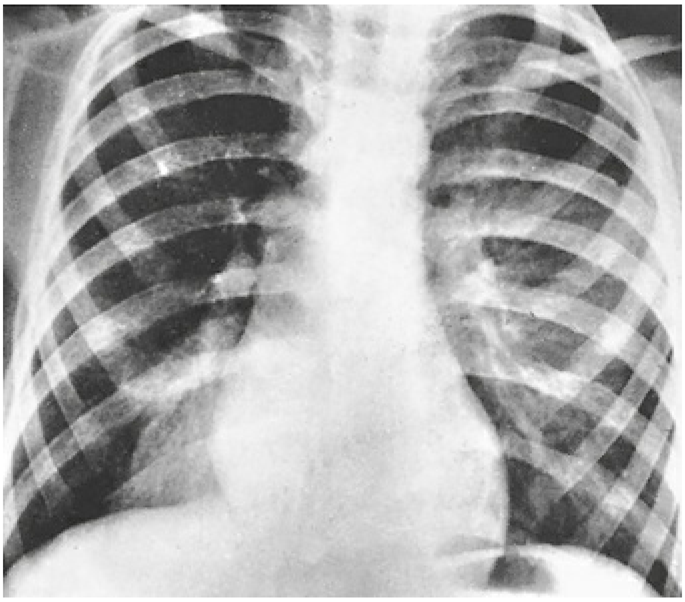

**FIG. 74.10** Chest X-ray of a neuroblastoma in a 6-year-old boy.

On radiographic examination, neurogenic tumors are round, oval, or spindle-shaped and are characteristically located posteriorly in the paravertebral gutter. On thoracic radiographs, a ganglioneuroma appears as an elongated lesion and may extend over several vertebrae. Typically a neurofibroma tends to be more rounded in outline. Calcifications within the tumor may be seen, more commonly in the malignant forms. Even though not demonstrated on radiographic examination, calcification may be found at the time of histologic examination. Bone lesions, such as intercostal space widening, costal deformation, vertebral involvement, and metastatic bone disease, are common. Staging with CT or MRI scans is routine and well prescribed in oncologic protocols.

The primary therapy for localized thoracic neurogenic tumors is surgical excision. Ganglioneuroma (benign) are generally amenable to resection. In malignant neurogenic tumors, principles and timing of surgical resection depend on the degree of extension at presentation. The extent of tumor resection and postoperative irradiation therapy also depend on tumor grade and histology. Radiotherapy must be given judiciously, because growth disturbances, pulmonary fibrosis, and other sequelae may develop.

Mediastinal chemodectomas are usually located anteriorly; they are likely to be associated with similar tumors in the carotid body and elsewhere. There is a tendency for these tumors to be multiple. Mediastinal pheochromocytomas make up less than 1% of all mediastinal tumors; extra-adrenal pheochromocytomas are more common in children than in adults. The tumor may be a cause of refractory hypertension in children as in adults.[33]

## Primary Mediastinal Cysts

Lesions occurring within the mediastinum may be predominantly cystic or predominantly solid. Cystic lesions are usually benign; solid lesions have higher malignant potential. Primary mediastinal cysts likely represent abnormalities in embryologic development at the site of the foregut just when separation of esophageal and lung buds occurs (Fig. 74.11).

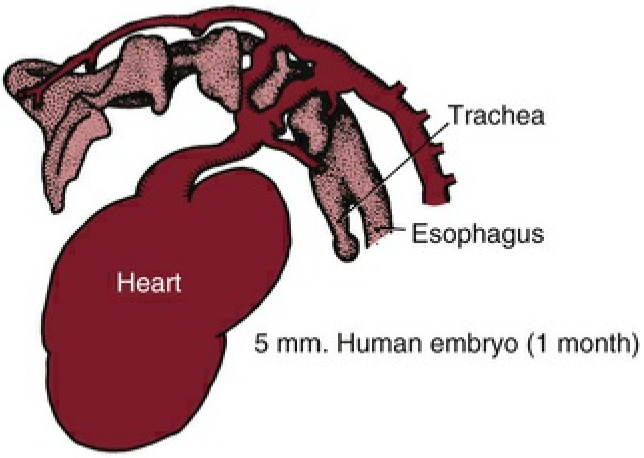

**FIG. 74.11** The foregut, which lies between the tracheal and esophageal buds, is the probable site of embryologic maldevelopment, which gives rise to the growth of foregut cysts.

Structures that arise from the foregut are the pharynx, thyroid, parathyroid, thymus, respiratory tract, esophagus, stomach, upper part of the duodenum, liver, and pancreas; thus abnormal development at this stage may give rise to bronchogenic cysts, esophageal duplication cysts, and gastroenteric cysts.

### Bronchogenic Cysts

Maier[34] classified bronchogenic cysts according to location as tracheal, hilar (Fig. 74.12), carinal (Fig. 74.13), esophageal, and miscellaneous (Fig. 74.14). This classification remains useful. Modern nomenclature also uses the term *foregut duplication cysts,* which is a correct embryologic description of their developmental origin.

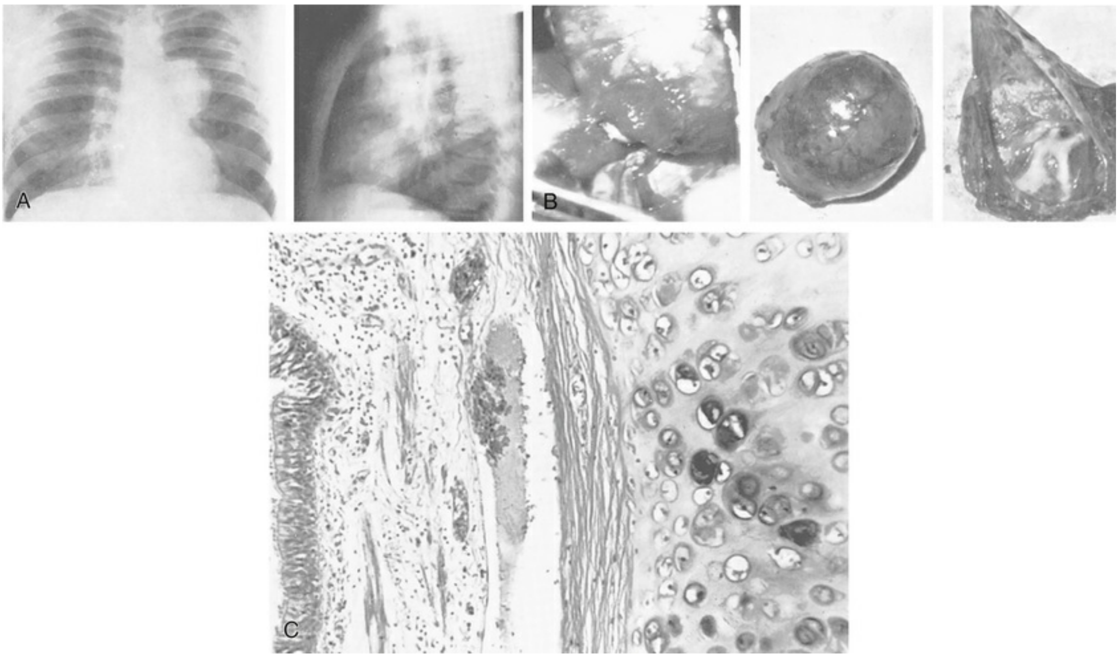

**FIG. 74.12** (A) Typical left hilar bronchogenic cyst with a rounded, smooth border and a density similar to cardiac density. (B) At the time of thoracotomy, a solid stalk was found attached to the left main bronchus. The cyst was unilocular and contained thick, yellowish mucoid material. The wall was thin with typical trabeculations. (C) Microscopic study revealed cartilage, smooth muscle, and pseudostratified, ciliated, columnar epithelium.

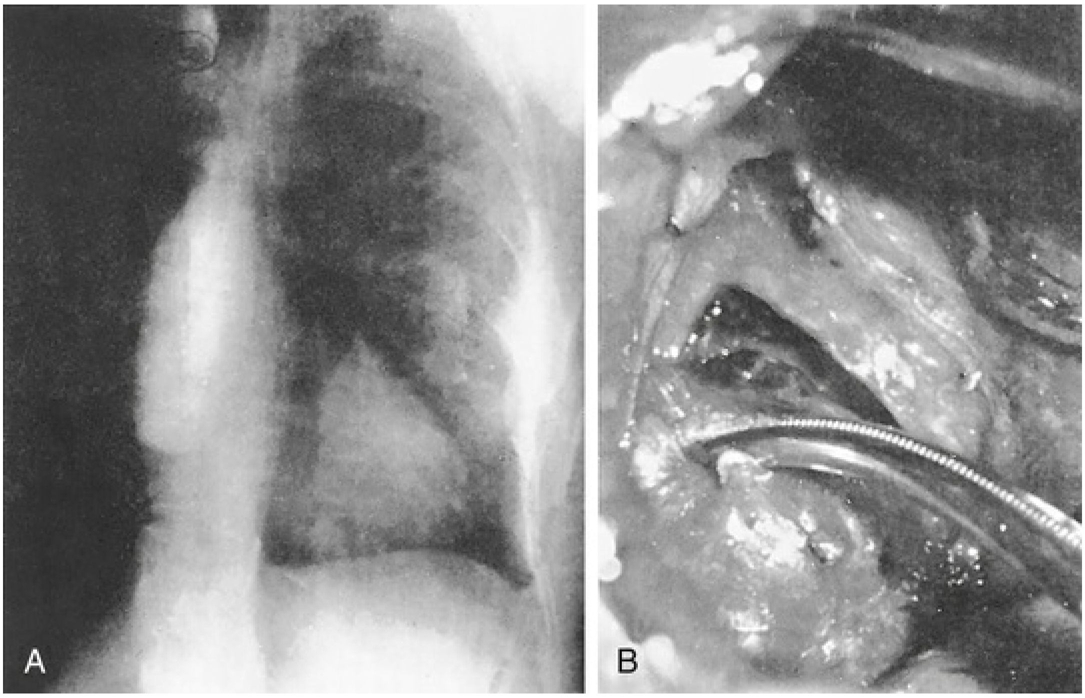

**FIG. 74.13** (A) Overexposed posteroanterior chest radiograph shows a carinal bronchogenic cyst. (B) At the operation, the location is clearly seen at the carina. A solid fibrous stalk is attached at the carina and is separated just beneath the instrument dissector.

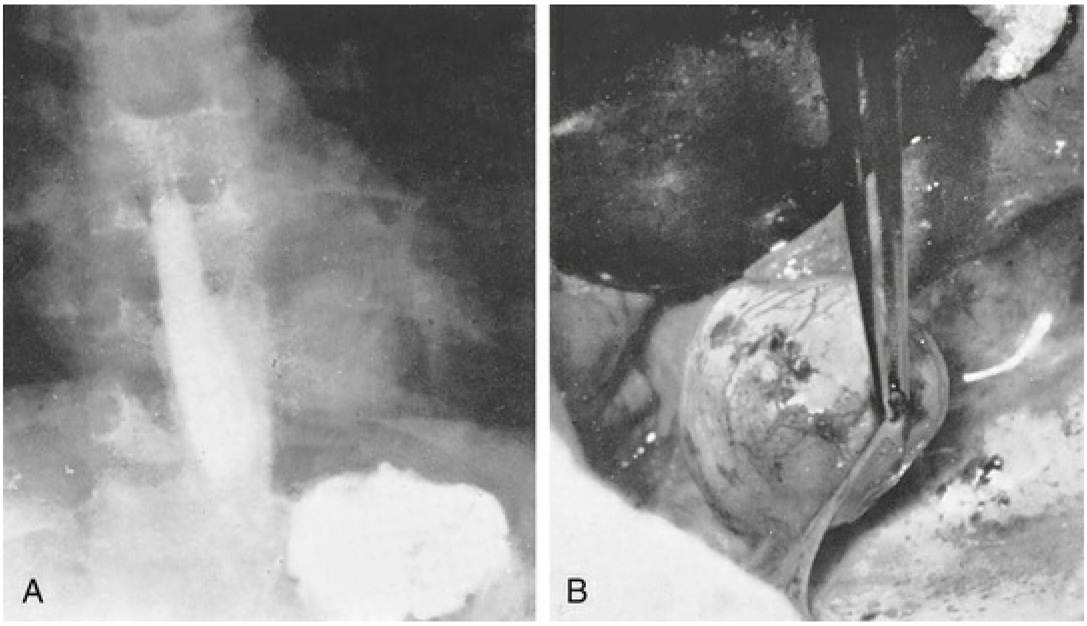

**FIG. 74.14** Bronchogenic cyst in a child. (A) Radiograph. (B) Photograph at surgery. The cyst is located retropleurally, overlying the distal thoracic aorta, and is not attached to the respiratory tract or

esophagus.

Bronchogenic cysts are usually located in the middle mediastinum, but have been described in all mediastinal locations. Under microscopic examination, bronchogenic cysts may contain any or all the tissues normally present in the trachea and bronchi (fibrous connective tissue, mucous glands, cartilage, smooth muscle, and a lining formed by ciliated pseudostratified columnar epithelium or stratified squamous epithelium). The fluid inside the cyst is either clear waterlike liquid or viscous gelatinous material.

Bronchogenic cysts are usually asymptomatic. There may, however, be frequent upper respiratory tract infections, vague feelings of substernal discomfort, and respiratory difficulty (cough, noisy breathing, dyspnea, and possibly cyanosis). Bronchogenic cysts may communicate with the tracheobronchial tree and show varying air-fluid levels accompanied by the expectoration of purulent material. If communication with the tracheobronchial tree is present, it may be visualized by bronchoscopy.

On radiographic examination, the bronchogenic cyst is usually a single, smooth-bordered, spherical mass (Fig. 74.15). It has a uniform density similar to that of the cardiac shadow. Calcification is unusual. Fluoroscopic examination of the cyst may demonstrate that it moves with respiration (due to attachment to the tracheobronchial tree) and its shape may alter during the cycles of respiration. These lesions are occasionally identified on prenatal ultrasound.

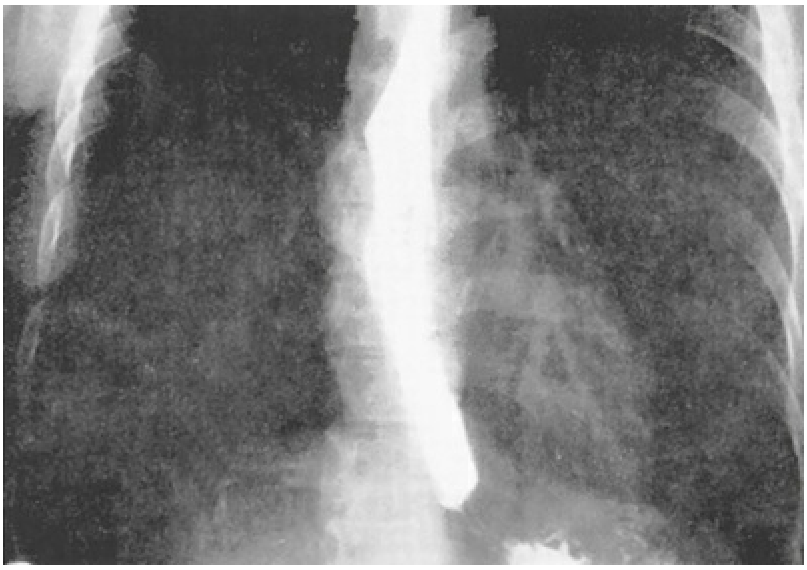

**FIG. 74.15** Esophogram of a hilar bronchogenic cyst with an esophageal indentation.

When the bronchogenic cyst is located just below the carina, it may cause severe respiratory distress due to compression of either one or both major bronchi (Fig. 74.16). Early diagnosis and prompt removal are necessary.

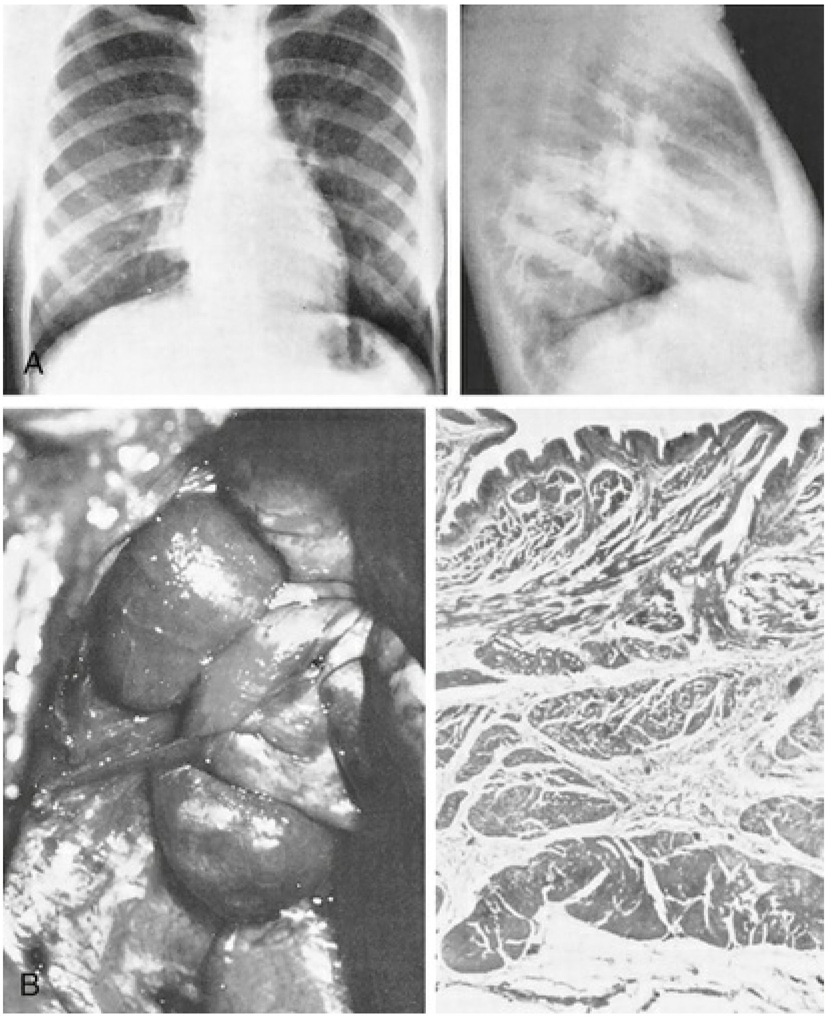

**FIG. 74.16** (A) Bronchogenic cyst in a child whose mother had tuberculosis. The child was treated with antituberculosis drugs for 1 year without change. (B) A dumbbell-shaped bronchogenic cyst was found in the region of the inferior pulmonary vein during an operation. The microscopic section shows a wall with ciliated epithelium, no cartilage, and a smooth muscle wall of two layers.

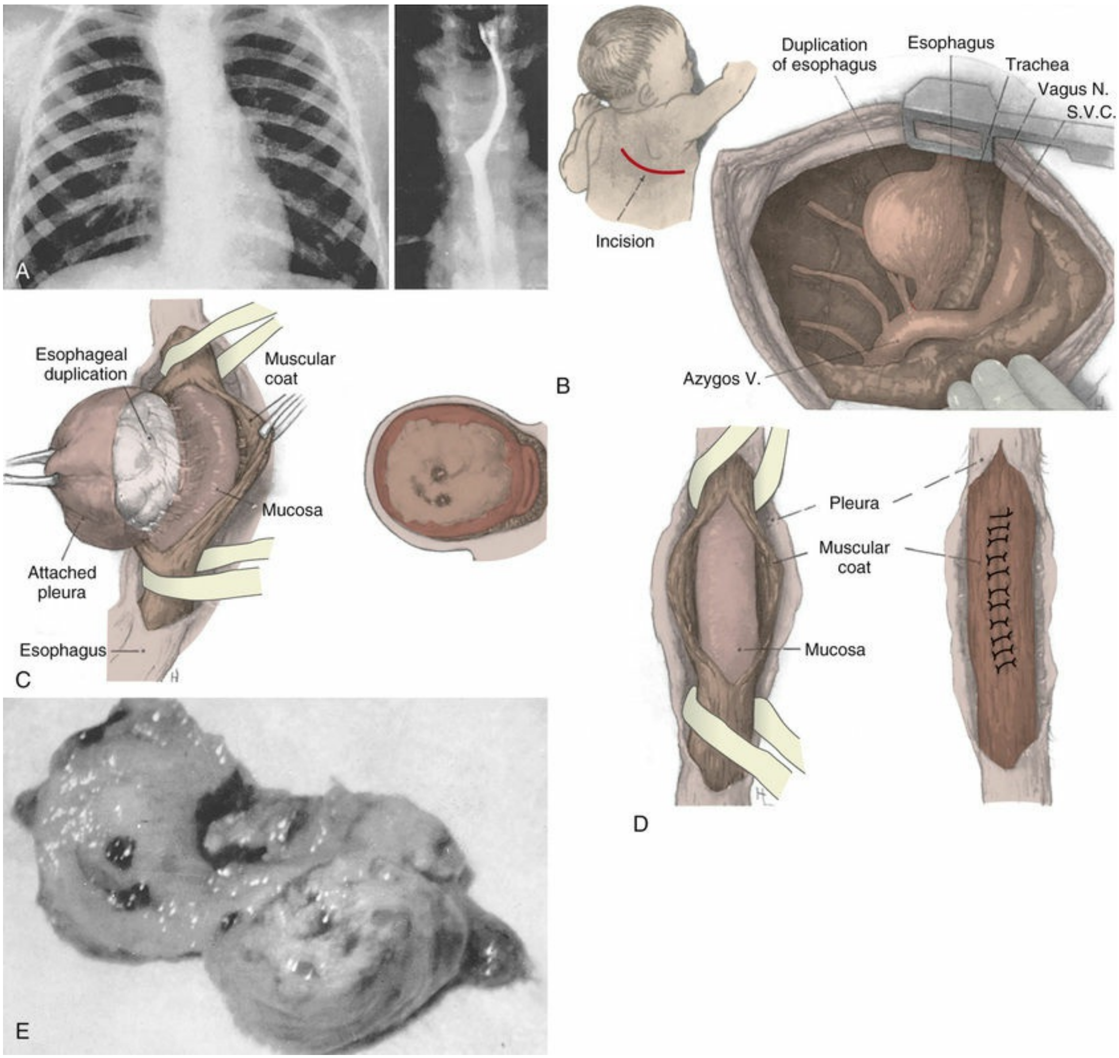
There are no meticulous population-based studies of bronchogenic cysts, so its incidence is conjecture. Phillipart and Farmer assembled perhaps the best composite review of all mediastinal masses; some 7% of mediastinal tumors were bronchogenic cysts.[35]

Bronchogenic cysts should be treated by surgical removal. Like most discrete lesions, most of these can be handled with thoracoscopic techniques. Regardless of approach, care must be taken when these lesions share a common wall with either the airway or the esophagus. If there has been antecedent infection, resection is complicated, as normal tissue planes may be obliterated.

## Esophageal Cysts (Duplication)

Esophageal cysts are located in the posterior mediastinum; they are usually on the right side and are intimately associated in the wall of the esophagus (Fig. 74.17). They occur more frequently in males than in females.



A

E

**FIG. 74.17** (A) Posteroanterior chest radiograph taken of a child with an upper respiratory tract infection. A mass is seen in the posterior superior mediastinum presenting into the right hemithorax. At the time of an esophogram, the esophagus is seen displaced toward the left by a smooth mass. (B–D) Drawings of findings at the operation. Note the plane of separation from the mucosa of the esophagus and the lack of communication with the esophageal lumen. (E) An opened operative specimen, the cavity of which was filled with mucoid fluid. The lining of the duplication was typical squamous epithelium.

There are two types of esophageal cyst; the more characteristic type resembles adult esophagus with the cyst lined by noncornified stratified squamous epithelium having a well-defined muscularis mucosae and striated muscle in the wall. Intimate association in the muscular wall of the esophagus is not, however, accompanied by communication with the lumen of the esophagus. A review of 36 patients suggests that early resection between the ages of 6 and 12 months leads to better conservation of normal pulmonary parenchyma and a reduction in complications.[36] Ciliated mucosa lines the second type, thus resembling the fetal esophagus.

Esophageal cysts may be associated with mild dysphagia and regurgitation but are usually asymptomatic. Barium esophagram shows smooth indentation of the esophagus. On esophagoscopy, there is indentation of the normal mucosa by a pliable, movable, soft extramucosal mass. Removal is indicated for the same reasons as bronchogenic cysts and thoracoscopic techniques are similar. Technically these lesions may be more difficult to excise, especially if they are extensive or cross the diaphragm.

## Gastroenteric Cysts

The third type of cyst arising from the foregut is the gastroenteric cyst, which typically lies in the posterior mediastinum against the vertebrae. Such cysts are typically posterior or lateral to and free of the esophagus, with attachments posteriorly. The normal fetal esophagus is lined by columnar epithelium, much of which is ciliated, which only gradually converts to the stratified epithelium of the mature organ. The change is generally complete, or almost complete, at birth. Thus if a cyst arises from the embryonic esophagus, it has a ciliated lining.

The enteric nature of a posterior mediastinal cyst is moderately certain if microscopic examination reveals a frank gastric or intestinal type of epithelium, but a better indication of the nature and origin is the presence of well-developed muscularis mucosae, and two or even three main muscle coats. Gastric glands are common, but esophageal, duodenal, or small-intestinal glands may also be found. At operation, the cyst sometimes seems grossly “stomach-like” or “bowel-like.” Cysts encountered in the posterior mediastinum show a highly developed mesodermal wall and even the presence of Meissner's and Auerbach's plexuses, whereas the lining epithelium varies from columnar ciliated to typical small intestinal. Two types of gastroenteric cysts have been described: (1) acid-secreting cysts, which are functionally active; and (2) cysts in which the mucosa has no functional activity.

Males are predominantly affected with this abnormality. Unlike other foregut cysts, posterior gastroenteric cysts are usually symptomatic. The symptoms are usually due to pressure on thoracic structures or rupture into bronchi with massive hemoptysis and death. Actual peptic perforation of the lung with hemorrhage has been reported.

Hemoptysis in young infants is difficult to distinguish from hematemesis; it may follow ulceration of a gastroenteric cyst (with gastric lining) of the mediastinum, with subsequent erosion into the lung. Gastric epithelium associated with intestinal or respiratory epithelium is apparently less secretory. Many functional cysts may lose their functional activity when the secretory areas of the mucosa are destroyed. Renin, pepsin, chlorides, and free hydrochloric acid have been demonstrated in the contents of some of the cysts.

Posterior gastroenteric foregut cysts of the mediastinum are frequently associated with two other types of congenital anomalies: mesenteric abnormalities and vertebral abnormalities. When these are suspected, MRI is the preferred diagnostic test. Both types may occur in the same case. In the embryo, the notochord and the endoderm are in intimate contact at one time; thus this combined developmental anomaly may result from abnormal embryonic development.

Penetration of the diaphragm by a cyst arising primarily from the thorax may occur; conversely, penetration of the diaphragm by the free end of an intramesenteric intestinal duplication is also possible.

A survey of the literature confirms that as many as two-thirds of patients with mediastinal cysts have vertebral anomalies, including hemivertebrae, spina bifida anterior, or infantile scoliosis. Most of these vertebral lesions involve the upper thoracic and lower cervical vertebrae, and the cyst tends to be caudal to the vertebral lesion. MRI may be helpful in demonstrating these lesions. The presence of spina bifida anterior, congenital scoliosis, Klippel-Feil syndrome, or similar but less well-defined lesions in the cervical or dorsal vertebrae suggests enteric cysts in the mediastinum or abdomen.

## Pericardial Coelomic Cysts

These mesothelial cysts are developmental in origin, and persistence is related to the pericardial coelom. The primitive pericardial cavity forms by the fusion of coelomic spaces on each side of the embryo. During the process, dorsal and ventral parietal recesses are formed. Dorsal recesses communicate with the pleuroperitoneal coelom, and the ventral recesses end blindly at the septum transversum. The persistence of segments of the ventral parietal recess accounts for most pericardial coelomic cysts.

The cysts are usually located anteriorly in the cardiophrenic angles, more frequently on the right, and occasionally on or in the diaphragm (Fig. 74.18). They are usually asymptomatic and are discovered on routine chest radiography. Rarely do they reach sufficient size to cause displacement of the heart or to produce pressure on the pulmonary tissue. Infection is unusual.

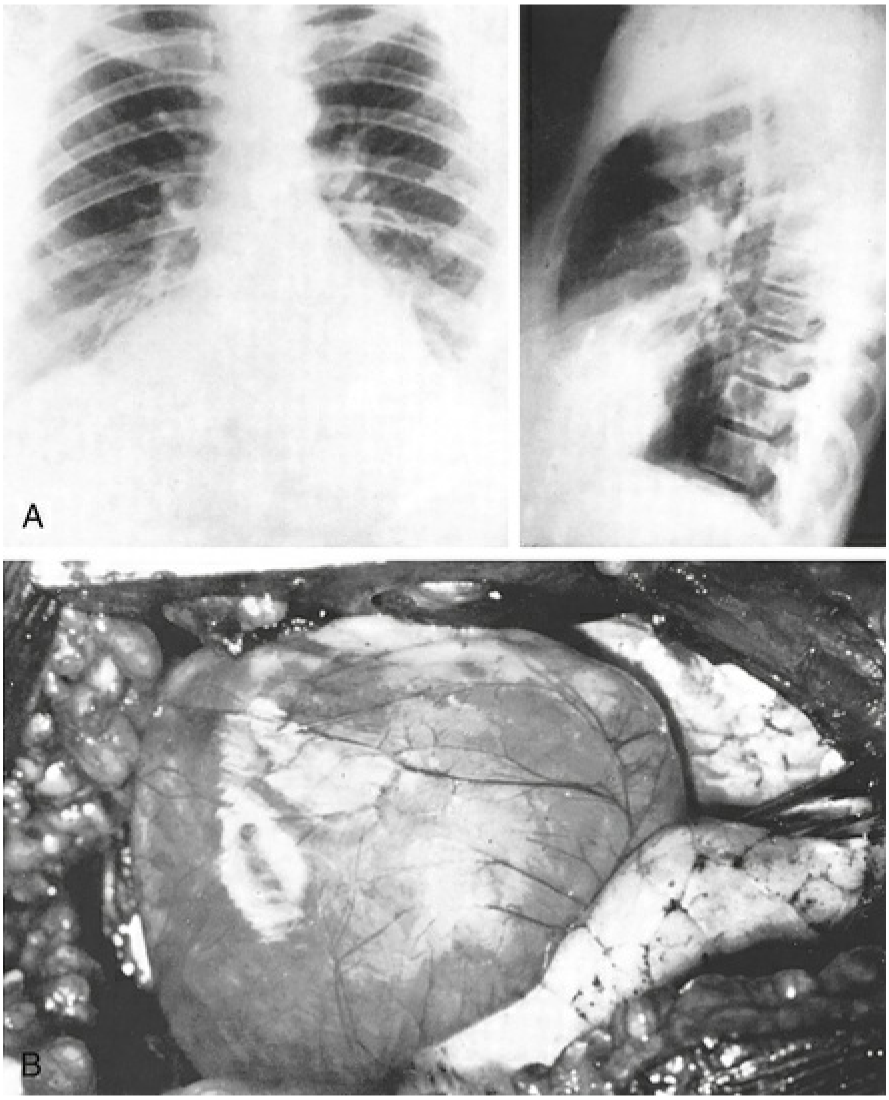

**FIG. 74.18** (A) Typical location of a pericardial cyst in posteroanterior and lateral chest radiographs at the right cardiophrenic angle. (B) A large cyst seen at the time of a thoracotomy.

Pericardial cysts are usually unilocular. The walls are thin, and the intersurfaces are smooth and glistening, lined by a single layer of flat mesothelial cells. The mesothelium is supported by fibrous tissue with attached adipose tissue.

These cysts are very rare; only two have been reported in children. Because they are benign, observation may be warranted. Alternatively, thoracoscopic excision can be undertaken.

## Intrathoracic Meningoceles

Intrathoracic meningoceles are not true mediastinal tumors or cysts; they are diverticuli of the spinal meninges that protrude through the neuroforamen adjacent to an intercostal nerve and manifest beneath the pleura in the posterior medial thoracic gutter. The wall represents an extension of the leptomeninges, and the content is cerebrospinal fluid. Enlargement of the intervertebral foramen is common; vertebral or rib anomalies adjacent to the meningocele are also frequent. The most commonly associated anomalies are kyphosis, scoliosis, and bone erosion or destruction. The walls of these cysts are formed by two distinct components, the dura mater and the arachnoidea spinalis, with small nerve trunks and ganglia occasionally incorporated.

A syndrome of generalized neurofibromatosis (von Recklinghausen disease), kyphoscoliosis, and intrathoracic meningocele may occur, but thoracic meningocele as an isolated defect is much less frequent; only four pediatric cases have been reported. This lesion is usually asymptomatic; it occurs on the right side approximately 3 times more often than on the left. Rarely the lesion may be bilateral. In patients with neurofibromatosis, posterior sulcus tumors are usually meningoceles and rarely neurofibromas.

On radiographic examination, the lesion is a regular, well-demarcated intrathoracic density located in the posterior sulcus; associated congenital anomalies of the spine and thorax may be noted. On fluoroscopic examination, pulsations may be noted in the sac; diagnosis may be confirmed by myelography or MRI.

When diagnosis is securely established, no therapy is indicated unless the lesion is symptomatic. Operative complications such as empyema, meningitis, and spinal fluid fistula have been greatly reduced with appropriate antibiotic therapy.

## Primary Cardiac and Pericardial Tumors

Primary tumors of the heart in infants may cause cardiac enlargement or enlargement of the cardiac silhouette, giving rise to symptoms in the lungs or esophagus. Usually the signs and symptoms of congestive heart failure are much more prominent than those of tumors of the respiratory system or esophagus.

Rhabdomyoma appears to be the only cardiac tumor showing a definite predilection for the younger age groups. This is particularly true of children with tuberous sclerosis, in whom rhabdomyoma of the heart is prone to occur. Such tumors are not considered true neoplasms and probably represent an area of developmental arrest in the fetal myocardium. It is not unusual for rhabdomyoma to regress spontaneously without having caused any appreciable impairment of cardiac function.

Myxoma is by far the most common primary tumor of the heart, accounting for slightly more than half of all primary cardiac tumors. It may be encountered at almost any age. The signs and symptoms vary widely but ultimately lead to cardiac failure that does not respond to the usual medical management. Most myxomas are in the atria, more frequently on the left than on the right. They tend to proliferate and project into the chambers of the heart, preventing normal cardiac filling by obstruction to the mitral or tricuspid valve. The origin appears to be in the atrial septum. Excision on cardiopulmonary bypass is curative.

Primary sarcoma of the heart is less common than myxoma but may occur at any age. As a rule, it does not proliferate into the chambers of the heart; it infiltrates the wall of the myocardium and frequently extends into the pericardial cavity.

An aggressive surgical approach is advised in the management of these cardiac tumors, using a variety of surgical techniques ranging from hypothermic circulatory arrest, on pump excision, and even cardiac autotransplantation.

Primary neoplasms of the pericardium are rare. On histologic examination, the predominant tumors are mesotheliomas (endotheliomas) and sarcomas, but leiomyomas, hemangiomas, and lipomas occasionally occur. Several case reports of pericardial hemangiomas have been reported in the literature, occurring in any age group. Cavernous hemangiomas are the most common type to present in this location, usually arising from the visceral pericardium.[37,38]

## Tumors of the Diaphragm

Tumors involving the diaphragm may cause chest pain and discomfort or pulmonary compression; thus they may simulate mediastinal or primary pulmonary neoplasms. Primary tumors of the diaphragm are extremely rare in the pediatric age group, with 41 cases reported in the world literature.[39]

Benign tumors of the diaphragm that have been reported, though not necessarily in children, are lymphangioma, hemangioma, lipoma, fibroma, chondroma, angiofibroma, neurofibroma, rhabdomyofibroma, fibromyoma, and primary diaphragmatic cysts.

Malignant tumors of the diaphragm that have been reported are rhabdomyosarcoma, fibrosarcoma, myosarcoma, leiomyosarcoma, and fibromyosarcoma. None of these tumors appear to have been reported in children.

## General Approach to Evaluation of Children With Suspected Tumors of the Chest

Infants or children presenting with respiratory symptoms should be first worked up in the usual manner for common respiratory illnesses. Those who do not recover promptly when treated appropriately, with the use of therapies such as expectorants, bronchodilators, and antibiotics, should be suspected of having a space-occupying lesion. The location, tissue type, and rate of growth will all affect whether a chest mass will produce symptoms and will also determine the rapidity of onset. A slow-growing space-occupying lesion may have a long indolent course that does not produce symptoms until it reaches a sufficient size. Typical symptoms include shortness of breath, wheezing, repeated infections not amenable to usual treatment, fevers, cough, and hemoptysis. Depending on the location of the lesion, a patient may present with cardiac dysfunction, esophageal involvement causing dysphagia, or growth into the sympathetic chain causing Horner syndrome, for example. The wide differential involving tumors of the chest requires a keen clinical eye to be able to correlate symptom development and progression with the possible location of a chest lesion.

When symptoms persist, a posteroanterior and lateral chest radiograph should be included in the initial workup. Prenatal ultrasound, now routine, has led to a greater understanding of the natural history of lesions presenting in the fetus.

Previously undiagnosed lesions are now seen with increasing frequency. When symptoms present after birth, chest radiographs should be the first step in the diagnostic workup. Only by such techniques can obstructive emphysema (Fig. 74.19), atelectasis (Fig. 74.20), and actual solid masses be seen at a stage of development when a resection may offer some hope of cure (Figs. 74.21–74.25).

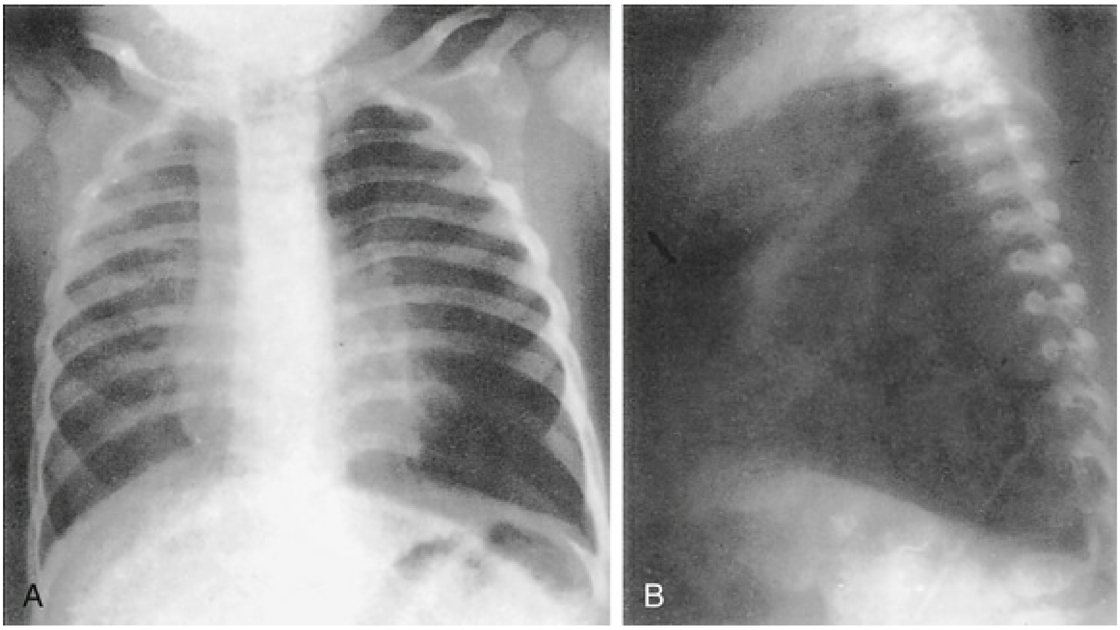

**FIG. 74.19** Chest radiograph revealing obstructive emphysema of the left lower lobe bronchus caused by partial occlusion of the lumen. (A) Posteroanterior view. (B) Lateral view. The left diaphragm is flattened, mediastinal and cardiac shadows are displaced toward the right, the left upper lobe is compressed, and there is increased radiolucency of the left lower lobe.

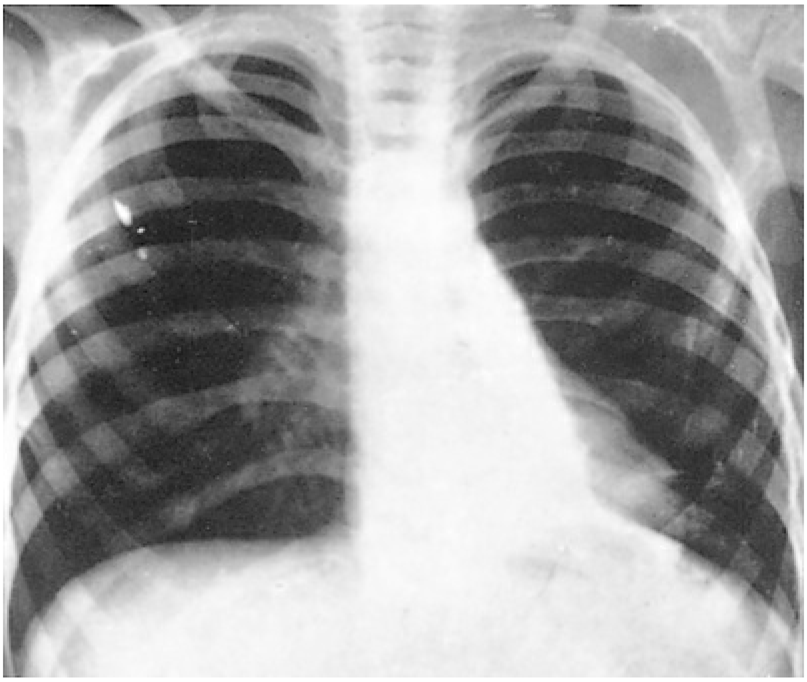

**FIG. 74.20** Chest radiograph revealing total atelectasis of the left lower lobe secondary to an inflammatory stricture of the left lower lobe bronchus. A retrocardiac position tends to confuse diagnosis in some cases.

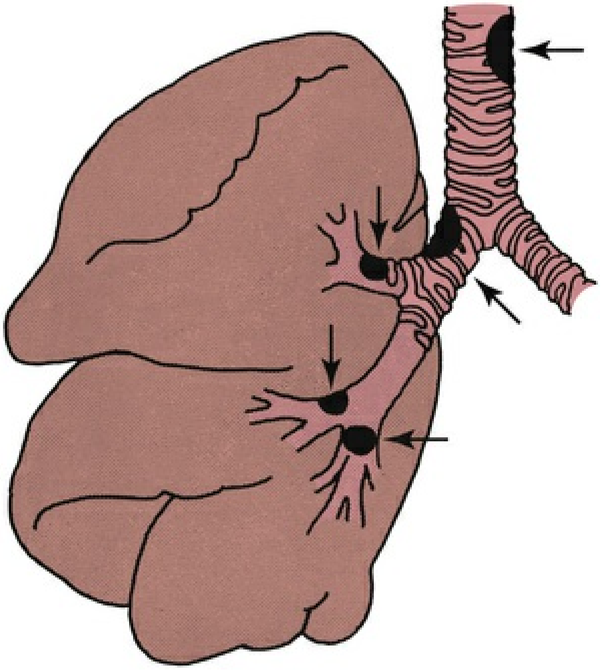

**FIG. 74.21** Diagram illustrating locations of lesions within the lumens of the major bronchi. The location of such lesions dictates the area of pulmonary involvement, unilaterality or bilaterality, and the extent

of signs and symptoms.

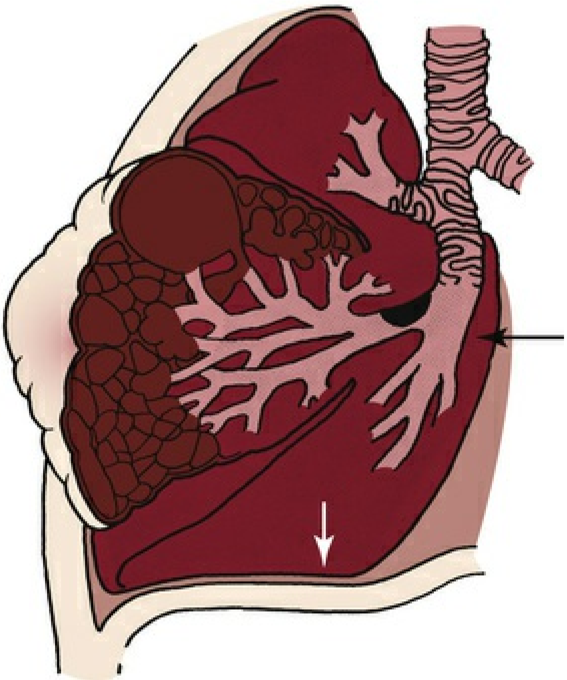

**FIG. 74.22** Diagram illustrating obstructive emphysema. A partial obstruction leads to the retention of air in the pulmonary parenchyma distal to the obstructed bronchus. Retention of air will cause an ipsilateral compression of the adjacent normally aerated lung tissue, widening of intercostal spaces, descent of the diaphragm, a shift of the mediastinum away from the lung with the partially obstructing lesion, and a wheeze accompanied by decreased breath sounds over the affected lung.

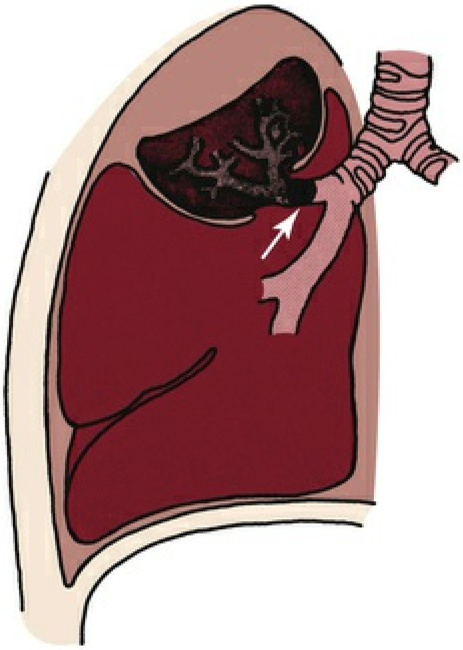

**FIG. 74.23** Diagram illustrating that persistence of a lesion with ultimate total obstruction gives rise to atelectasis, an absence of breath sounds over the affected lung tissue, an overexpansion of the surrounding lung tissue, and a shift of the diaphragm to a more normal position, with a return of the mediastinum to midline. Bronchial secretions may actually decrease in amount.

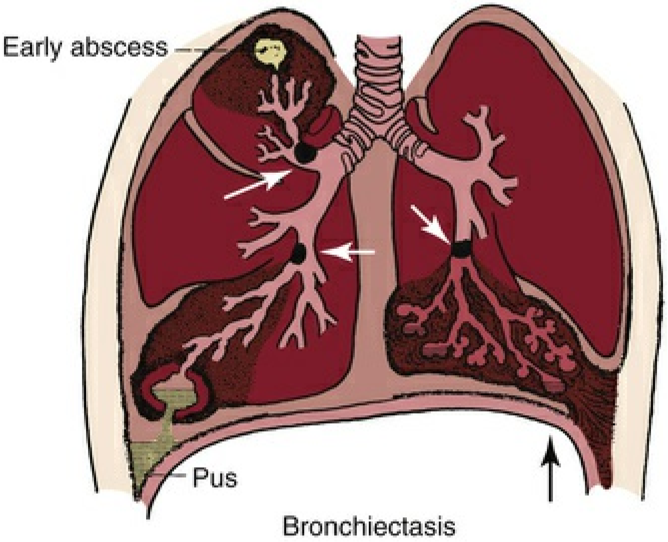

**FIG. 74.24** Diagram illustrating that persistence of an obstructing lesion leads to permanent destructive changes in the pulmonary parenchyma distal to the lesion, such as abscess formation, chronic

pneumonitis with fibrosis, pleurisy, empyema, and bronchiectasis, with parenchymal contracture secondary to fibrosis.

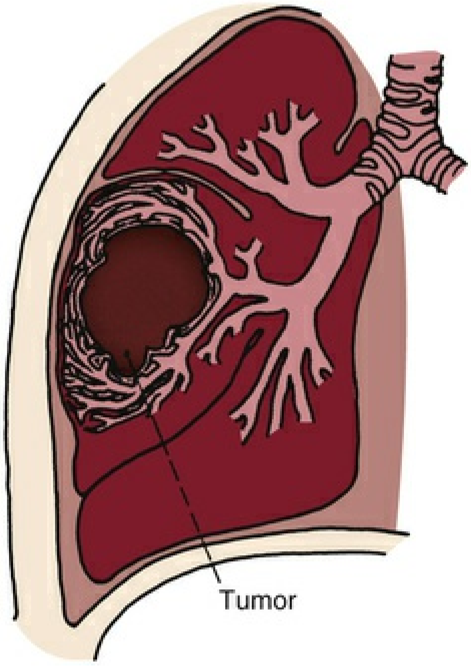

**FIG. 74.25** Diagram illustrating that if a tumor is within the pulmonary parenchyma, pressure on the adjacent lung and bronchi will give rise to a surrounding zone of pneumonitis that may actually show incomplete, temporary improvement with antimicrobial therapy.

In addition to undergoing an exhaustive history and physical examination, children with persistent symptoms and radiographic lesions should have other studies to rule out infections (e.g., mycobacterial or fungal) and genetic lung disorders. Examination of the bone marrow may give diagnostic evidence of a blood dyscrasia (e.g., leukemia or myeloma) or even metastatic malignancy, such as neuroblastoma.

Radiographic examination of the chest with special views such as apical lordotic and right and left oblique may be required. In addition, other imaging techniques such as ultrasound, CT, or MRI may be necessary for final definition. Ultrasonography is useful in locating and assisting in the needle aspiration of pleural fluid collections (Fig. 74.26). Mediastinal, pulmonary, and diaphragmatic densities are best detailed with axial CT of the thorax, which has added greatly to accuracy in study of all these areas (Figs. 74.27–74.29). MRI has had a substantial impact on thoracic diagnostic workup in the last decade. It can distinguish masses in the mediastinum from vascular structures and is more sensitive than CT in detecting intraspinal extension. The two studies may be complementary, since CT demonstrates calcifications and bronchial abnormalities that are not seen on MRI. Thoughtful use and sequencing of these studies should be based on the location of the abnormality and a provisional working diagnosis, given the risk of radiation dose with different imaging modalities.

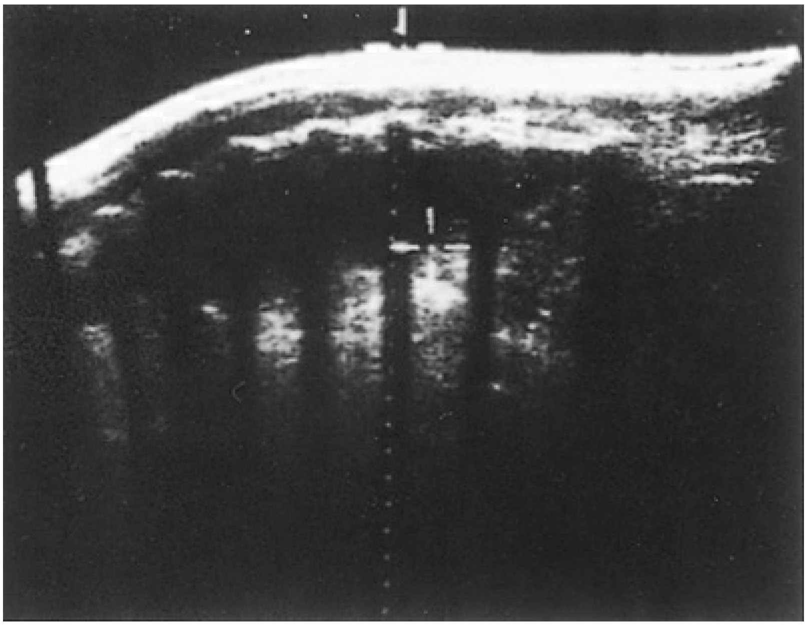

**FIG. 74.26** Typical ultrasonogram of pleural fluid. With such accurate localization, needle aspiration is easily carried out.

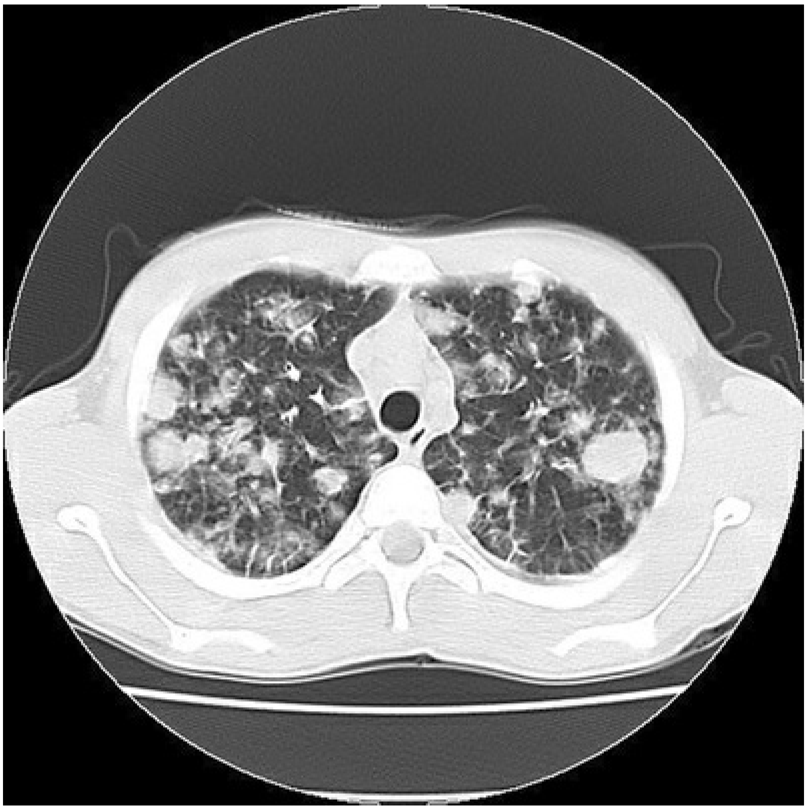

**FIG. 74.27** Computed tomography study of the chest showing metastatic pulmonary disease in a 14-year-old boy with testicular rhabdomyosarcoma.

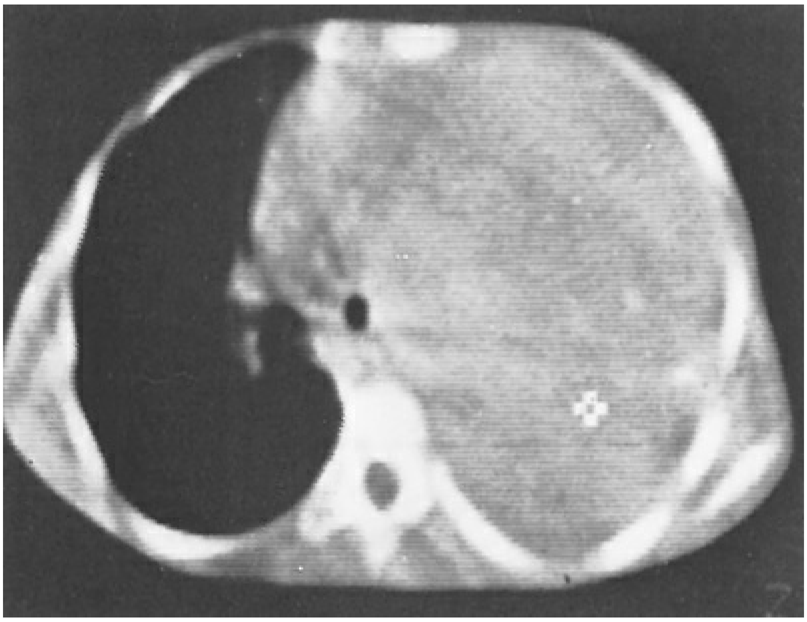

**FIG. 74.28** Computed tomography scan of a child with small-cell carcinoma.

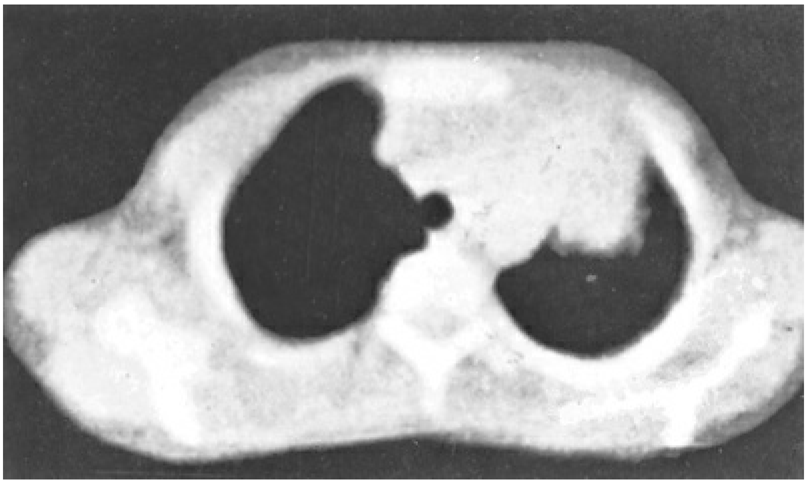

**FIG. 74.29** Computed tomography scan of the mediastinum and lung in a child with Hodgkin disease.

Echocardiography and occasionally cardiac catheterization demonstrate any displacement of the heart due to masses in the lung, mediastinum, or pericardium. Esophagrams are used to identify vascular rings, along with CT angiograms or magnetic resonance angiograms (MRA) of the chest. Aortograms may be used to define bronchial arteries in patients with massive hemoptysis and can assist with the diagnosis of congenital vascular malformations of the pulmonary tree and congenital sequestration.

Bronchoscopy is an essential procedure for the study of the tracheobronchial tree. This procedure permits visual study of the vocal cords, larynx, trachea, and major bronchi, and their segmental orifices. Congenital anatomic abnormalities may be visualized; prognosis in extensive lesions is evaluated by study of the carina and trachea. Bronchoscopy-guided transbronchial biopsy has been described in children for the diagnosis of chronic bronchiolitis, sarcoidosis, interstitial lung disease, and acute rejection in transplant recipients.[40,41] There are reports of resecting mass lesions bronchoscopically with the aid of energy hemostasis (usually laser). Aspiration of secretions is another potential therapeutic contribution from bronchoscopy. Bronchoalveolar lavage (BAL) allows sampling from distal airways and alveoli; investigation must include cytologic studies for malignant cells, routine bacterial smear, culture and sensitivity studies, acid-fast smear and cultures, and fungal smear and cultures.

Biopsy of palpable lymph nodes may aid in the diagnosis of abnormal processes in the lung. The scalene lymph nodes are usually the primary target because they drain the pulmonary parenchyma. Scalene lymph node biopsy, mediastinoscopy, or, now more directly, thoracoscopy with biopsy of available mediastinal nodes are of great assistance in the diagnosis of sarcoidosis, in lymphatic malignancies (e.g., Hodgkin disease) and lymphosarcoma, and in primary neoplasms of the lung and mediastinum. CT-guided percutaneous biopsy is now common in children, with a reported diagnostic rate of 85%.[42]

Lymph nodes obtained at the time of biopsy should be subjected to histologic study, and a portion must be sent to the bacteriology laboratory for routine bacterial smear and culture, studies for sensitivity of the organism to antimicrobials, acid-fast smear and culture, and fungal smear and culture (Fig. 74.30).

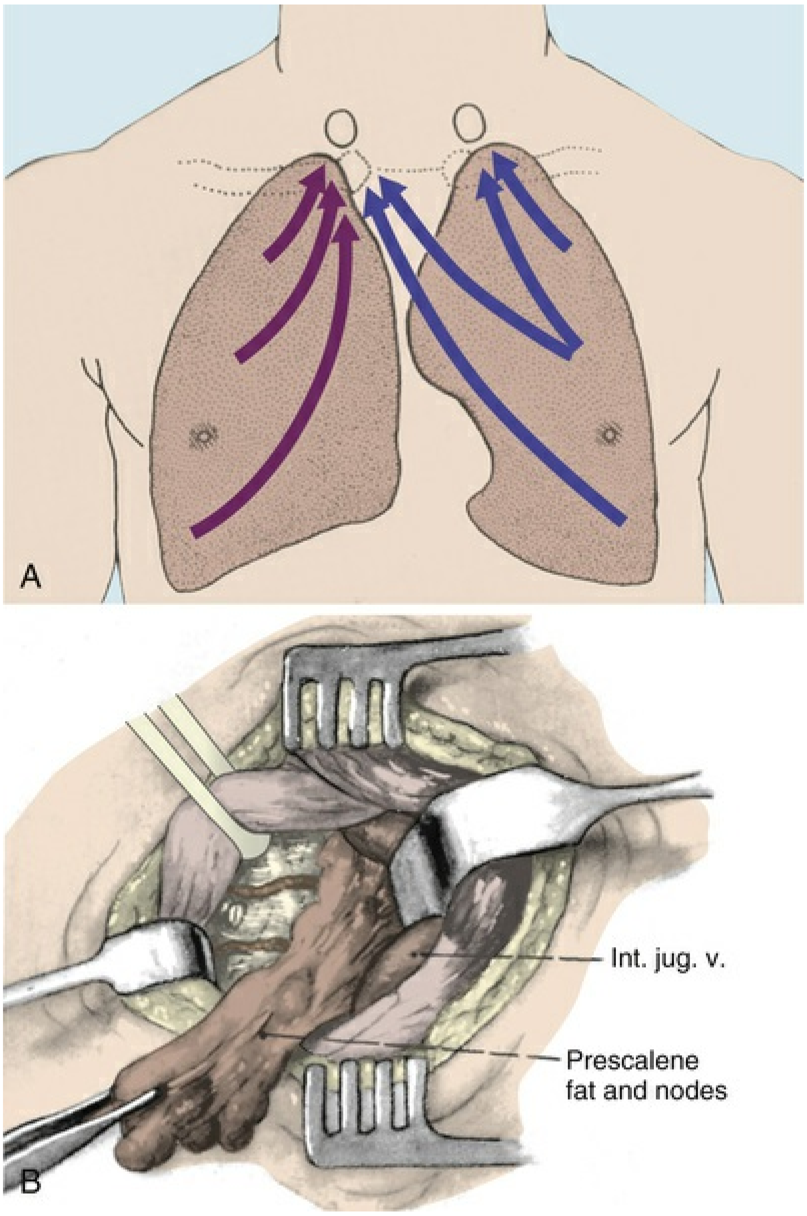

**FIG. 74.30** (A) Disease within the right lung usually drains into the right scalene lymph node group. Disease within the left lung may drain to either scalene node group in a pattern similar to that indicated on the illustration. Generally, left lung disease requires bilateral scalene node biopsy, whereas right lung disease requires only right scalene node biopsy. Regardless of the side of lung disease, all palpable nodes in the scalene node area should be examined by biopsy. (B) The scalene group of nodes is contained in the fat pad bounded medially by the internal jugular vein, inferiorly by the subclavian vein, and superiorly by the posterior belly of the omohyoid muscle. The base of the triangle is formed by the anterior scalene muscle. Retraction of the internal jugular vein is

essential to obtain access to all nodes in this group.

When all other methods have failed to produce a definitive diagnosis, thoracoscopy or thoracotomy should be considered. The use of single-lung ventilation (selective bronchial intubation or the use of balloon occlusion catheters) and preoperative placement of a radiologically guided blood patch can greatly facilitate the pursuit of tiny lesions. If the situation seems to present an inoperable problem, biopsy may still afford useful information (Fig. 74.31).

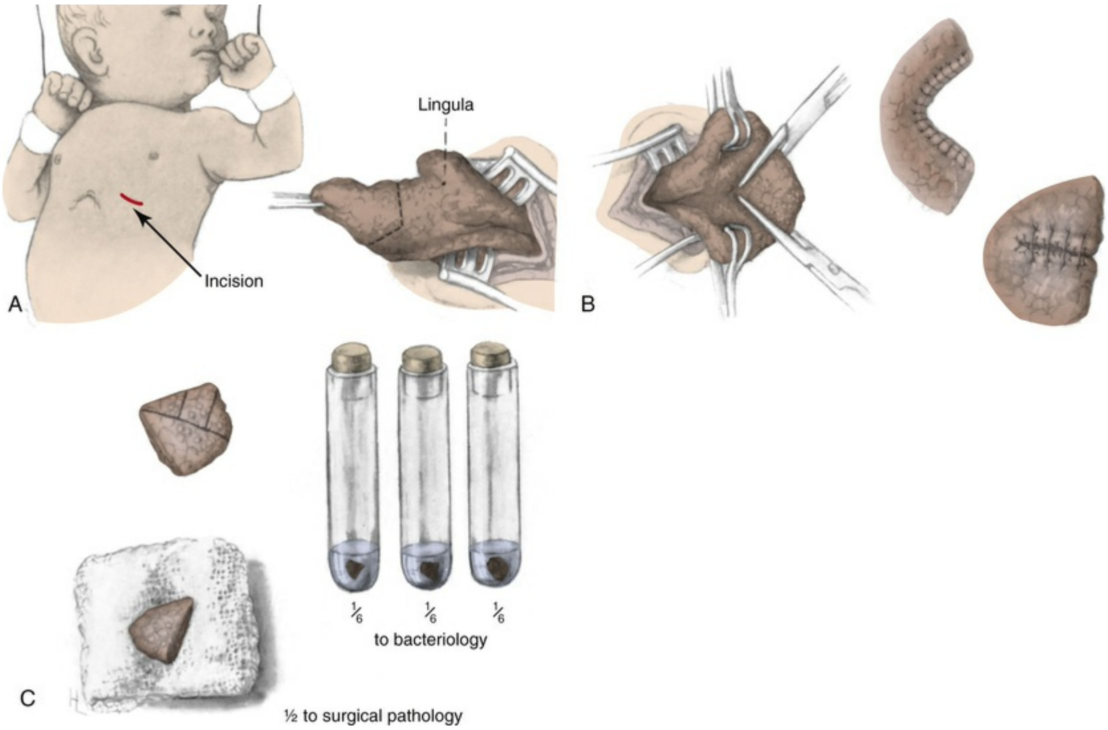

**FIG. 74.31** (A–C) An adequate lung biopsy with specimens for bacteriology and pathology laboratories is essential. In general, a small open thoracotomy has many advantages over the blind needle biopsy technique.

While thoracoscopy has been in use for a century, its use in children is a little over 3 decades old. Today it is the *primary mode of treatment* for not only limited procedures such as biopsy, decortication, and bleb resection but also for more extensive operations such as lobectomy, pneumonectomy, thymectomy, and repair of tracheoesophageal fistula.[43] Its rise has been facilitated by several technological improvements, including improved optics and light sources, and the development of specially designed instrumentation including hemostatic energy sources. Endoscopic linear staplers have made wedge biopsies and resections safe and simple procedures, leading many physicians to aggressively treat tumors that they may have just observed in the past.[44]

## Management and Treatment of Thoracic Tumors

Due to the wide differential diagnosis involving potential masses in the chest, prompt diagnosis is essential in determining the correct course of treatment. Lesion-specific treatments have already been previously discussed in their respective sections. In general, a good starting point is to determine whether a lesion is benign or malignant, to decide if the potential morbidity and possible mortality of a surgical resection is warranted, particularly given the preponderance of vital structures within the chest. Treatment also depends on whether the space-occupying lesion is causing symptoms. In cases of clear malignancy, treatment options have often been clearly delineated. However, as discussed previously, with lesions such as plasma cell granulomas and lipomas, a sizable percentage of these masses can be completely asymptomatic and discovered incidentally. In such cases, where lesions appear benign, not enlarging, and not producing any symptoms, there can be benefit in watchful waiting without aggressive therapy that may potentially result in undue harm. Another important consideration in the pediatric population is whether the lesion will regress over time like a hemangioma.

Ultimately masses in the chest often require a multidisciplinary approach, given the wide differential diagnosis of chest tumors in the pediatric population. Management, including whether surgical biopsy or resection is indicated, should include consultation from a broad range of subspecialties, which may include pulmonology, anesthesia, oncology, pediatric general surgery, cardiothoracic surgery, and neurosurgery. This may require transfer to a tertiary care center that specializes in treatment of these, often rare entities. While the scope of the differential diagnosis can be large, a careful, studied approach can ascertain the correct diagnosis and a multidisciplinary approach can lead to an effective approach that brings maximum benefit to the patient.

## Acknowledgments

We would like to acknowledge Dr. Thomas M. Krummel and Dr. Timothy A. Plerhoples for their significant contributions to this chapter.

## Improving Health Care Value for Complex Patients Through Coordinated Care

*Robin T. Cotton MD, FACS, FRCS(C), Karthik Balakrishnan MD, MPH, FAAP, FACS*

## Historical Perspective

While multidisciplinary coordinated care is rapidly becoming the norm for complex patients and diseases, the Cincinnati Children's Hospital Medical Center aerodigestive model was a pioneering example of this approach. The development of the Cincinnati aerodigestive program was an outgrowth of advances made in the care of premature and critically ill infants, in which significantly increased survival rates led to children presenting with subsequent problems arising from either their underlying conditions or their management. Many children, particularly those with a history of prolonged endotracheal intubation or pulmonary disease, were tracheotomy-dependent and in need of airway reconstruction. Other patients required the care of multiple subspecialists in fields, including otolaryngology, pulmonary medicine, gastroenterology, and surgery. Beyond their anatomic and physiologic problems, many of these children also had functional problems such as oral aversion, feeding difficulty, and aspiration. As a result, these patients presented multiple challenges: complex diagnostic and therapeutic needs, associated social and financial health care burdens placed on their families, and the need for ongoing care across a range of specialties.

In this context, it was essential for involved pediatric subspecialties to develop a model for the delivery of efficient, unfragmented care built on constant communication between specialists and families, longitudinal tracking and follow-up of patients, and coordinated scheduling of appointments, diagnostic tests, and procedures. Since the development of this model at the Cincinnati Children's Hospital Medical Center, it has spread across the country and around the world, with other leading pediatric and adult hospitals adopting very similar approaches to children with complex aerodigestive disorders.

In view of this success, the objective of this section is to provide the reader with more detail regarding the structure of the coordinated aerodigestive care model. We also describe criteria by which we select children who might benefit from this horizontally integrated approach to medical and surgical care.

## Patient Selection

Selection criteria for inclusion of patients in an aerodigestive care program vary between centers. Some centers, particularly those with patients traveling long distances frequently for visits, have developed specific criteria to assist pediatricians and other referring providers in deciding whether a patient might benefit from referrals that could involve significant travel and financial costs. This approach allows patients to avoid visits that may not provide benefit and allows involved specialists to focus on those patients to whom they might offer the most benefit. Other centers have elected to use less specific criteria, improving access for many patients but increasing the number of referrals that may not lead to a comprehensive treatment plan.

Regardless of the specifics of each aerodigestive program, certain characteristics and diseases serve to define "typical" aerodigestive patients (Table 75.1). The reader will notice that these components cover a wide spectrum of patients with interrelated symptoms and pathologies. The pathologies may be congenital, acquired, or a combination of the two.

**Table 75.1**

**Typical Complaints Leading to Aerodigestive Program Referral**

| Category | Common Symptoms/Complaints | Common Etiologies |
|---|---|---|
| Airway | Stridor/noisy breathing<br>Dyspnea with exertion<br>Cyanosis<br>"Dying spells"<br>Tracheostomy/ventilator dependence<br>Voice problems | Airway stenosis<br>Laryngomalacia<br>Tracheomalacia<br>Extrinsic airway compression<br>Vocal fold hypomobility/immobility<br>Vocal fold scarring<br>Nasal obstruction (in neonates and infants) |
| Pulmonary | Supplemental oxygen requirement<br>Ventilator dependence<br>Frequent respiratory infections | Bronchopulmonary dysplasia<br>Aspiration<br>Bronchiectasis<br>Chest wall abnormalities<br>Primary ciliary dyskinesia<br>Immunodeficiency |
| Gastrointestinal and swallowing | Oral aversion<br>Poor feeding<br>Choking<br>Aspiration<br>Dysphagia | Functional swallowing disorders<br>Neurologic/neuromuscular diseases<br>Laryngeal cleft<br>Tracheoesophageal fistula<br>Vocal fold disorders<br>Eosinophilic esophagitis<br>Reflux<br>Esophageal stricture<br>Esophageal dysmotility<br>Poor gastric emptying<br>Cricopharyngeal disorders |
| Sleep apnea | Central sleep apnea<br>Obstructive sleep apnea | Multiple |

## Screening and Evaluating Potential Patients

Potential patients from either within or outside the institution are initially screened via a detailed telephone intake interview by a registered nurse or nurse practitioner who will remain the patient's main contact point throughout their aerodigestive care cycle. Information obtained at this stage provides a basis for a preliminary evaluation and management plan. After a thorough review of the patient's medical history, a lead physician is chosen based on the patient's primary presenting problem. At weekly interdisciplinary meetings involving all participating specialties, the patient's lead physician and designated nurse practitioner discuss ongoing clinical issues with other team members and finalize a diagnostic plan. The recommended tests and procedures are then scheduled in a coordinated fashion so as to minimize travel and time burdens on patients and their families, eliminate unnecessary visits to the hospital, and avoid the repeated use of anesthetics.

After the initial diagnostic assessment, team members conduct a thorough review of diagnostic results at weekly meetings to develop a comprehensive management plan. This plan is then communicated to the patient and family by a team representative (usually the nurse practitioner). Further scheduling and execution of the treatment plan is carried out through close collaboration among all team participants.

## The Interdisciplinary Team

Ideally, the interdisciplinary team should comprise physicians and other professionals with expertise in the evaluation and treatment of these challenging patients. Subspecialists play a major role in patient care in otolaryngology, pulmonary medicine, gastroenterology, surgery, and anesthesia; the care they provide is coordinated by nurse practitioners and nurses. Intensivists, radiologists, geneticists, and pediatricians with expertise in developmental and behavioral issues are also key team members, as are speech language pathologists and dieticians with expertise in pediatric care. Other interdisciplinary programs (e.g., the feeding team and sleep center) provide care for selected patients; a wide array of other health professionals becomes involved as needed (Fig. 75.1).

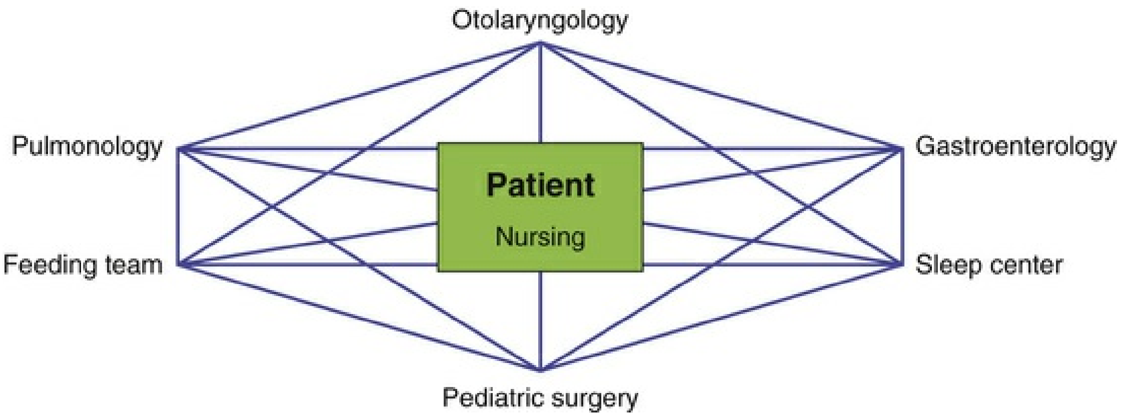

**FIG. 75.1** Schematic representation of cross-specialty relationships in the interdisciplinary aerodigestive care model.

Assembling a successful aerodigestive team requires not only recruiting necessary personnel, but active engagement of every team member as well as the patient and family. Recent data on multidisciplinary pediatric care suggest that successful multidisciplinary teams develop specific cultural and professional attitudes that facilitate this approach to care. These characteristics may include a culture of respect, a sense of individual provider responsibility and ownership within the larger group, equal partnership between team members, and active involvement of parents in the care process.[1] Furthermore, such teams can evolve and become more effective over time, particularly if team members embrace the idea of ongoing shared learning and improvement.

## Value in Coordinated Aerodigestive Care

The concept of value has gained traction in many areas of health care, to the point that "value-based payment" is steadily being incorporated into government and private reimbursement plans and used as a method to promote efficient care.[2,3] On the most basic level, value is defined as health outcomes achieved compared with costs of care.[4] Increasing value therefore requires improved outcomes (with a comparatively smaller increase in costs), reduced costs (without worse outcomes), or ideally both. Analyses of these components of value suggest that coordinated multidisciplinary care in certain settings may provide both improved diagnosis and treatment and reduced provider time requirements and associated costs.[5,6] Some reports also suggest improved clinical outcomes; for example, in pediatric patients with diabetes and obesity.[7–9]

In the case of patients with complex airway and swallowing problems, formal studies of the effects of multidisciplinary care on outcomes and costs are lacking. However, some data suggest that benefits of patient-specific coordinated care plans may be particularly evident for complex patients and for patients who are higher health care utilizers.[10] Early studies specifically targeting aerodigestive patients suggest that charges, while a poor proxy for actual costs, may be decreased through this approach.[11,12] Similarly, the number of clinic visits and anesthetic episodes appear to decrease when multidisciplinary aerodigestive care is provided, compared with theoretical estimates for noncoordinated care.[13] Early reports on diagnosis, treatment, and outcomes in multidisciplinary aerodigestive care are also encouraging.[14–16]

It is worth noting that as aerodigestive programs develop within their respective institutions, they may evolve and transform further to add even greater value. For example, in 2013, the Cincinnati Children's Hospital Medical Center aerodigestive program (formerly the Aerodigestive and Sleep Center) divided into the current Aerodigestive and Esophageal Center and the multidisciplinary Upper Airway Center. The latter program focuses on sleep apnea and upper airway obstruction, and complements the activities of the aerodigestive program by providing additional otolaryngology, pulmonology, and neurology expertise in conditions that affect many children with and without aerodigestive disorders.

## Summary

Advances in neonatal and pediatric medicine over the past four decades have created a growing population of children and adolescents who suffer from complex disorders involving the airway and aerodigestive tract. Our experience agrees with published data suggesting that optimal patient-centered care is best provided through a coordinated interdisciplinary team approach.

This approach has the potential to improve diagnostic and therapeutic outcomes, to reduce burden on patients and families, and to reduce costs of care. We therefore suggest that multidisciplinary coordinated aerodigestive care is an appropriate and high-value strategy, particularly for these complex and resource-intensive patients.

# Aspiration

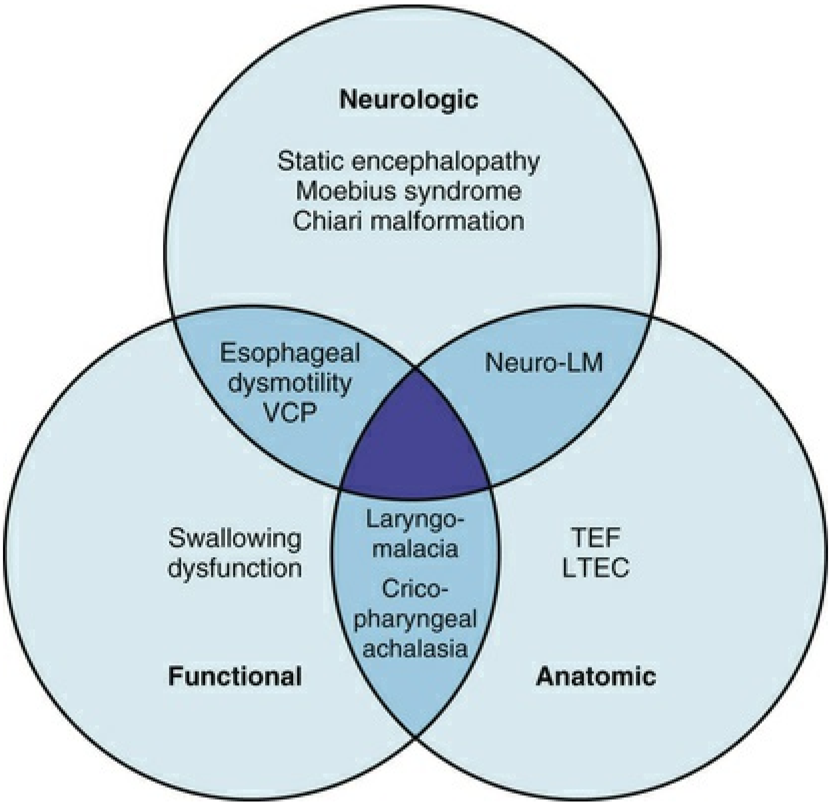
*R. Paul Boesch DO, MS, Emily M. Deboer MD*

## Introduction

Aspiration refers to the penetration of material below the subglottic area and into the lower airways. There are two main aspiration syndromes: (1) an acute aspiration event quickly progressing to acute pneumonitis and possibly respiratory failure, and (2) chronic repeated aspiration of very small volumes that leads to a persistent smoldering inflammatory state and eventually results in chronic lung injury. Acute aspiration of a large volume of gastric contents or even small volumes of hydrocarbon-containing liquids induces a severe toxic injury to airway mucosa with mucosal edema, bronchorrhea, and airway obstruction. Injury to terminal respiratory units causes pulmonary edema and an acute respiratory distress syndrome (ARDS)-like presentation that may be life-threatening.[1,2] Injury to terminal respiratory units is more common with hydrocarbon aspiration as the volatile liquid produces a vapor that is subsequently inhaled deeper into the lungs; long-term pulmonary fibrosis may follow hydrocarbon aspiration. Nonvolatile lipid-containing liquids (e.g., mineral oil) are not absorbable, and aspiration results in persistent lipoid pneumonia, bronchiolar obstruction, and chronic lung injury. For lipoid pneumonia, repeated bronchoalveolar lavage (BAL) may be both diagnostic and therapeutic.[3]

Chronic pulmonary aspiration is a common problem in pediatrics and remains a diagnostic and therapeutic challenge. Chronic aspiration is almost always a consideration in the evaluation of the "aerodigestive" patient and therefore will be the focus of the remainder of this chapter.

Chronic pulmonary aspiration represents the repeated passage of food material, gastric refluxate, or saliva into the subglottic airways in sufficient quantities to cause chronic or recurrent respiratory symptoms.[4,5] Aspiration results from failure of the airway protection that occurs in the setting of repeated opportunities for aspiration to occur. These opportunities may be nearly continuous, such as with severe hypopharyngeal pooling of oral secretions, or intermittent, such as with reflux of gastric contents above the upper esophageal sphincter or with swallowing dysfunction. Aspiration may be limited to specific consistencies, such as during swallowing of thin liquids. In general, aspiration is the result of one or more of the following: anatomic abnormalities within the aerodigestive tract, disruptions of the complex neurologic sensorimotor networks of swallowing and respiration, or functional disorders of the esophagus or muscles of deglutition (Fig. 76.1).



Neurologic
Static encephalopathy

Chronic aspiration is very common in aerodigestive patients, as they generally present with complicated underlying medical conditions, including feeding failure, gastroesophageal reflux (GER), neurologic injury, chronic respiratory disease, tracheostomy, impaired laryngeal function, and airway lesions resulting in obstructed breathing, or abnormal connections between the airway and gastrointestinal tract. Aspiration is more common in patients with certain congenital syndromes or in those born very prematurely. Because of their complex multisystem disorders, it may be difficult to distinguish between the symptoms of other underlying conditions (e.g., bronchopulmonary dysplasia or tracheobronchomalacia) and chronic aspiration. The symptoms of chronic aspiration are common to many respiratory conditions, and a reliance on symptoms of dysphagia and recurrent pneumonias will fail to identify many children with significant chronic lung injury from aspiration. The most common symptoms of chronic aspiration include: chronic cough, wheezing, congestion, choking or gagging with feeds, failure to thrive, apnea, intermittent fever spikes, and recurrent chest infections. The parental report of “wet vocal quality” or “wet breathing” may be the most predictive symptoms of aspiration.[6]

Chronic pulmonary aspiration can result in significant morbidity. Children may be hospitalized for recurrent pneumonias and commonly develop progressive lung injury and bronchiectasis. Significant bronchiectasis may persist into adulthood and result eventually in respiratory failure. Chronic pulmonary aspiration is the leading cause of death in neurologically impaired patients and those with congenital syndromes such as Cornelia de Lange and Cri du Chat.[7,8] Some children, particularly those without neurologic injury, are diagnosed inappropriately as having asthma and may develop irreversible lung injury before chronic aspiration is suspected, identified, and treated. The histopathology of chronic aspiration is that of bronchiolocentric organizing pneumonia with giant cells and granuloma formation; the gold standard diagnosis is identification of vegetable matter (Fig. 76.2).[9–12] This correlates with findings of bronchiolar obstruction and injury seen on high-resolution computed tomography (CT) of the chest: centrilobular (“tree-in-bud”) opacities, and bronchiectasis.[10,13,14] In animal models of chronic aspiration, repeated aspiration of small food particles results in the greatest injury as a chronic foreign body reaction causes damage to the architecture of the lung parenchyma. In mouse models of a single small aspiration event, the inflammatory response to small food particles is amplified by acidification of the aspirated material.[15]

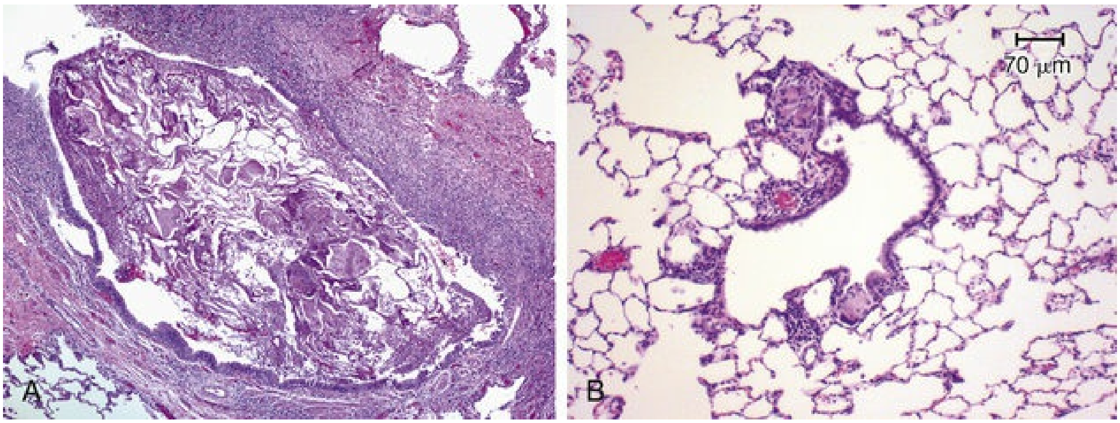

**FIG. 76.2** Histopathology of chronic aspiration. (A) Lung biopsy from a 6-year-old suspected of interstitial lung disease but found to have bronchiolocentric inflammation filling of the airway lumen with inflammatory cells, giant cells, and vegetable matter. (B) Early development of peribronchiolar inflammation with giant cells in a 10-week-old rat following tracheal instillation of 0.4 mL/kg of soy infant formula and ground rat chow 3 times a week for 6 weeks.

## Aspiration Caused by Swallowing Dysfunction

Normal swallowing is a complex process that is dependent upon intact anatomy and well-organized sensory and motor function of specific cranial and cervical nerves. The oral phase is voluntary and includes acceptance and preparation of the food bolus, which includes sucking or chewing and manipulating a bolus on the tongue. The bolus is usually delivered to the pharynx in voluntary fashion, but premature spillage of material into the hypopharynx can occur if oral movements are not coordinated. Once bolus delivery occurs, the involuntary pharyngeal phase is triggered and airway protection takes place. This is a sequential event involving cessation of respiration, adduction of the true vocal folds in association with horizontal approximation of the arytenoid cartilages, closure of the false vocal folds, and retroversion of the epiglottis. The combination of elevation of the larynx and contraction of intrinsic laryngeal muscles allows the epiglottis to serve as a gutter, diverting food and liquids laterally into the pyriform sinus region. The larynx is elevated under the base of the tongue, facilitating the stretching and opening of the cricopharyngeus, as the pharyngeal constrictors shorten the pharynx and propel the bolus through the upper esophageal sphincter. Once passage of the bolus occurs, the larynx returns to its resting position and the airway reopens. The bolus is subsequently transported to the stomach by peristalsis, aided by gravity. Protection against aspiration is provided by the functional anatomy of swallowing and by protective reflexes; any breakdown in the structure, effectiveness, or coordination of these components may result in failure of safe swallowing. A more complete description of the swallowing process and mechanisms of aspiration during swallowing can be found in Chapter 77.

## Development of Swallowing

Development of swallowing begins early in fetal life, and the aerodigestive tract development is integrated with that of the respiratory centers of the brainstem. Central pattern generation in the brainstem controls and coordinates movements of mastication, respiration, and deglutition through adaptive networks of interneurons densely bundled within the nucleus ambiguus and nucleus tractus solitarius.[16,17] Ultrasound studies have demonstrated pharyngeal swallowing as early as 10 to 14 weeks gestation, nonnutritive sucking and swallowing at 15 weeks, and sucking with anterior to posterior tongue movements between 18 and 24 weeks gestation. At 26 to 29 weeks gestation, reflexes between taste buds and facial muscles can be demonstrated, and nonnutritive sucking on a pacifier may be observed. Some infants can feed by mouth at 32 to 33 weeks, although 34 weeks is the earliest that infants can sustain full nutrition and hydration orally. At 34 weeks, sucking becomes more rhythmic and organized. Beyond term, swallowing matures, characterized by increased sucking and swallowing rates, longer sucking bursts, and larger volumes per suck. At 3 to 4 months of age, lateral tongue movements aid in bolus formation, allowing children to eat pureed consistency from a spoon by 6 months of age.

## Swallowing Dysfunction in Specific Populations

Chronic pulmonary aspiration secondary to swallowing dysfunction most often occurs secondary to central or peripheral neurologic disease, functional immaturity, or anatomic limitations (Box 76.1). While most children who aspirate have some combination of these factors, there are children who have swallowing dysfunction (usually delayed initiation of swallowing) with aspiration sufficient to cause chronic respiratory symptoms and lung injury without any identifiable anatomic, neurologic, or developmental limitations.[18–20] These children may require gastrostomy tube placement, but generally the swallowing dysfunction resolves between 2 and 3 years of age.

### Box 76.1

### Conditions Associated With Chronic Pulmonary Aspiration

- Prematurity
- Congenital anatomic abnormalities
  - Esophageal atresia
  - Tracheoesophageal fistula
  - Laryngotracheoesophageal cleft
  - Choanal stenosis or atresia

- Cleft palate
  - Macroglossia
  - Laryngomalacia
  - Micrognathia
  - Vascular ring
  - Tracheal stenosis
  - Cystic hygroma
  - Laryngeal/pharyngeal vascular malformation
- Acquired anatomic abnormalities
  - Laryngeal/pharyngeal tumors
  - Laryngeal/pharyngeal trauma
  - Tracheostomy
- Congenital syndromes
  - CHARGE association
  - Möbius
  - Pfeiffer
  - Cornelia de Lange
  - Cri du chat
  - Down syndrome
- Gastrointestinal
  - Esophageal dysmotility
  - Esophageal foreign body
  - Cricopharyngeal achalasia
  - Gastroesophageal reflux
- Central nervous system
  - Depressed consciousness
  - Static or progressive encephalopathy
  - Traumatic brain injury
  - Cerebrovascular accident
  - Hydrocephalus
- Peripheral neurologic
  - Arnold Chiari malformation
  - Vocal cord paralysis
  - Neurologic-variant laryngomalacia
- Neuromuscular
  - Muscular dystrophy
  - Myotonic dystrophy
  - Spinal muscle atrophy

Myasthenia gravis
Guillain-Barré syndrome
Otherwise normal child with isolated aspiration

The newborn infant and especially the preterm infant are particularly susceptible to aspiration caused by tenuous coordination between sucking, swallowing, and breathing. Children and adults typically initiate swallowing during the mid-expiratory phase, with an obligatory deglutition apnea, followed by further expiration to help prevent aspiration of residual liquid.[21,22] Term infants younger than 6 months of age will most often swallow at the very end of inspiration and the onset of expiration.[22] Premature infants have more varied phase relationships due to variable rates of development of coordination between central deglutition and respiration.[23,24] Fatigue of the swallowing mechanism can also develop toward the end of a prolonged feeding session, especially in infants with respiratory disease and increased work of breathing.

Chronic aspiration is highly prevalent in children with neurologic impairment, such as static encephalopathy and neuromuscular disorders. Children with neurologic impairment frequently require prolonged feeding times. Choking with feeding, chest infections, and dysphagia may be present in nearly all children with severe cerebral palsy.[25–27] Aspiration may occur before, during, or after a swallow and often does not provoke cough clearance. Common mechanisms include poor oral preparation, neck extension impairing laryngeal elevation, premature spillage of liquids, poor pharyngeal clearance with excessive residual, and poor esophageal opening.[28] Aspiration is the most common cause of death in these patients.[29] Children with Down syndrome are at increased risk for aspiration, and an instrumental evaluation of swallowing is indicated in all infants with marked hypotonia, slow feeding or choking, persistent respiratory symptoms, and unexplained failure to thrive.[30] This population may have anatomic, neurologic, and functional abnormalities that place them at high risk of aspiration. The prevalence of feeding disorders is also very high in children and adolescents with inherited neuromuscular disorders, such as spinal muscle atrophy, Duchenne muscular dystrophy, and myotonic muscular dystrophy.[31–34] While some diseases have specific contributing characteristics (e.g., macroglossia in Duchenne muscular dystrophy), nearly all are associated with prolonged transit time, poor laryngeal elevation, decreased pharyngeal squeeze, and persistent pharyngeal residual related to neuromuscular weakness. These patients are particularly subject to fatigue with prolonged oral feeding.

Peripheral neurologic diseases and injury can result in chronic pulmonary aspiration. Vocal cord paralysis (bilateral more than unilateral), which may result from a difficult delivery or surgery within the mediastinum, may interfere with coordination of respiration and swallowing and impair protective posterior glottic closure. Congenital syndromes that result in lower cranial nerve dysfunction, such as Möbius syndrome or CHARGE association (coloboma, heart defect, atresia choanae, retarded growth and development, genital hypoplasia, and ear anomalies), are frequently complicated by chronic aspiration. Among children with CHARGE association, dysphagia and aspiration are as common as most of the major associations.[35,36] Similarly, dysphagia with vocal cord dysfunction, pharyngoesophageal dysmotility, and aspiration can be a presenting feature of Arnold-Chiari malformations due to compression of the brainstem and the subsequent effect on lower cranial nerve function.[37,38] Cricopharyngeal achalasia may be associated with Arnold-Chiari malformation but also may be an independent congenital cause for aspiration.[39–41] Cricopharyngeal achalasia creates opportunities for aspiration due to delayed passage of food bolus into the esophagus and increased pooling of food and oral secretions in the hypopharynx.

Anatomic abnormalities anywhere along the aerodigestive tract may impact deglutition and result in increased risk for chronic aspiration. Children with craniofacial malformations (e.g., choanal stenosis and cleft palate) are susceptible to chronic aspiration caused by decreased coordination of swallowing and breathing. Crowding of the pharyngeal airway caused by macroglossia or retrognathia creates risks for aspiration. Neck cysts and tumors may narrow and distort the upper aerodigestive tract as well as impair the movements of laryngeal and pharyngeal structures of deglutition. These include cystic hygromas, lymphatic malformations, neuroblastomas, and hemangiomata. The upper airway anatomy also can be distorted by caustic ingestion, thermal inhalational injury, or trauma. Lingual and palatine tonsil hypertrophy also may be associated with aspiration, particularly in neurologically impaired patients, and treatment may improve dysphagia.[42,43] Any lesion resulting in persistent or intermittent upper airway obstruction can disrupt the timing of the swallow. Laryngomalacia is the best recognized of these causes, as feeding problems are the second most common presenting symptom after stridor.[44–46] In children with laryngomalacia caused by tight aryepiglottic folds or tall prolapsing arytenoids, surgical treatment can effectively improve both stridor and aspiration.[47] Supraglottoplasty should be considered cautiously, however, in patients with apparent laryngomalacia caused by poor upper airway tone (i.e., “neurologic-variant laryngomalacia”), as aspiration may be worsened following surgery in these patients.

Anatomic abnormalities, such as congenital esophageal atresia with tracheoesophageal fistula (EA/TEF) and laryngotracheoesophageal cleft (LTEC), also result in aspiration during swallowing, though not due to abnormalities in deglutition. These cause direct connections between the esophagus and the airway. EA/TEF is typically detected at birth and repaired. Even after repair, children with EA/TEF often continue to aspirate. The dysphagia associated with repaired EA/TEF is multifactorial and due to not only abnormal esophageal motility and gastroesophageal reflux but also abnormalities of the tracheal wall including tracheomalacia.[48,49] Oropharyngeal dysphagia and oral aversion are also seen in children with repaired EA/TEF with or without associated congenital anomalies. Aspiration of thin liquids drunk quickly is the typical history for a LTEC. H-type TEF and LTEC are difficult to detect, and diligent investigation by a skilled rigid bronchoscopist is generally required. Even mild LTEC (types 1 and 2) may be associated with significant symptoms (e.g., stridor, feeding problems, recurrent respiratory infections), even when radiographic swallowing studies do not demonstrate frank aspiration (Videos 76.1▶ and 76.2▶).[50,51]

Children with tracheostomy tubes are at increased risk for chronic pulmonary aspiration due to their underlying medical conditions as well as the presence of the tracheostomy. The presence of a tracheostomy tube affects many important components of swallowing: impaired laryngeal elevation, alterations in timing, and prevention of the rise in subglottic pressure. While an association between impaired swallowing and the presence of a tracheostomy tube has been documented, there is no study that demonstrates the development of de novo aspiration following tracheostomy placement in children.[52–54] Children with tracheostomies who chronically aspirate may benefit from the use of a one-way speaking valve when anatomically appropriate. This restores physiologic positive end expiratory pressure (PEEP) and allows subglottic pressure to elevate with swallowing. This can also be achieved with positive pressure applied to the tracheostomy tube by continuous positive airway pressure (CPAP) or a ventilator.

## Evaluation of Swallowing

Swallowing function can be evaluated by clinical examination by a trained speech and language pathologist, by radiographic investigation, or endoscopically. Each method has strengths and weaknesses. Clinical evaluations by trained providers provide excellent assessment of feeding behaviors, aversions, and oral motor skills. They can screen for possible aspiration but cannot evaluate silent symptoms. One study reported a negative predictive value of 89% for aspiration of liquids, yet the reported positive predictive value was worse: 54% for liquids and 18% for solids.[55] When the clinical exam suggests aspiration, an instrumental evaluation of swallowing, either radiographic or endoscopic, should be performed to confirm it. Thorough descriptions of radiographic videofluoroscopic swallow studies (also known as modified barium swallows) and fiberoptic endoscopic evaluation of swallowing (FEES; Videos 76.3 and 76.4), which can directly evaluate the oral, pharyngeal, and esophageal phases of swallowing, are reviewed in Chapter 77. Generally, a videofluoroscopic swallow (VSS) study is a standard evaluation for direct aspiration ("from above") for children in whom clinical evaluation has suggested abnormal swallowing.

## Role of Radiographic and Endoscopic Tests in the Evaluation of Aspiration

Radiographic swallow studies and FEES are both valuable tools for the evaluation of deglutition, but they have unique strengths and weaknesses (Table 76.1). They are equally sensitive in their abilities to detect delayed initiation of swallow, penetration, aspiration, and postswallow residue.[56–58] A prospective, randomized trial in dysphagic adults found no differences in pneumonia outcomes whether feeding recommendations were made based on FEES or videofluoroscopic swallow study results.[59] The sensitivity of radiographic swallow studies can be improved by studying many swallows, especially as this may bring out the effects of fatigue. However, radiographic assessment of the child who has not been orally feeding (because of prolonged illness or oral aversions) is very limited. FEES is useful in these situations, as aspiration risk can be evaluated by assessing vocal cord function, excessive pooling of oral secretions, or by placing a few drops of colored food dye on the tongue and observing for aspiration or penetration.[60] Laryngeal sensation and protective reflexes can be further assessed by the addition of sensory testing (FEES-ST) in which graded bursts of air are applied to an aryepiglottic fold while observing for a laryngeal adductor response.[60,61] This allows FEES to evaluate children who may aspirate oral secretions or to assess a nonorally feeding child's safety to begin eating by mouth. Detection of aspiration through a laryngeal cleft can be improved by FEES due to its superior visualization of laryngeal anatomy. FEES is particularly useful in the assessment of postoperative aspiration risk for a child with a high-grade subglottic stenosis in whom airway reconstructive surgery is being planned. Both radiographic swallow studies and FEES are useful and complementary because of the different types of information they provide.

### Table 76.1

**Comparison of VSS and FEES**

| Videofluoroscopic Swallow Study | Fiberoptic Endoscopic Evaluation of Swallowing |
|---|---|
| Improves clinical examination of | Improves the clinical examination of swallowing |

| | |
|---|---|
| swallowing | |
| Evaluates oral, pharyngeal, AND esophageal phases of deglutition | Blind to actual moment of swallow<br>Does not evaluate esophageal phase |
| Limited evaluation of anatomy | Evaluates functional anatomy of swallow |
| Evaluates multiple consistencies | Evaluates multiple consistencies |
| May lack sensitivity: Less eaten → less sensitive | Evaluates airway protective ability and sensation (even if the patient does not eat) |
| Feeding recommendations made at time of study | Feeding recommendations made at the time of study |
| Widely available | Not widely available |
| Radiation exposure | No radiation |
| Not portable, noninvasive | Portable but invasive |
| | Good caregiver feedback |

## Aspiration of Gastroesophageal Reflux

Not all aspiration occurs directly via dysfunctional swallowing. There is a well-documented relationship between GER and chronic respiratory symptoms, such as wheezing, chronic cough, nocturnal cough, apnea, and recurrent chest infections.[62–65] While there are multiple possible mechanisms for GER-related respiratory symptoms, it is clear that chronic aspiration of gastric contents does occur.[66–68] The effect of chronic microaspiration of acidic material on the development of *chronic* lung injury is not entirely clear. With reflux aspiration, there are other factors besides pH; pepsin, bile acids, and food particulates are all present in gastric fluid and may play a role in the pathophysiology of lung injury. Experimental instillation of weakly acidic liquid ($pH > 2.5$) into the lungs of animals results in an immediate inflammatory response and pneumonitis.[69] The acute effects of a single small-volume instillation subsequently resolve. In an animal model of chronic aspiration, histopathologic changes were completely independent of acidity and were more related to the presence of the food particulates.[12,15] If it is the gastric contents themselves, independent of acidity that results in lung injury, then acid suppression may not prevent the chronic lung injury from aspiration. In addition, the use of acid-suppressing medications increases gastric colonization by bacteria and may result in aspiration of material with greater bacterial density.[70,71] This potential has been demonstrated in multiple adult studies of ventilator-associated pneumonia, but not in the single prospective trial in a pediatric intensive care unit.[70,72–75]

GER is quite common in children with chronic respiratory diseases.[65,76–78] The risk of aspiration from reflux is increased when there is coexisting swallowing dysfunction, decreased laryngeal sensation, tachypnea, or upper airway obstruction. GER and aspiration may also occur in cases of esophageal dysmotility, compression, or stenosis, and these cases are particularly difficult to manage.

## Evaluation of Reflux Aspiration

There are several diagnostic modalities available for the diagnosis of GER, yet none are sufficiently sensitive and specific to reliably prove aspiration. While a certain amount of acid exposure may be expected to cause esophagitis, the establishment of norms for reflux aspiration is not possible. Certainly, some individuals may have a moderate amount of reflux and not aspirate, while others may protect their airways so poorly that any amount of reflux results in aspiration and lung injury. Therefore episodes of reflux to or above the upper esophageal sphincter should be thought of as opportunities to aspirate, rather than proof of aspiration itself.

## Biomarkers of Aspiration

Biomarkers obtained from the lungs have been sought and evaluated in order to identify children with significant aspiration, especially those who are suspected of aspirating refluxate. The most extensively studied biomarker is the calculation of a quantitative index of lipid-containing macrophages in BAL fluid. Theoretically, an increased prevalence of lipid-filled macrophages in the lower airway suggests aspiration of food during swallowing or following reflux from the stomach. While several studies have found higher levels of lipid in the BAL of children with chronic aspiration than those without, many others have not.[65,79–84] This inconsistency is even more striking viewed across studies, even when the methodology for lipid-laden macrophage index (LLMI) is the same (Fig. 76.3). This variability may represent an inherent limitation in the LLMI itself, it may reflect differences in groups characterized as aspirators due to lack of a gold standard, or it may demonstrate that the presence of GER and respiratory symptoms only presumes aspiration as the mechanism. This last point is highlighted by two studies evaluating the correlation of proximal reflux events, detected by esophageal impedance and pH monitoring, to LLMI. Borrelli and colleagues found correlation between reflux episodes to the proximal esophagus (total and nonacid) in children with recurrent consolidation, asthma, and laryngotracheitis, though only two subjects had LLMI greater than the commonly cited threshold of 100.[85] Rosen and coworkers also evaluated children with possible GER and respiratory symptoms.[86] The authors compared proximal reflux events between those that had LLMI greater than and less than 100 and found a trend toward fewer events in those with LLMI greater than 100. We conclude that the overall sensitivity and specificity for LLMI to diagnose aspiration is poor.

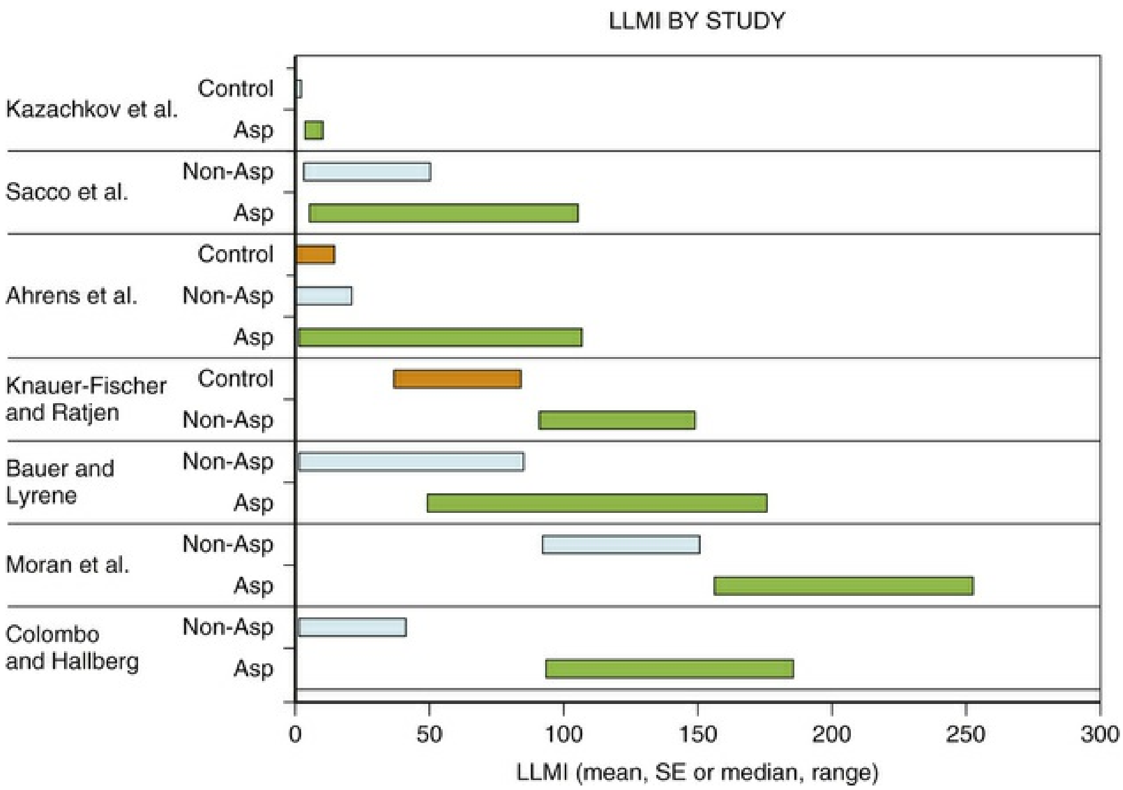

**FIG. 76.3** Comparison of lipid-laden macrophage index on bronchoalveolar lavage across studies. Comparison of lipid-laden macrophage indices *(LLMIs)* across studies to demonstrate overlapping ranges between controls, children with aspiration *(Asp)*, and children without aspiration *(Non-Asp).* Despite a similar grading

system, nonaspirating children in some studies have a higher LLMI than aspirating children in others.

As elevated lipid-containing macrophages would not be expected to be specific for aspiration caused by reflux, recent efforts have sought to evaluate biomarkers of gastric origin. Gastric pepsin is the most extensively evaluated of these biomarkers. Krishnan and colleagues found pepsin in the tracheal aspirates of those children undergoing endoscopy who had both respiratory symptoms and esophagitis, but not in those without.[87] Since then, pepsin has been evaluated as a biomarker of aspiration in intubated premature infants, pediatric critical care patients, and lung transplant recipients.[88–93] In intubated premature infants, pepsin is almost invariably found in endotracheal aspirates, with concentrations increasing over time; higher concentrations are associated with development of severe bronchopulmonary dysplasia.[88,89] In these studies, pepsin did not appear to arrive in the airway via production by airway epithelium or hematogenous spread, yet the almost ubiquitous presence of pepsin (even in infants not enterally fed) would seem to limit its utility as a biomarker of significant reflux aspiration. Similarly, the finding of pepsin in tracheal aspirates of older intubated children (whether fed by nasogastric or nasojejunal tube) may signify that pepsin may not be a clinically useful biomarker of aspiration, or that reflux aspiration is omnipresent in most intubated infants and children, regardless of feeding status, after a few days. One study evaluating pepsin in BAL (as opposed to tracheal aspirates) in pediatric patients demonstrated no correlation between BAL pepsin and any index on esophageal impedance, except nonacid events.[94] The only respiratory disease that was correlated to BAL pepsin in this study was asthma. The relationship between airway pepsin and reflux indices is at best unclear, highlighting the concept that reflux episodes represent opportunities to aspirate rather than providing direct evidence of aspiration. The relationship between lung disease and airway pepsin has been less studied, other than for lung transplant rejection, where a relationship has been documented.

## Treatment Considerations for Reflux

## Aspiration

There are various treatment options for GER, and a full discussion is beyond the scope of this chapter. Consultation with aerodigestive teams or gastroenterologists is beneficial. When considering therapeutic options for reflux aspiration (as opposed to reflux esophagitis), it is essential to recognize that acid suppression does not reduce the number of reflux events, only the pH of such events. Acid suppression in the context of reflux aspiration may result in the aspiration of material with a higher bacterial density caused by colonization of the proximal gastrointestinal (GI) tract.[71,75,95] Perturbations in local lung defense (e.g., chronic inflammation and degradation of surfactant proteins) combined with the increased bacterial density of aspirated material may result in increased infection and lung injury.[96] Therefore children who are unable to adequately protect their airways from aspiration caused by reflux require an intervention, generally surgical, which will decrease the number of reflux events to their proximal esophagus. Surgical options generally include transpyloric feeding (i.e., gastrostomy-jejunostomy or jejunostomy tubes) or fundoplication. Fundoplication is the most commonly utilized surgical procedure and is often successful in resolving reflux, and in some studies demonstrates efficacy in reducing respiratory symptoms attributed to reflux.[97–100] Unfortunately, in neurologically impaired children, there is a greater incidence of both chronic aspiration and GER, and a greater likelihood of failure of fundoplication, an increased incidence of postfundoplication retching, and a decreased efficacy in the reduction of respiratory symptoms.[97,100–105] In children with esophageal dysmotility, a fundoplication must be created carefully so as not to impede the forward transit of food or oral secretions through the esophagogastric junction because this may worsen aspiration. Jejunostomy feedings may allow adequate feeding and decrease respiratory symptoms caused by aspiration without the concerns for gas bloat or retching; however, there are other issues.[106,107] Jejunostomies do not prevent reflux of gastric secretions, do not allow the convenience of bolus feeding, and carry the risks of intussusception and repeated displacement. Another use for gastrojejunostomy is diagnostic. In a child with an existing gastrostomy, a trial of conversion to a gastrostomy-jejunostomy tube may test the potential impact of an antireflux procedure on respiratory symptoms that are suspected to be caused by reflux aspiration.

## Aspiration of Oral Secretions

Chronic aspiration of saliva is the least-commonly recognized form of aspiration and may not be diagnosed until significant lung injury has developed. The oral cavity contains a high density of bacteria and yeast that can cause lung infections if aspirated in sufficient quantity.[108] Most neurologically impaired children who aspirate oral secretions do so because of severe swallowing incoordination and absent laryngeal sensation rather than excessive production of saliva.[109] Other conditions commonly associated with both swallowing dysfunction and aspiration of saliva include CHARGE association, Möbius syndrome, congenital high airway obstruction syndrome (CHAOS), and vocal cord paralysis. It is unusual for a child without severe swallowing dysfunction to aspirate oral secretions. Children with cricopharyngeal achalasia, severe esophageal dysmotility, stricture, or diverticulum are exceptions. These children may pool saliva excessively in their hypopharynx and aspirate at night because of a combination of depressed protective reflexes during sleep and the absence of gravity assistance in the drainage of secretions from the esophagus into the stomach.

### Evaluation of Salivary Aspiration

Aspiration of saliva is best evaluated by FEES or FEES-ST, as pooling and aspiration of oral secretions can be visualized directly. The lack of a compensatory cough or laryngeal adductor reflex further supports the likelihood that significant pathologic aspiration of saliva is occurring. Radionuclide salivagrams are performed by placing a small quantity of radiotracer in the buccal space and recording serial images until there is clearance from the mouth. The presence of activity in the trachea or bronchi indicates aspiration of saliva. While these tests are likely very specific, they are infrequently positive in children highly suspected of aspiration and correlate poorly with other tests for aspiration.[110–113] In children with a tracheostomy, aspiration of saliva can be evaluated by placement of 1 to 2 drops of green food dye in the buccal space, a few times a day, for several days and having a caregiver keep a diary of suctioning of colored secretions from the tube. While the basis of the test is the same as the radionuclide salivagram, repeated administration captures a longer window of time and may improve sensitivity.

## Treatment of Salivary Aspiration

Treatment of salivary aspiration may be medical or surgical. Oral anticholinergic medications decrease salivation; therefore they may decrease the amount of saliva available to aspirate. However, these medications do not specifically affect saliva production, and adverse effects are common. These include behavioral changes, constipation, dry mouth, urinary retention, flushing, nasal congestion, vomiting, and diarrhea.[114–116] Of greater concern is the potential for the thickening of tracheal and bronchial secretions that could result in the life-threatening mucus plugging of airways or tracheostomy tubes. For this reason, they should be used with great caution in infants, in children with neuromuscular diseases, and in those with small tracheostomy tubes. Production of saliva can be specifically reduced either by the injection of salivary glands with botulinum toxin, the ligation of salivary ducts, or the removal of salivary glands. The submandibular glands are most frequently treated by injection, excision, or duct ligation, as they are responsible for most baseline saliva production. Parotid glands are the major secretors of saliva in anticipation of eating; therefore they are commonly treated, by injection or duct ligation, at the same time as the submandibular glands. Botulinum toxin injection, duct ligation, and gland excision have all demonstrated efficacy in reduction of drooling and decreasing respiratory infections.[117–121] Botulinum toxin injection results in a limited duration of effect (which may or may not be desirable), while the effects of salivary gland excision or duct ligation are generally long lasting.

# Evaluation of Lung Injury Caused by Aspiration

In those individuals with identified abnormalities in swallowing function sufficient to cause lung injury, the extent of the lung injury from aspiration should be sought. Chest radiographs are readily available and are usually abnormal in children with chronic aspiration. Hyperaeration, segmental or subsegmental infiltrates, and peribronchial thickening may be seen—usually in multiple lobes and in a dependent distribution. However, the findings on plain chest radiograph are very nonspecific and are of little use in differentiating chronic aspiration from other diffuse lung diseases. Furthermore, chest radiographs are not very sensitive with regard to detecting bronchiectasis from chronic aspiration.

High-resolution chest computed tomography (HRCT), performed with a breath hold and formatted with thin slices, is more sensitive than plain radiographs in the detection and definition of early airways and parenchymal disease in pediatric patients.[122,123] Ideally suited to evaluate diffuse lung diseases, HRCT is capable of identifying signs of small airway disease, such as centrilobular ("tree-in-bud") opacities, bronchial thickening, and subsegmental atelectasis, and it is the current gold standard for the diagnosis of bronchiectasis. These findings on HRCT are representative of those found on lung histopathology.[10,13,14] While they are not specific for chronic pulmonary aspiration, their presence in a multilobe-dependent distribution in a child with known dysphagia or GER provides convincing evidence for aspiration lung injury (Fig. 76.4). Though specific protocols may vary, volumetric submillimeter images should be obtained during a controlled inspiratory breath hold (this can be done volitionally in a cooperative child or with the aid of anesthesia). Although there is appropriate concern over excessive exposure to ionizing radiation, current protocols can deliver doses as low as several weeks of ambient radiation exposure.[124] It is necessary to be aware of the protocols used in one's own institution.

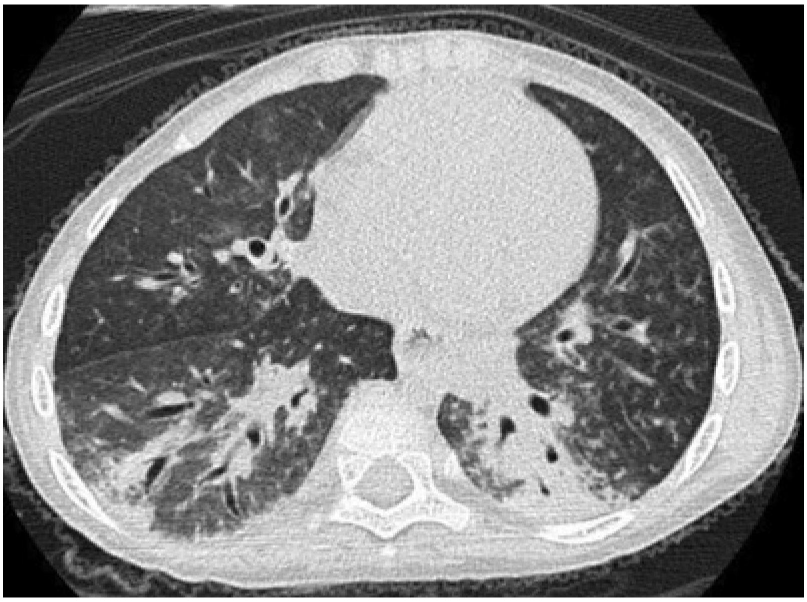

**FIG. 76.4** Lung injury caused by chronic aspiration. Chest high-resolution computed tomography shows dependent bronchiectasis, consolidations, and centrilobular opacities in a child with chronic aspiration caused by recurrent tracheoesophageal fistula.

## Multidisciplinary Approach to Chronic Aspiration

The evaluation and treatment of a child suspected of chronic pulmonary aspiration is best performed by a multidisciplinary team. By way of example, how else might we sort out the causes for respiratory symptoms in the following child: 2 years old, 25-week premature birth with chronic lung disease, tachypnea, wheezing with chest congestion, hypoxemia with sleep and illness, snoring with sleep, moderate tracheobronchomalacia, and a deep interarytenoid notch? In addition, the child has mild oral aversion, premature spillage, and laryngeal penetration with liquids. He is status postfundoplication with a small paraesophageal hernia and takes some feeds orally and some by gastrostomy. Clearly, a child such as this has a complex interaction of pulmonary, airway, and gastrointestinal pathology. Chronic aspiration may be a component of the symptoms and, if left untreated, would lead to progressive lung injury and associated morbidity. A broad evaluation of all the contributing factors is required, with the development of a coordinated approach to systematically address the most significant contributors to disease but without disrupting successful compensatory mechanisms that the child may have developed. With advancements in perinatal medicine, children such as these are increasingly common.

The key components of such a multidisciplinary team include a pulmonologist, otolaryngologist, gastroenterologist, and a speech and language pathologist. Given the frequency with which certain inherited diseases result in aerodigestive disorders, a geneticist can be a very useful person on the team. Other supporting team members include a cardiothoracic surgeon, general surgeon, neurosurgeon, radiologist, cardiologist, neurologist, anesthesiologist, and occasionally an orthopedist. With so many services potentially involved, coordination of care is of paramount importance.

Ideally, each service involved would have an opportunity to obtain a primary history and examine the child, and then the providers would meet as a group and plan a coordinated evaluation. It is beneficial to have one individual identified as the primary provider to discuss the plan with the caregivers and answer their questions. This prevents the family from having to seek out different providers with different questions and then interpret various recommendations. All children suspected of chronic pulmonary aspiration should have their swallowing evaluated by videofluoroscopic swallowing study, FEES, or both. The method for the evaluation of swallowing should be determined based on available expertise, the child's clinical situation, and the relative strengths and weaknesses of each test. Evaluation for GER may also be considered. For children with impaired swallowing or GER, HRCT can identify when there has been aspiration lung injury. If dependent bronchiectasis is present, it may be difficult to determine if this is a result of prior or ongoing aspiration. This is especially true when children are referred for evaluation after having had their feeding method altered or having received a fundoplication.

## Evaluation of the Aerodigestive Tract

Once a diagnosis of chronic aspiration sufficient to cause lung injury is made, a search for underlying causes should be undertaken. This always includes a thorough assessment of the anatomy of the aerodigestive tract. A fundamental component of this is bronchoscopy. Bronchoscopy may be undertaken using rigid or flexible instruments, and there are relative strengths and weaknesses to each. Flexible bronchoscopy provides assessment of the entire upper and lower airways and can identify pathology from the nose to the distal bronchi. Flexible bronchoscopy is particularly well suited for identifying dynamic airway lesions, such as laryngomalacia, pharyngomalacia, tracheomalacia, and bronchomalacia, which a rigid bronchoscopy approach may obscure. In addition, flexible bronchoscopy allows for the performance of BAL. Paired with HRCT, BAL can help determine if lung injury is caused by prior or ongoing aspiration. The presence of increased secretions with an inflammatory profile on BAL in a child with CT evidence of aspiration injury would provide supporting evidence for ongoing aspiration, even though it lacks the specificity to prove it outright. Additionally, microbiologic testing can help with assessment and treatment.

Rigid bronchoscopy should be considered an essential evaluation in a child with chronic aspiration. While evaluation of upper airway dynamics and ability to obtain diagnostic BAL are limited, rigid instruments are far superior to flexible ones for the identification of laryngeal clefts, H-type tracheoesophageal fistula, and cricopharyngeal achalasia (Fig. 76.5). Even in a patient with a known laryngeal cleft, most of the time flexible bronchoscopes fail to detect or evaluate the extent of the cleft. The direct approach to the posterior larynx, cricoid, and proximal trachea with instruments capable of manipulating tissue makes this identification possible. Even rigid bronchoscopists can easily miss laryngeal clefts (especially types 1 and 2) unless a specific effort is made to look for them. In reality, the practice of combined bronchoscopy, rigid and flexible, performed concurrently, offers certain distinct advantages. With this approach, including an awake flexible laryngoscopy, both the pulmonologist and the otolaryngologist can see the static and dynamic airway anatomy firsthand in its entirety, can observe the status of the lower airways, and can have a dialog regarding an integrated care plan. The addition of evaluation by a gastroenterologist, as part of a “triple endoscopy,” adds an evaluation for potential reflux aspiration, acid esophagitis, eosinophilic esophagitis, and anatomic abnormalities of the upper gastrointestinal tract. This is especially important if the child is being evaluated in preparation for airway reconstruction. Given that these children often require both medical and surgical interventions, this combined approach makes sense, and the multidisciplinary evaluation leads to a consistent, cohesive, assessment and plan to be delivered to the family.

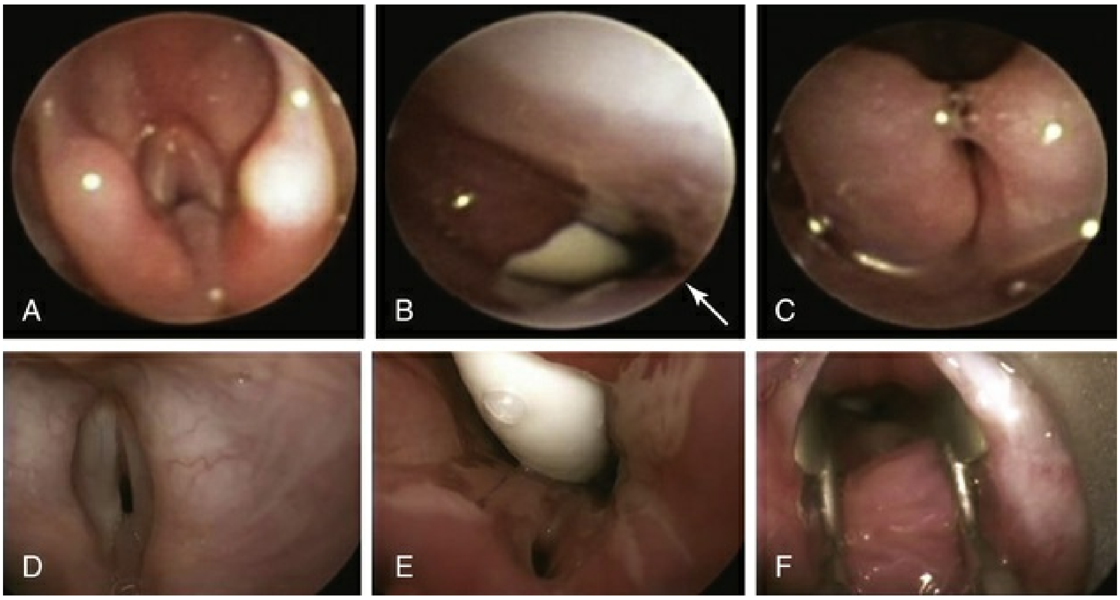

**FIG. 76.5** Evaluation of laryngoesophagotracheal cleft (LTEC) by rigid and flexible bronchoscopes. (A–C) Evaluation of LTEC (type 3) with flexible bronchoscope: (A) Redundant tissue in the interarytenoid space or posterior commissure is very suspicious for LTEC. (B) Note that the distal extent of cleft cannot be seen clearly *(arrow)*, though the scope can slide posteriorly and into the esophagus. (C) A postcricoid “seam” is also suspicious for LTEC. Note that it is very unusual to be able to see even such a large cleft this well with a flexible bronchoscope. (D–F) Evaluation of the same patient with a rigid bronchoscope: (D) Similar view of redundant tissue in interarytenoid space. (E) Direct approach to posterior glottis and upper trachea, as well as laryngeal suspension, aids in a clear definition of the distal

extent of cleft. (F) Various instruments can be utilized by the otolaryngologist to further define the extent of the cleft.

# Feeding and Swallowing Disorders

*Claire Kane Miller PhD, MHA, Jennifer Maybee OTR/L, MA, CCC-SLP, Jeremy Prager MD, MBA, Scott Pentiuk MD, MEd*

## Introduction

The maturation of feeding and swallowing skills evolves in a natural and seemingly effortless progression in typically developing infants and children. Given that the pharynx is a shared pathway for breathing and swallowing, precise coordination of respiration and swallowing ensures maintenance of airway protection during feeding. Intact anatomy and function of the aerodigestive tract and normal development of neural control mechanisms are essential. Feeding and swallowing dysfunction (pediatric dysphagia) occurs in infants and children because of a multitude of factors, including structural anomalies in the aerodigestive tract, static or degenerative neurologic conditions affecting the range and strength of the necessary musculature, and cardiopulmonary conditions that result in respiratory compromise with oral feeding attempts. Etiologies of dysphagia are not mutually exclusive, and often multiple interacting factors are present.

The multifactorial nature of feeding and swallowing disorders necessitates the involvement of multiple disciplines in the evaluation and management process. Therefore a team approach is efficacious in the consideration of issues that involve disciplines including, but not limited to, otolaryngology, gastroenterology, pulmonary medicine, radiology, occupational therapy, nutrition therapy, and speech pathology. This chapter will review the clinical and procedural evaluation and management of infants and children presenting with feeding and swallowing from a multidisciplinary perspective.

## Epidemiology

There is no universal, standardized clinical assessment instrument available that covers the range of ages and conditions that have accompanying pediatric dysphagia. Therefore standardized data collection and reporting are not possible, and the true epidemiology of pediatric dysphagia is largely unknown in infants and children. Available assessment protocols are targeted toward specific age ranges and condition types, for example, for characterizing preterm infant feeding behaviors, assessing oral motor skill development, and documenting signs and symptoms of dysphagia in specific diagnoses or conditions.

It has been widely reported that at least 25% of typically developing children experience some type of feeding difficulty, such as chewing difficulty, choking, or texture refusal.[1–3] The likelihood of feeding and swallowing dysfunction increases sharply in developmentally delayed or medically fragile children, who present with structural, neurologic, or metabolic issues affecting feeding and swallowing, with reported estimates ranging between 40% and 70%.[3–5] Dysphagia has been frequently reported in the context of cerebral palsy, with estimates citing a 75%–80% or higher probability of feeding and swallowing difficulty, and in patients with Down syndrome, with estimates of 50%–60%.[6–8] Comprehensive evaluation and management of feeding and swallowing issues is essential to defining the anatomic and physiologic factors affecting feeding and swallowing efficiency and safety.

# Anatomy, Physiology, and Development

The larynx serves three functions: connection of the upper and lower respiratory airway, closure for protection of the lower airway during swallowing, and generation of sound for voice. Identification of the maturational changes that occur in the anatomy of the aerodigestive tract and in the ontogeny of feeding and swallowing development is fundamental in delineating physiologic abnormalities and in defining the effect of compensatory strategies for improvement of laryngeal function.

In terms of anatomy, there are differences in the size and location of the structures associated with the key laryngeal functions in the infant as compared with the child or adult. At birth, the larynx is positioned relatively high in the neck, located adjacent to cervical vertebrae C1 to C3, and later descending to levels C6 to C7. The overall size of the infant larynx is approximately one-third that of the adult, with the membranous portion of the true vocal folds (TVFs) measuring approximately 2–3 mm and the bulkier cartilaginous portion measuring 3–4 mm. The thyroid cartilage of the pediatric larynx is rounded, the epiglottis may have an omega shape, and the cricoarytenoid joints and vocal processes are proportionately larger than in the adult larynx.[9] The delicate respiratory epithelium that lines the infant airway is particularly prone to injury from prolonged or traumatic intubation, and the subglottic region is often the site for reactive stenosis.[10]

The small size and shape of the oral cavity relative to the tongue facilitates early sucking as the buccal fat pads provide lateral stability for efficient tongue motion. As the infant grows, the prominent buccal pads decrease, the oral cavity increases in size, and the relative size of the tongue decreases. More space is available for differentiated tongue movements during both feeding and speaking. Elongation of the pharynx occurs as does the maturational descent of the larynx from C3 to C6 by approximately 3 years of age. As the larynx descends, increased neuromuscular control of the structural elements of the pharynx is critical for maintenance of airway protection during swallowing.[11]

In addition to the anatomic interrelation of the structures involved in feeding and swallowing, there is common neural control that is composed of cortical influences, peripheral afferent signals, nerve networks, and efferent responses driven by motor neurons. Branches of cranial nerves (CNs) primarily innervate the oral, nasal, pharyngeal, and laryngeal structures: V, VII, IX, X, XI (vagal branch), XII, and branches of the upper cervical nerves. There are further structural and regulatory interrelationships within the brainstem, specifically the medulla (e.g., central pattern generator). Afferent input for swallowing is primarily located in the nucleus tractus solitarius (NTS); efferent control is localized in the nucleus ambiguus (NA) and the dorsal motor nucleus of CN X. Similarly, afferent input is received by the NTS for respiration, with efferent respiratory control via premotor neurons in the NTS and NA that project to the spinal cord motor neurons and innervate the respiratory skeletal musculature.

## Feeding Skill Development

Feeding gradually evolves from a reflexive behavior in infants to a cortically regulated behavior during the first 2 years of life (Table 77.1). Anatomic changes in oral and pharyngeal structural relationships, as well as maturation of the central nervous system during the first 2 years of life, are reflected in the transition to mature oral motor/feeding and swallowing skills. Sucking occurs early *in utero* and continues as the primary means of obtaining nutrition for the first 3–4 months of life.[12] As the motor and digestive systems mature, smooth solids such as pureed foods are introduced at approximately 4–6 months of age. Head control and stability improve with differentiation of tongue movements at 7–9 months of age, at which time increased food textures are typically presented. Continued emergence of active oral motor movements such as tongue lateralization and rotary chewing facilitate the transition to table foods at approximately 1 year of age. By approximately 2 years of age, oral motor/feeding and swallowing skills are in place, with refinements in oral motor movements as the child continues to mature.[13]

---

**Table 77.1**

| Age Range | Skill | Food Types |
|---|---|---|
| Birth to 4 months | Sucking predominates | Liquid (breast milk, formula) |
| 4–6 months | Anteroposterior tongue movements for efficient transfer of smooth solids | Pureed, smooth, semisolid foods |
| 7–9 months | Efficient sucking, emergent skills for cup drinking<br>Emergence of tongue lateralization<br>Vertical chewing motion in response to solids | Semisolids with increased textures (e.g., cottage cheese, regular applesauce, fruited yogurt)<br>Solid items (e.g., very easily dissolvable cereal pieces, soft cookies, shredded cheese) |
| 9–12 months | Increasing lateral tongue movements for mastication of foods<br>Vertical chewing pattern with emergence of lateral tongue movements<br>Transition to cup drinking<br>Trend toward less formula intake as solid intake increases | Fork-mashed or slightly blended table foods<br>Transitioning toward easy-to-manage solid foods (e.g., scrambled eggs, toast strips, pasta pieces, crunchy but dissolvable cookies, and crackers) |
| 12–18 months | Consistent tongue lateralization<br>Emergence of mature rotary chewing pattern | Easy-to-manage solid foods (e.g., crackers, breads, casseroles, soft fruit pieces, and tender meat such as flaked fish or chicken) |
| 19–24 months | Chewing efficiency increases<br>Cup drinking | Table foods requiring greater mastication (e.g., tender meats, steamed vegetables, and fruits) |
| 24 months | Oral motor/feeding skills have emerged, with refinement in skills to continue | Wide range of textures |

## Phases of Swallowing

The swallowing process is composed of the oral preparatory, oral, pharyngeal, and esophageal phases. For an efficient oral phase of swallowing to occur, it is crucial to have normal anatomy and intact gross discriminative and special sensory input from olfaction via CN I and the oral cavity via CN V (V2 and V3), VII, IX, and X. It is also essential to have intact muscular strength and coordination of the buccal and oral musculature. Adequate oral preparation of the bolus, followed by posterior transfer of the bolus to the hypopharynx via tongue base retraction and simultaneous closure of the soft palate against the posterior pharynx occurs. After the oral bolus is transferred to the hypopharynx, airway protection must occur during the pharyngeal swallowing phase to prevent aspiration. Tactile receptors in the pharynx provide sensory stimulation to the medullary swallow center, and swallowing is initiated via the NA and the dorsomedial vagal nucleus.[14]

Airway protection during the pharyngeal phase of the swallow occurs as a sequence involving the cessation of respiration (swallowing apnea), adduction of the TVFs in association with the medial approximation of the arytenoid cartilages, compression of the ventricular vocal folds, and retroversion of the epiglottis.[15] At the initiation of the swallow, the larynx is elevated under the base of the tongue, facilitating the stretching and opening of the cricopharyngeus, as the pharyngeal constrictors shorten the pharynx and propel the bolus into the upper esophageal sphincter. After passage of the bolus has occurred, the larynx returns to its resting position, the airway reopens, and respiration resumes. Swallowing apnea and glottic closure are linked events, although swallowing apnea has been described to occur as a result of a dedicated neural command.[16] The exact neural control mechanisms are unknown, although past and recent investigations suggest that a designated neural command from the central pattern generator within the medullary brainstem occurs.[14,16,17] The specific respiratory phase patterns and duration of apneic pause in relation to normal and abnormal swallowing parameters in the pediatric population is presently unknown; however, there are emerging data regarding respiration and nutritive swallowing parameters in the infant population.[18]

The neurologic arch that allows for airway protection is described as the laryngeal adductor reflex (LAR).[19] The supraglottic area contains chemoreceptors, mechanoreceptors, thermal receptors, and baroreceptors (i.e., stretch/pressure receptors) that are highly sensitive to specific kinds of sensory input. The LAR is activated by mechanical or chemical stimulation of the supraglottic mucosa in the region of the aryepiglottic fold.[19] The internal branch of the superior laryngeal nerve transmits sensory information via the special visceral afferent fibers to the inferior nodose ganglion. The information passes to the nucleus solitarius, which is responsible for the regulation of swallowing and respiration. The efferent response initiated at the NA and dorsal motor nucleus of CN X results in glottic closure and inhibition of respiration with or without a swallow.[20–23]

The actions of the intrinsic laryngeal musculature are of major importance to airway closure during swallowing. The intrinsic muscles (i.e., cricothyroid, posterior cricoarytenoid, lateral cricoarytenoid, thyroarytenoid [vocalis], and the transverse and oblique arytenoids) serve to adduct, abduct, and tense the vocal folds, as well as open and close the laryngeal valve. The cricothyroid stretches and tenses the vocal fold and is innervated by the external branch of the superior laryngeal nerve. The posterior cricoarytenoid is the sole abductor of the vocal folds and is innervated by the recurrent laryngeal nerve. The lateral cricoarytenoid adducts the interligamentous portion of the vocal fold and is supplied by the recurrent laryngeal nerve. The thyroarytenoid and the transverse and oblique arytenoids are likewise innervated by the recurrent laryngeal nerve. The thyroarytenoid works to relax the vocal folds. Its medial portion, the vocalis, relaxes the posterior vocal ligament while maintaining and increasing tension of the anterior portion. The transverse and oblique arytenoids close the intercartilaginous portion of the glottis.

During the pharyngeal phase of the swallow, the upper esophageal sphincter relaxes and allows the bolus to enter the esophagus, initiating the esophageal phase of the swallow. Peristaltic contractions propel the bolus through the esophagus, and the lower esophageal sphincter subsequently relaxes to allow the bolus to pass into the stomach. Propagation of the peristaltic wave is reliant upon the intrinsic myenteric plexus and on vagal afferents. The transit time of the esophageal phase is much longer than the pharyngeal phase, between 3 and 9 seconds.[14]

## Etiology/Pathogenesis

The upper aerodigestive tract is the confluence of the respiratory, digestive, and phonation systems. Precise integration of functions is required for protection of the lower airway from aspiration during swallowing. There is a variety of anatomic and neurologic etiologies that may affect the structural integrity and interrelated physiology of feeding and swallowing. Many children with complex airway conditions also have concomitant neurodevelopmental delays that place them at even higher risk for feeding and swallowing disorders.[24]

The implications for untreated dysphagia are significant and include failure to maintain proper nutrition/hydration status, aspiration pneumonia, and long-term pulmonary complications such as chronic lung disease from ongoing aspiration. Outcome data related to the persistence or resolution of pediatric dysphagia are limited. Empirical research is limited by the inconsistencies in the classification of dysphagia and in the terminology used to describe the physiologic aspects of dysphagia. The use of standardized clinical pathways and data reporting systems during the workup of dysphagia, for both clinical and instrumental assessment, will facilitate the accumulation of standardized data needed to track the course of the dysphagia in association with specific conditions and diagnoses to predict outcomes.

# Conditions Associated With Feeding, Swallowing, and Airway Protection Problems

Difficulty with the oral, pharyngeal, or esophageal phases of swallowing may occur because of structural, neurologic, cardiorespiratory, metabolic, or inflammatory disorders (Table 77.2). The etiologies may be congenital or acquired, and the interactions of the developing respiratory, neurologic, and gastrointestinal (GI) systems create numerous variables to consider.

**Table 77.2**

**Conditions Associated With Dysfunction in the Oral, Pharyngeal, and Esophageal Phases of Swallowing**

| Oral/Preparatory | Pharyngeal | Esophageal |
|---|---|---|
| Cleft lip/cleft palate | Cricopharyngeal | Tracheoesophageal fistula |

| | | |
|---|---|---|
| Choanal atresia<br>Macroglossia<br>Micrognathia<br>Oral hypotonia<br>Oral sensory-motor dysfunction<br>Cranial nerve paralysis | achalasia<br>Arytenoid prolapse<br>Laryngeal cleft<br>Vocal cord paralysis<br>Laryngo-pharyngitis | Eosinophilic esophagitis<br>Vascular ring<br>Gastroesophageal reflux disease<br>Esophageal dysmotility<br>Achalasia<br>Esophageal stricture |

Anatomic abnormality in any of the structures from the nasal cavity to the GI tract has the potential to disrupt the processes of feeding, swallowing, and ability to achieve and maintain airway closure and protection. Anatomic defects in the oral cavity or oropharynx create difficulty in the oral phase of swallowing and include craniofacial syndromes, cleft lip and cleft palate, and macroglossia.[25,26] Congenital defects of the larynx, trachea, or esophagus (e.g., laryngomalacia, laryngeal cleft, or tracheoesophageal fistula) are associated with airway compromise, as well as esophageal phase abnormalities.[27] In particular, congenital or acquired conditions involving the supraglottic, glottis, or subglottic airway require airway surgical interventions that may have an effect on laryngeal function for airway protection, swallowing, and voicing.[26–29] Any necessary reconstruction procedures involve anatomic alteration of the laryngeal anatomy; therefore careful preoperative assessment of laryngeal anatomy and function pertinent to swallowing and phonation is required. Surgical reconstruction may alleviate the obstructive structural defects, although problems may persist with phonation and laryngeal function during swallowing.[30,31] Tracheoesophageal fistula repair can alter nerve function and esophageal motility leading to prolonged bolus clearance and increased risk for gastroesophageal reflux (GER) and esophageal mucosal injury.[32] There is also the risk of stricture formation at the repair site, as well as possible recurrence of the fistula, leading to aspiration.

Neurologic conditions are by far the most common etiology of potential feeding, swallowing, and airway protection problems. Neuromotor impairment as a result of cortical dysfunction, abnormality in the brainstem, or cervical cord injury may affect laryngeal functions that are critical for adequate feeding/swallowing, phonation, and airway protection. Such problems include cerebral palsy, vocal fold paralysis, Arnold-Chiari malformation, cricopharyngeal achalasia, and CN abnormalities associated with syndromes such as the CHARGE association (Coloboma, Heart defect, Atresia choanae, Retarded growth and development, Genital hypoplasia, Ear anomalies), and Moebius syndrome.

Cardiorespiratory compromise secondary to airway abnormalities (e.g., subglottic stenosis, airway edema, and other structural issues) may be reflected in an infant's inability to coordinate respiration and swallowing, and it is often apparent during initial attempts at oral feeding. Feeding-related apnea or episodes of bradycardia may occur. In older infants and children, problems with respiratory compromise are reflected in poor respiratory support during phonation and poor coordination or inappropriate timing of airway protection during swallowing, resulting in coughing, choking, noisy breathing, or recurrent episodes of pneumonia, bronchitis, or atelectasis.[33]

Inflammatory processes such as esophagitis from chronic GER or chronic inflammation/irritation secondary to eosinophilic esophagitis may result in airway manifestations that can interfere with the development of oral motor and feeding skills and with swallowing.[34–36] These diseases are increasingly being recognized in children with complex airway disease. Chronic reflux or irritation to the laryngeal area has been associated with airway reconstruction failure.[28] Hyposensitivity in the pharyngeal and laryngeal area from chronic reflux irritation may result in poor sensory awareness and a higher risk for aspiration.[22]

## Specific Airway Conditions and the Effect on Feeding and Swallowing

Pathologic airway conditions in pediatric patients include congenital or acquired subglottic stenosis, glottic stenosis, laryngotracheal stenosis, laryngeal webs or atresia, and tracheal lesions. Congenital subglottic stenosis is relatively rare and typically occurs in conjunction with genetic syndromes or laryngeal malformations. Acquired laryngotracheal stenosis is more common, occurring after manipulation or insult to the airway. Such conditions comprise subglottic stenosis because of prolonged or traumatic intubation, hypopharyngeal stenosis secondary to trauma or caustic agent inhalation or ingestion, vocal fold paralysis as a result of surgical intervention, and tracheal stenosis following intubation. Tracheotomy with later surgical intervention for reconstruction and expansion of the airway is often necessary. The surgical reconstruction techniques are selected based upon the extent and location of the airway lesion and are designed to expand or resect the airway. Avoidance of damage to the recurrent laryngeal nerve, as well as to intact laryngeal structures, is a primary goal. As discussed previously, an important consideration is the effect that the necessary surgical interventions may have upon the laryngeal functions of phonation and airway protection during swallowing. As children with complex airway conditions often have persistent aspiration or severe reflux, they may be candidates for fundoplication prior to airway reconstruction. It should be noted that these procedures can worsen unrecognized esophageal dysmotility, leading to symptoms of gagging and retching.[37]

Airway expansion procedures may involve the placement of anterior and/or posterior grafts that are stabilized via an indwelling airway stent during the postoperative period. Swallowing is possible during the period that the stent is in place; however, difficulties may arise, depending upon the necessary location of the stent. If placement of the stent is necessary at the glottic level, swallowing dynamics are affected. If the stent location extends to the level of the arytenoids or to the base of the epiglottis, swallowing dynamics may be significantly compromised. Patients who undergo placement of posterior grafts may be at risk for destabilization of the cricoarytenoid joint and lateral cricoarytenoid muscles and are therefore at risk for difficulty with airway protection during swallowing and significant degrees of dysphagia.[31]

Safe and efficient feeding and swallowing skills are dependent upon postural stability, appropriate strength and range of jaw, cheek, lip, and tongue movements, the capacity to process sensory information, and upon the ability to establish and maintain airway protection during oral intake. The coordination and strength of lip, tongue, and jaw patterns during feeding may be limited by underlying muscle tone abnormalities and/or sensory processing dysfunction. Neurologic conditions may interfere with appropriate coordination of oral motor movements during feeding and have a negative impact on the timing of swallowing and airway closure. Underlying structural issues may preclude closure of the airway during swallowing. As such, clinical signs and symptoms of feeding and swallowing dysfunction observed during the clinical assessment may signal feeding inefficiencies or threats to airway protection. Changes in physiologic status during feeding are of concern, such as decreased oxygen saturation or increases in respiratory or heart rate. Increased stridor with the respiratory effort of feeding, coughing, choking or gagging, color changes, or an increased wet, vocal quality should be noted. Of note, "silent" aspiration (no overt sign of airway protection threat) has been shown to be prominent in infants and in children with neurologic impairment and feeding difficulties.[38–40] Therefore the possibility of silent aspiration should be considered and can be ruled out during an instrumental swallowing assessment.

## Imaging, Instrumental Assessment of Swallowing Function, and Airway Protection

As discussed in Chapter 76, plain chest radiographs and high-resolution computed topography (CT) of the chest (dynamic and static) are not diagnostic tests for aspiration but provide information regarding lung disease and the progression or resolution over time.

If clinical signs or symptoms of possible difficulty with airway protection during swallowing are noted during the clinical feeding evaluation, or if the child presents with chronic pulmonary problems suspicious for aspiration, objective studies to assess airway protection during swallowing are indicated. The most common instrumental examinations include the videofluoroscopic swallow study (VSS) and fiberoptic endoscopic evaluation of swallowing (FEES). Indications for the pediatric FEES study and the videofluoroscopic swallowing study are listed in Table 77.3. The relative advantages and disadvantages of each examination are summarized in Table 77.4.

## Table 77.3

### Indications for Videofluoroscopy and/or Fiberoptic Endoscopic Evaluation of Swallowing

| **Videofluoroscopic Swallowing Study** | **Fiberoptic Endoscopic Evaluation of Swallowing** |
|---|---|
| Baseline assessment of swallowing function: Need overall view of oral, pharyngeal, and esophageal phases of swallowing | Known or suspected structural abnormality with implications for airway protection during swallowing |
| Need to view sequential swallow sequences | Questionable secretion management ability |
| Need to exclude structural problem in the esophagus, stomach, or duodenum as a source of dysphagia | Patient accepts minimal amounts of food/liquid orally |

## Table 77.4

### Advantages and Disadvantages of Pediatric Fees

| **Advantages** | **Disadvantages** |
|---|---|
| Specific focus on airway protection during swallowing | Possible discomfort with scope passage |
| Provides assessment of patient ability to manage secretions | Presence of scope may induce gagging and vomiting in patients with hypersensitive responses |
| Does not require alteration of food or liquid with contrast | View is obscured during swallowing contraction; can only view events before and after “white-out” |
| No radiation exposure | Focus of exam is limited to primarily the pharyngeal phase |
| Can determine readiness to transition to oral feeding in regard to airway protection ability | Lack of view during rapid sequential swallowing (bottle feeding) |
| Effect of compensatory strategies on improvement of swallowing function/safety can be determined during exam | Contraindicated for patients with choanal atresia, nasal stenosis, nasal obstruction, pharyngeal stenosis |
| Visual picture of swallowing may provide beneficial feedback to family | Requires special training |

# Videofluoroscopic Swallow Study

The pediatric VSS provides visualization of all phases of the swallow under fluoroscopy.[40,41] Delineation of tongue motion during bolus preparation and adequacy of tongue base retraction for swallowing initiation are analyzed. Bolus transfer through the pharynx and upper esophageal sphincter is clearly visualized.

Abnormalities in the swallowing process, such as premature or inefficient oral bolus transfer, delayed initiation of swallowing response (Video 77.1), inadequate pharyngeal clearance following swallowing (Video 77.2), penetration of the bolus into the larynx (see Video 77.2), and aspiration of the bolus into the airway below the vocal folds (Video 77.3), are readily identified. Patient reaction or response to abnormalities in the swallowing process can be assessed. For example, protective reaction or adequacy of clearing response to episodes of aspiration can be ascertained.

Compensatory strategies can be implemented to assist with maintenance of airway protection during swallowing or to improve swallowing efficiency. Positioning adjustments, increasing liquid viscosity/texture alteration, altering the bolus delivery system (e.g., nipple or cup flow rate) or postural strategies (e.g., chin flexion or head tilting) may be implemented to assess effect on swallowing dynamics and improving airway protection during swallowing.

Disadvantages to the pediatric VSS include radiation exposure to the patient and to the feeder. The necessary addition of barium to the food and liquid potentially decreases the child's willingness to eat or drink during the examination. Implementing compensatory strategies adds to the overall radiation exposure time, limiting the extent to which options can be tested. Infants or children who have only negligible amounts of oral intake are not appropriate candidates for a VSS because an enough contrast must be ingested to obtain adequate imaging. See Fig. 77.1 for a sagittal view of swallowing structures as seen during the VSS exam.

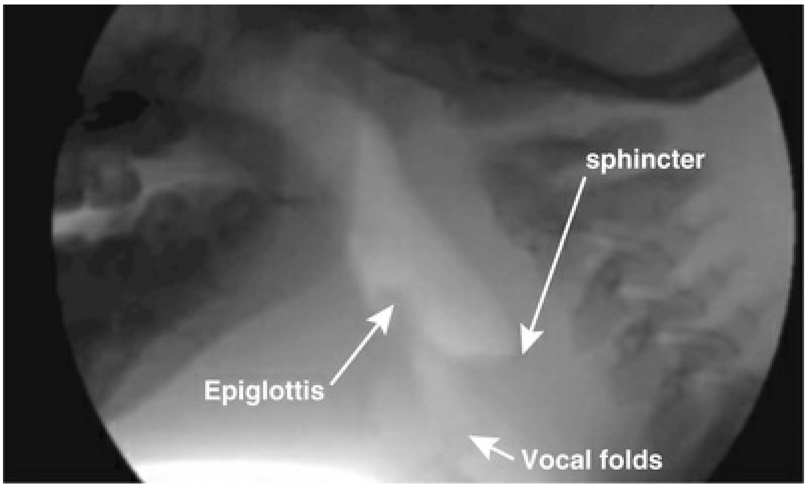

**FIG. 77.1** Sagittal view of swallowing structures as seen via videofluoroscopic swallow study.

## Fiberoptic Endoscopic Evaluation of Swallowing

A FEES study to assess adequacy of airway protection during swallowing is indicated for patients who have never fed orally or who have minimal oral intake. The FEES is a useful tool for patients with brainstem or CN involvement (allows visualization of asymmetrical pharyngeal contraction) and as an interval exam that does not involve radiation exposure for patients requiring serial swallow studies. In addition, patients with congenital, traumatic, or surgical upper airway anomalies (either preoperative or postoperative) are excellent candidates given that the otolaryngologist gains information from the flexible laryngoscopy exam. FEES is also a good alternative method for patients who are too medically fragile to be transported to the radiology department for a VSS, or who cannot be positioned adequately for a VSS. Assessment of swallowing dynamics during breast feeding (Video 77.4) is possible, a distinct advantage of the FEES examination in comparison to videofluoroscopy.[42]

FEES is accomplished by transnasal passage of a pediatric flexible endoscope, allowing direct visualization of pharyngeal and laryngeal structures, function, management of secretions, intactness of sensation, and spontaneous swallows.[43] The device may be passed by an otolaryngologist or a speech language pathologist, depending upon practice pattern and licensing. The swallowing assessment is performed using the patient's normal foods and liquids (which may be mixed with a small amount (<1 mL overall) of food dye to aid in visualization of the bolus.[43–45] Information regarding secretion management and ability to generate spontaneous swallows can be achieved without requiring the patient to ingest food or liquid. See Video 77.5 for an example of poor laryngeal clearance of secretions during the FEES exam. The focus of the pediatric FEES study is on airway protection ability and sensation, as well as anatomic abnormalities and their potential role in dysphagia. Compensatory strategies to assist with achieving airway protection during swallowing (e.g., those used during the VSS) can be implemented without concern for prolonged radiation exposure. As noted previously, patients who are being evaluated for possible airway reconstruction procedures are particularly appropriate candidates for FEES because information regarding integrity of structures and function is made available.[46] Assessment of current swallowing ability and laryngeal function provides the information necessary to proceed with surgical intervention designed to rebuild and preserve total laryngeal function. A clinical swallowing assessment in conjunction with the pediatric FEES examination has been shown to identify patients with difficulty achieving airway protection preoperatively and to identify patients likely to require short-term swallowing treatment postoperatively.[46]

One distinct advantage of the pediatric FEES exam is the ability to obtain information regarding the patient's laryngopharyngeal sensory threshold, fundamental to airway protection integrity. The adequacy of the LAR for protection from aspiration can be assessed by gently tapping the endoscope in the region of the aryepiglottic fold, for observation of reflex glottic closure. Disadvantages to the pediatric FEES examination include potential discomfort with endoscope passage, although topical anesthesia (1 : 1 mixture of oxymetazoline and 2% pontocaine) can be administered nasally prior to the exam to increase patient comfort. In addition, use of lidocaine gel on the scope facilitates numbing of the nasal passageway and may also increase patient comfort with the procedure. In dysphagic adults a standard dose of atomized lidocaine (0.2 mL of 4% lidocaine) administered in combination with 0.2 mL nasal decongestant (oxymetazoline HCL) was shown to improve exam tolerability and did not impact pharyngeal swallowing function.[47] Studies of topical anesthesia have not been performed in the pediatric population on a large scale. Administration of topical anesthetic during FEES is not indicated in infants younger than 12 months or in patients with significant neurologic involvement due to concern that the anesthetic could impact pharyngeal sensation and swallowing function; however, viscous lidocaine on the scope may be used to increase comfort during the examination.[43] In addition, swaddling, having the patient be held by a familiar caregiver, and introducing a pacifier or bottle during the exam are effective calming measures. In some institutions, other team members are present during the FEES exam, including occupational therapists to assist with positioning, compliance with state regulations, and observation of oral feeding during the exam and child life/therapeutic recreation specialists to provide distraction and calming measures. Patients with oral hypersensitivity or oral aversion may have a gagging reaction in response to the tactile stimulation of the instrument and may therefore have difficulty participating in a functional exam. FEES may be contraindicated in patients who present with choanal atresia, nasal stenosis, nasal obstruction, or pharyngeal stenosis, because passage of the endoscope can be impeded. Selection of this modality would be at the discretion of the otolaryngologist and speech language pathologist involved in the patient's care.

Differences in anatomy across infants and children to adolescents and young adults necessitate the use of varied endoscope sizes during pediatric FEES. Standard-sized endoscopes (3.5–4.0 mm) are appropriate for most infants and children, although the use of a smaller endoscope (2.0–2.4 mm) is more commonly used for comfort and may be necessary if structural abnormalities of the nasal passageway or midface are present. Transnasal passage of the endoscope may be carried out by either the otolaryngologist or the speech pathologist, depending upon the laws governing the scope of practice for the latter in a particular state. The nasal exam may demonstrate etiologies of nasal obstruction (e.g., turbinate hypertrophy), as well as providing evaluation of the nasal surface of the soft palate during speech or feeding. This may be particularly useful in patients at risk for submucosal cleft of the soft palate and nasopharyngeal regurgitation.

As the scope is advanced into the hypopharynx during the anatomical assessment, consideration is given to any pooled secretions that may be present, because difficulty with secretion management has been associated with significant swallowing abnormality. Spontaneous swallow efforts to clear secretions should be noted. Laryngeal penetration and aspiration of secretions and the patient's protection reaction (or lack thereof) can be clearly visualized.

Interpretation of swallowing parameters during FEES includes assessment of the timeliness of swallowing onset, laryngeal penetration prior to swallowing onset, aspiration before or after the swallow, and the adequacy of hypopharyngeal clearance following the swallow (Fig. 77.2). In addition, patients with poor esophageal motility and severe reflux may be seen to regurgitate during the exam (Video 77.6). Patients with cricopharyngeal achalasia may demonstrate failure to relax the upper esophageal sphincter, resulting in stacking of material in the pyriform sinuses.

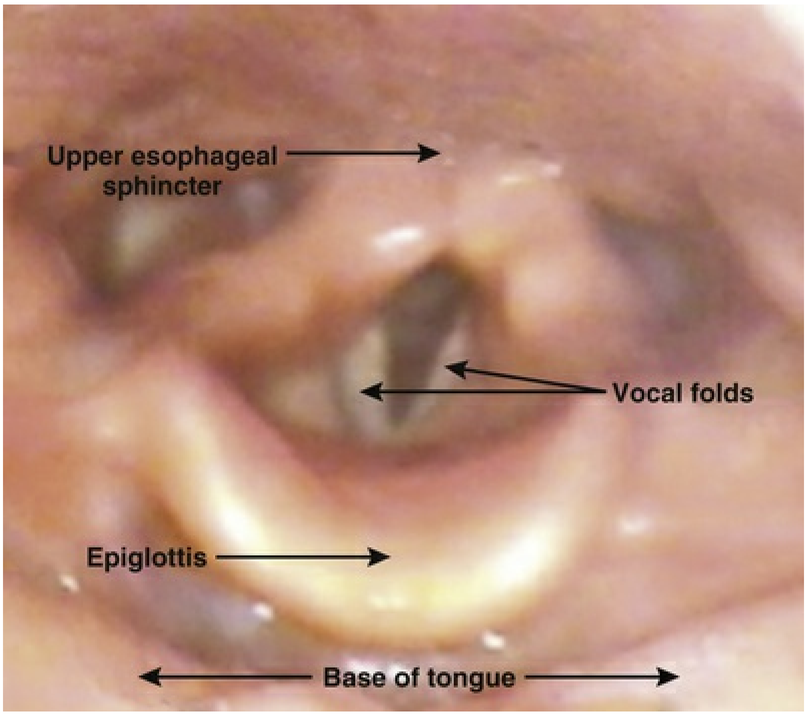

**FIG. 77.2** Endoscopic view of swallowing structures as seen during fiberoptic endoscopic evaluation of swallowing.

The depth of laryngeal penetration prior to swallowing onset can be clearly visualized. Aspiration is often visualized only prior to the swallow or detected after the swallow. The upward motion of the larynx, retroversion of the epiglottis, and contraction of the pharynx during the swallow result in subsequent deflection of light, and "white-out" at the actual moment of the swallow. The loss of view during sequential swallowing such as during bottle feeding is not advantageous; the VSS is superior for visualization of swallowing dynamics during consecutive chain swallowing cycles. See Fig. 77.2

for endoscopic view of swallowing structures as seen during the FEES exam.

Additional testing may be performed as indicated by the patient's history and exam. Further imaging studies include an upper GI or esophagram to define the upper GI anatomy, as well as get a broad view of motility. Endoscopy remains important for detecting mucosal abnormalities such as laryngitis or esophagitis, as well as structural abnormalities. This can include assessment with microlaryngoscopy, bronchoscopy, and upper endoscopy. In multidisciplinary aerodigestive programs, these procedures are often coordinated and performed sequentially to limit exposure to anesthesia, as well as to maximize shared communication and planning between subspecialties and families.

Impedance probe monitoring is another useful test for GER and provides information regarding esophageal clearance, acidity of the refluxate, and symptom correlation. Although impedance is gaining popularity in the evaluation of children, esophageal manometry remains the gold standard for motility.[48,49] Children with frequent vomiting or evidence of severe GER may also benefit from a gastric emptying scan. An MRI of the brain may be needed to evaluate for possible neurologic causes of dysphagia and aspiration, such as Arnold-Chiari malformation.

## Diagnosis, Management, and Treatment

The clinical oral motor feeding assessment is often the initial step in the overall diagnostic evaluation of feeding and swallowing problems. The presentation of feeding and swallowing dysfunction can be variable and often requires the input from multiple providers. The insidious nature of silent aspiration may be a complicating factor and should be considered during the clinical assessment process. Clinical assessment provides the initial framework for consideration of medical and developmental history, direct assessment of oral sensorimotor skills, and documentation of clinical signs and symptoms of possible swallowing dysfunction. Direct observation of clinical signs and symptoms of compromised airway protection during feeding, as well as suspicion based on history and diagnoses associated with dysphagia, prompt referral for further procedures and instrumental assessment of swallowing function.

## Evaluation and Management

Identification and management of feeding, swallowing, and voice disorders is ideally done by a multidisciplinary team comprising otolaryngologists, gastroenterologists, pulmonary medicine specialists, speech pathologists, occupational therapists, dietitians, behavioral psychologists, and social workers.[50]

Obtaining a detailed history of the child's medical history, development, diet, and feeding patterns is essential for feeding and swallowing assessment. Clinical interview questions include the types of foods and liquids typically ingested, tolerance of different textures and volume, and the child's typical behavior during meals. Specific inquiries should be made regarding respiratory status, history of recurrent respiratory infections or pneumonia, upper airway noise, stridor associated with feeding, and any interventions or operations involving the aerodigestive tract. A thorough clinical assessment of nonnutritive and nutritive oral motor skills is conducted. Clinical assessment of oral motor/feeding skills should include assessment of parent-child interaction during feeding, because disordered interactions may exacerbate feeding difficulties. Clinical signs and symptoms of possible swallowing dysfunction have been noted, including gagging, coughing, choking, color changes, increased noisiness during or after feedings, periods of apnea or bradycardia associated with feeding, increased difficulty with secretion management, frequent suctioning needs, or evidence of food or liquid in the tracheostomy tube.[51]

## Treatment Strategies

The approach to intervention for feeding and swallowing should be individualized for each patient and depends on the constellation of issues present. Treatment approaches include direct rehabilitative maneuvers/exercises and the use of compensatory strategies such as sensory stimulation, diet modifications, alterations in positioning for feeding, the use of specialized feeding equipment, and the implementation of specific behavioral approaches to facilitate positive and productive feeder/child interactions. The specific approach is determined by the medical issues present, the child's developmental level, and the types of sensory and motor issues that are contributing to the feeding and swallowing dysfunction.

To ensure optimum nutrition, supplemental feeding via nasogastric tube or gastrostomy may be helpful during the oral feeding treatment period. The supplemental feeding allows the child to receive calories needed for adequate growth as they develop more functional swallowing skills and progress with feeding therapy. Treatment techniques focus on improving the child's oral motor skills to assist with feeding efficiency and ability to progress with food of increased texture. Treatment may also include methods to assist with overcoming sensory processing and oral sensory discrimination issues that may be contributing to the overall oral feeding difficulty. In cases of severe dysphagia, supplemental feeding methods may provide total nutrition; however, allowing the child to have some degree of oral stimulation, even if this consists only of tastes without appreciable volume, promotes social interaction at mealtime and may assist in preventing the development of oral aversion or resistance to oral feeding. If advancing the volume of oral feeding is appropriate during treatment, collaboration with the managing physician and a registered dietician is important during the transition period to ensure that appropriate nutritional status is maintained.

It is important to recognize the behavioral issues that may occur in this population. In general, oral aversion and resultant poor oral intake may have a strong underlying behavioral component.[52] Parents or caretakers may be afraid to present oral feedings because of their child's medical complexity, or they may view the child as “vulnerable” and therefore may not provide mealtime structure or organization. Children with complex airways and multiple medical issues who undergo periods of time without oral intake can develop aversions that persist even after their underlying condition is corrected.

In a select group of children, innovative feeding practices are needed. For example, giving pureed foods into the gastrostomy can decrease gagging and retching behaviors following fundoplication surgery. This method of feeding can decrease symptoms and allow children to be more receptive to taking food orally.[53]

Empiric data are limited regarding the efficacy of therapeutic strategies to assist with development of compensatory swallowing techniques postoperatively in airway reconstruction patients. Introduction of a modified supraglottic swallowing sequence to assist with achieving compensatory airway closure during swallowing has been described as effective in small patient samples.[31] Indirect treatment strategies include the alteration of textures and liquids (i.e., thickening liquids) to slow liquid flow and provide an increased time interval for use of supraglottic strategies to assist with airway closure. Alternating solid intake with liquid intake to assist with pharyngeal clearance has also been described as an effective strategy in the postoperative airway reconstruction period.

## Summary

Analysis of specific laryngeal functions associated with swallowing in the pediatric population is accomplished best through clinical and instrumental examinations. Identification of current laryngeal function and awareness of changes that may occur in association with specific reconstruction procedures assist clinicians in designing appropriate and effective treatment plans. Based on the number of interacting factors and possible comorbidities, a team approach to airway and swallowing assessment and management is essential to the child's ultimate health outcome and quality of life.

# Gastroesophageal Reflux Disease and Eosinophilic Esophagitis in Children With Complex Airway Disease

*Scott Pentiuk MD, MEd, Philip E. Putnam MD*

Children who have complex airway conditions often have concomitant gastrointestinal (GI) disease—most notably gastroesophageal reflux disease (GERD), eosinophilic esophagitis (EoE), dysphagia, or disordered motility. These children often have a history of prematurity and neurodevelopmental delay, along with other attendant comorbidities associated with prolonged NICU admissions. They may also have syndromes that lead to structural abnormalities such as esophageal atresia with or without tracheoesophageal fistula (TEF). These GI conditions may contribute to the disordered breathing that is commonly caused by lung disease of prematurity complicated by structural anomalies (congenital or acquired). Simultaneous management of the airway and the GI disease is required for optimal outcome.

# Gastroesophageal Reflux Disease

## Epidemiology

Children who have complex airway anomalies may be at higher risk for GERD. The exact prevalence of GERD in this population is unknown, though it is generally believed to be up to 70% in children who have complex medical conditions such as developmental delay or a history of TEF repair.[1,2]

## Pathophysiology

It is important to distinguish gastroesophageal reflux (GER) from GERD. Reflux occurs in normal individuals and is the inconsequential transient return of gastric contents into the esophagus, whereas GERD is defined as symptoms and/or mucosal changes related to excessive stomach acid regurgitation into the esophagus and oropharynx.[3] Normal children demonstrate reflux into their esophagus multiple times per day, half of which are generally nonacidic in nature.[4] Most episodes of GER in healthy individuals last less than 3 minutes, occur after meals, and cause few or no symptoms.[5] In patients who have a history of swallowing dysfunction, there is evidence that episodes of reflux reaching the level of the proximal esophagus can cause airway damage and lead to pneumonia and respiratory tract infections.[6] GERD may be caused by the altered thoracoabdominal pressure relationships that exist in children who have obstructive airway disease. Thus GERD is frequently a consequence rather than a primary cause of asthma symptoms or pulmonary disease in cystic fibrosis. Nevertheless, GERD may contribute to symptoms in these conditions.

GERD is also associated with weight gain and obesity in adults.[7]

Evidence for this association in pediatric age patients is less compelling. Nevertheless, clinical consideration of GERD in children should recognize the potential for interactions between excess weight, sleep-disordered breathing, asthma, and GERD.[8]

## Clinical Features/Symptoms

The symptoms of GERD affecting the airway are wide-ranging and include reactive airway disease, chronic cough, hoarseness, and difficulty swallowing.[3,8] Mucosal abnormalities, including laryngeal edema, cobblestoning, and mucosal erythema, are nonspecific and do not prove the presence of reflux disease. Likewise, the absence of these findings does not exclude the presence of reflux.[3,9]

True acidic GER can lead to mucosal injury in the larynx, conducting airways, and lung tissue. Acidic aspiration has long been known to cause mucosal sloughing and neutrophilic inflammation in alveolar tissue.[10] There is evidence that acid reflux decreases laryngeal sensitivity, which could increase the risk for aspiration.[11] Even nonacid reflux has been linked with a higher frequency of chronic lung disease in adults.[12] On the other hand, poorly controlled asthma did not benefit from treatment with esomeprazole in patients who also had asymptomatic GERD in a 24-week placebo-controlled blinded study, which shows the difficulty in establishing the cause-effect relationship between reflux disease and laryngeal or airway symptoms.[13] GERD may be present as a comorbidity that has no impact on the airway, or it may cause or exacerbate airway symptoms.

Data regarding the relationship between GERD and reconstructive airway surgery are sparse. Carron and colleagues demonstrated that simulated GER caused increased inflammation in cartilage grafts in a rabbit model after laryngotracheoplasty compared with controls.[14] However, they were unable to show that reflux led to increased failure in the rabbit cartilage grafts. Several authors note that the treatment of children with proton pump inhibitor therapy to prevent GER improves outcomes in children after airway reconstruction, but these studies are all retrospective or represent just expert opinion.[15–17] Zalzal and coworkers showed that children who had documented GERD had similar outcomes to those who did not have GERD after laryngotracheal reconstruction for laryngeal stenosis, irrespective of treatment.[18] Regardless, there is sufficient concern that GER might negatively impact the results of airway reconstruction surgery that empiric antireflux therapy is often prescribed.

## Diagnosis/Testing

The diagnosis of GERD depends on the demonstration that there are untoward consequences from reflux events and there is no single gold standard test.[3] The diagnosis may be made presumptively based on clinical history alone when there is effortless regurgitation or heartburn. When regurgitation is not present in a child who has symptoms that could be caused by GERD, additional testing to detect reflux events or to document esophageal mucosal injury is possible. There is no single test that proves that reflux is responsible for a particular airway symptom, but a successful empiric trial of a proton pump inhibitor or $H_2$ blocker is suggestive.

Children with persistent symptoms, or who need diagnostic studies prior to therapy, may undergo endoscopic evaluation or multichannel intraluminal impedance plus pH-metry (MII-pH). The latter is a 24-hour study that measures the frequency, duration/clearance, height of reflux, and duration of acid exposure in the esophagus by means of a catheter placed via the nose. Upper GI endoscopy permits visual inspection and biopsy of the esophageal mucosa to detect acid injury, ranging from microscopic abnormalities on histology to gross mucosal ulceration. However, there is controversy as to how to interpret the biopsy findings as due to acid reflux disease.[3] Children who aspirate refluxed gastric contents may have pepsin identified in their bronchoalveolar lavage, though the absolute sensitivity and application of this test remain to be determined.[19] Upper GI series with barium is not adequate for the diagnosis of GERD as the ingested contrast media commonly refluxes back into the esophagus, even in normal individuals. However, the test is commonly performed to evaluate the upper GI anatomy in patients who vomit or have dysphagia, and can help identify anatomic abnormalities such as esophageal stricture, hiatal hernia, or TEF.[3]

## Management

Standard medical therapy for GERD is acid suppression with either a proton pump inhibitor or $H_2$ blocker. Both types of medication decrease acid production from gastric parietal cells. Tachyphylaxis, or decreased response, is an issue with histamine receptor antagonists such as ranitidine.[20,21] Proton pump inhibitors appear to be more effective in treating erosive esophagitis than H2 blockers and in suppressing gastric acid production.[22] It is important to remember that nonacid reflux will still occur even with adequate doses of medication. Many children may continue to complain of symptoms even on acid suppression with no evidence of inflammation on biopsies: the so-called nonerosive reflux disease (NERD).

The length of a treatment course is unclear. In adults with true erosive esophagitis, mucosal healing with proton pump inhibitors can take up to 2 months.[23] However, many patients remain on medication indefinitely. Emerging data demonstrate several risks of long-term side effects of proton pump inhibitors (PPIs). These include adult data on decreased bone density as well as pediatric studies showing increased risk for respiratory infections and *Clostridium difficile* infection.[24–26] This indicates that consideration of whether a child needs to continue long-term acid suppression is warranted. Children who symptomatically do not respond to acid suppression may require additional evaluation for EoE or gastroparesis, as discussed later in this chapter.

Medical therapy to limit the number of reflux episodes, irrespective of acidity, is quite limited. Metoclopramide has been used for GERD, but it has limited effectiveness and there is a high risk of side effects, including tardive dyskinesia.[23] Children with recalcitrant GERD may benefit from antireflux surgery, as it effectively abolishes reflux and its attendant symptoms. Aspiration of refluxed gastric contents is controlled by fundoplication, but aspiration during swallowing is not affected. Fundoplication is associated with a number of complications, such as gagging/retching, gas bloat, or dumping syndrome, so it should be reserved for those patients who cannot be managed medically.[27]

# Disorders of Motility

It is important to consider that children with complex airway conditions may also have gastric or esophageal motility disorders. Esophageal dysmotility can be idiopathic but may also relate to nerve disruption following surgery, such as TEF repair or Nissen fundoplication. Children may present with inability to swallow, regurgitation, or intractable GER symptoms. Upper GI may show poor clearance of contrast in the absence of a stricture. MII-pH testing is normally employed to detect reflux and associated symptoms with retrograde fluid movement in the esophagus, but the analytical software may be used to evaluate antegrade esophageal emptying of swallowed (and refluxed) material. Esophageal peristalsis may be diminished, absent, or even retrograde on manometric testing.

Disorders of gastric emptying present with symptoms such as nausea, early satiety, and vomiting, often from meals ingested many hours prior.[28,29] In children for whom there is concern for poor stomach emptying, a nuclear gastric emptying scan can provide a quantitative assessment, but does not establish the underlying cause of delay.

Treatment for motility disorders of the esophagus is often supportive, as there are no commonly employed medications that improve esophageal peristalsis. Children may need to restrict bolus size and often require a significant proportion of their calories by liquid formulas. Because of the risk of worsening gagging and retching after surgery, we typically do not recommend fundoplication in children with esophageal or gastric dysmotility, though there are few data in the literature.

Erythromycin is an antimicrobial with a prokinetic side effect that is employed to improve gastric emptying. It does not have significant impact on GER, but it can improve the symptoms of impaired gastric emptying. Other possible therapies include endoscopic administration of Botox to the pylorus, with or without concomitant pyloric dilatation (for temporary relief) or surgical pyloroplasty (for long-term relief).[30] Gastric pacemakers remain under development, particularly in pediatrics.[29]

# Eosinophilic Esophagitis

An increasingly recognized cause of inflammation of the esophagus is EoE. Minimum criteria for the diagnosis of this clinico-pathologic entity are the presence of greater than 15 eosinophils/high power field (HPF) on microscopic examination of biopsies from the esophagus, the absence of response to PPI, and the absence of GERD or any other condition that could promote eosinophilic inflammation.[31–33]

## Pathophysiology

Although concepts are still evolving, basic science studies to date have demonstrated that EoE is a disorder of epithelial homeostasis. Important factors in pathogenesis include defects in the barrier function of the epithelium that are promoted by the downregulation of genes encoding the proteins that are involved in maintaining the adhesion between squamous cells (e.g., desmoglein and calpain-14).[34,35] This may allow dietary antigens access to deeper levels of the epithelium than normal, and susceptible individuals then mount a non-IgE mediated immune response via Th2 pathways. Dysregulation of immune mediators such as eotaxin 3 and IL-13 contribute to disease susceptibility and maintenance. Although tissue eosinophilia is a marker of disease activity, lymphocytes and mast cells also participate in the inflammatory infiltrate.

More than 70% of affected individuals are male, and two-thirds of patients are otherwise atopic, with asthma, eczema, and/or IgE-mediated food allergy. There is a strong familial predisposition for EoE, as indicated by up to a 64-fold increased relative risk among first-degree relatives (e.g., male siblings).[36] The pattern of inheritance does not suggest single gene or Mendelian inheritance within families. Family and twin studies support a strong genetic link but also indicate that there must be an environmental trigger to initiate the disorder in susceptible individuals.

Symptoms from EoE are nonspecific and vary by age at presentation. Younger children often present with feeding problems, whereas abdominal pain or vomiting are characteristic features in elementary school-aged children.[37] Preteens, adolescents, and adults present dysphagia or food impaction.[38]

EoE has been diagnosed in children who present with recurrent croup, chronic cough, sinusitis, congestion, or choking episodes.[39,40] At our institution, undiagnosed EoE has been discovered in tracheostomy-dependent children who previously failed airway reconstruction, although its precise role in that failure remains uncertain. Nevertheless, because there is sufficient concern that EoE might pose difficulties after airway reconstruction, we manage EoE and confirm histologic recovery from it prior to reconstructive airway surgery.

## Diagnosis of Eosinophilic Esophagitis

The process of establishing a diagnosis of EoE is relatively straightforward. Depending on the clinical circumstances and the level of concern for the diagnosis based on presentation, the endoscopy may be done prior to or after an 8-week course of high-dose PPI.[31] The diagnosis of EoE is excluded if eosinophil numbers do not exceed 15/HPF. If the endoscopy is performed prior to a PPI trial and eosinophils are present, a second endoscopy after an appropriate PPI trial is required to confirm or exclude the diagnosis. The issue can be confounded by the co-occurrence of GERD with esophagitis and EoE. In addition, there is now recognized a non-GERD esophageal mucosal eosinophilia that nevertheless responds to PPI treatment (now called PPI-responsive esophageal eosinophilia).[41]

The endoscopic features of EoE are characteristic but nondiagnostic, and include thickening, furrowing of the esophageal mucosa, and small white plaques that are eosinophilic microabscesses on the surface.[31] However, the disease can be patchy, and an estimated 25% of cases present with a normal endoscopic appearance. As such, it is essential that biopsies be obtained irrespective of the endoscopic appearance, and that a minimum of five biopsies of the esophagus be taken to minimize the risk of missing the diagnosis by sampling error.[42] In addition to the inflammatory infiltrate, common histologic changes, including basal zone hyperplasia, rete peg elongation, and dilated intercellular spaces, are key features of epithelial reactivity.[43]

## Treatment of Eosinophilic Esophagitis

Remission of the inflammation occurs in the absence of stimulation by provocative antigens. Precise identification of the offending antigens is a challenge, as food allergy testing by standard skin prick testing and serum specific IgE levels usually fail because the mechanism of immune response to the antigen in EoE does not primarily involve IgE. Empiric elimination of common provocative antigens (e.g., milk, soy, egg, seafood, nuts, and wheat) offers a starting point for antigen elimination and has proven to be effective in up to 80% of patients.[44] Total antigen avoidance with nutritional support by an amino acid–based formula is extremely effective (95% to 98% of patients remit) but is often a challenge to promote and maintain in older children, who may require an NG tube or G-tube for formula administration.[45]

An alternative to antigen elimination is the use of “topical” steroids such as fluticasone or budesonide, which, when swallowed rather than inhaled, directly reduce the mucosal inflammation in up to 90% of patients.[46,47] Although the FDA has not approved any medication for use in EoE, these medications are widely employed. They must be maintained indefinitely, as the recurrence rate of the disease is virtually 100% if they are discontinued.

Unfortunately, symptom resolution does not imply resolution of the histologic inflammation, so repeat endoscopy is recommended to confirm histologic remission of the disease with any change in therapy or diet, even if symptoms have diminished.[31,48,49] Chronic persistent eosinophilic inflammation is associated with lamina propria fibrosis, reduced esophageal wall compliance, and stricture development. The resulting dysphagia can be improved by esophageal dilatation, although diet or medical therapy is preferred to manage the inflammatory process directly.[50] EoE is a chronic disorder for which there is no cure, and maintenance of remission, confirmed histologically, is essential to avoid long-term dysphagia.

# Laryngeal and Tracheal Airway Disorders

*Alessandro De Alarcòn MD, MPH, Jeremy Prager MD, MBA, Michael Rutter BHB, MBChB, FRACS, Christopher Todd Wootten MD*

## Introduction

Advances in the management of critically ill infants with extreme prematurity, complex congenital anomalies, airway trauma, and infectious diseases concomitantly created a new subset of patients with complex airway problems rather than isolated subglottic or tracheal stenosis. The overall management of these patients often includes surgical airway intervention. Evaluation requires a global perspective, with assessments of both the airway and the child's overall health status, thereby ensuring optimization of general health prior to surgical intervention. This broad-based approach is crucial to the success of airway reconstruction.

We have found that minimizing the risk of operative failure can best be achieved through the collaborative efforts of a well-coordinated interdisciplinary team. Thorough clinical and operative examinations should be performed, with involved health professionals being aware of conditions and risk factors that can significantly impact clinical outcomes.

This chapter presents an overview of the critical aspects of otolaryngologic management of this complex patient population in the context of the collaborative model used at our institutions. We briefly discuss the initial assessment, mitigating factors that can affect airway reconstruction, and perioperative management of specific airway pathology.

# Operative Assessment

The interdisciplinary team performs the operative evaluation, with input from each physician being crucial. This evaluation comprises three endoscopic procedures performed consecutively with the patient under a single anesthesia: (1) flexible bronchoscopy with bronchoalveolar lavage (BAL), (2) microlaryngoscopy and rigid bronchoscopy,[1] and (3) esophagogastroduodenoscopy (EGD) with biopsy. For patients in whom gastroesophageal reflux (GER) is suspected or in whom GER would have negative consequences, objective evaluation of GER is recommended. Each component of this endoscopic evaluation is aimed at identifying possible pathology[2] and risk factors that can affect the success of airway reconstruction.

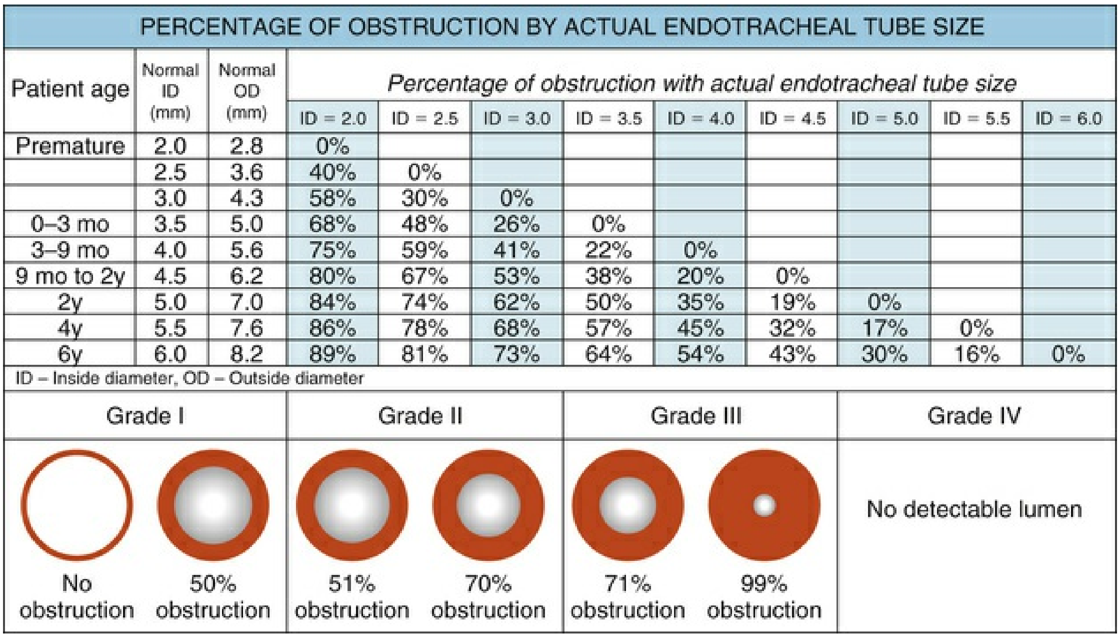
## Flexible Bronchoscopy

Flexible bronchoscopy offers several advantages over rigid bronchoscopy. It facilitates identification of areas that can cause airway obstruction and that may be underappreciated or missed with a rigid bronchoscope. More specifically, flexible bronchoscopy provides better assessment of disorders such as glossoptosis, laryngomalacia, tracheomalacia, and bronchomalacia.[3] Evaluation of the distal airway may provide additional information on vascular compression, bronchiectasis, and assessment of aspiration by BAL. (See Chapter 9 for a more detailed discussion.)

## Microlaryngoscopy and Rigid Bronchoscopy

Prior to evaluation in the operating room, vocal cord mobility should be assessed in an office setting in the awake child with transnasal flexible laryngoscopy, because vocal cord movement is poorly assessed with the child under general anesthesia. This may be done as part of a fiberoptic endoscopic evaluation of swallowing (FEES) or as part of a voice evaluation. Microlaryngoscopy and rigid bronchoscopy are performed with the primary goal of identifying anatomic levels of airway obstruction from the larynx to the carina. The supraglottis is evaluated with attention given to the possibility of supraglottic obstruction, such as laryngomalacia and supraglottic stenosis. The vocal fold level is then evaluated for posterior glottic stenosis, anterior glottic web, and laryngeal cleft. It should be noted that the posterior glottis is an area that is suboptimally evaluated by flexible bronchoscopy. If vocal fold immobility is suspected or seen on the FEES evaluation, or on voice evaluation, the cricoarytenoid joints should be palpated to determine if there is any fixation of the joint.

Rigid bronchoscopy is performed using a combination of Hopkins rod telescopes and rigid bronchoscopes. The subglottis is then evaluated. If subglottic stenosis (SGS) is present, it is classified by the Myer-Cotton scale[4] and sized using increasingly larger endotracheal tubes until the largest tube that has a leak at less than 20 cm of water pressure is determined (Fig. 79.1). In addition, the length of stenosis and the proximity to the vocal folds is assessed and documented. If a tracheotomy is in place, attention is paid to the evaluation of the suprastomal area, considering the possibility of suprastomal collapse, granuloma, intratracheal skin tract, and a high tracheotomy. The trachea is evaluated to the level of the carina, looking for additional pathology, including tracheal stenosis, complete tracheal rings, tracheoesophageal fistula (TEF), TEF pouches, vascular compression, and tracheomalacia.



PERCENTAGE OF OBSTRUCTION BY ACTUAL ENDOTRACHEAL TUBE SIZE

| Patient age | Normal ID (mm) | Normal OD (mm) | *Percentage of obstruction with actual endotracheal tube size* | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|
| | | | ID = 2.0 | ID = 2.5 | ID = 3.0 | ID = 3.5 | ID = 4.0 | ID = 4.5 | ID = 5.0 | ID = 5.5 | ID = 6.0 |
| Premature | 2.0 | 2.8 | 0% | | | | | | | | |
| | 2.5 | 3.6 | 40% | 0% | | | | | | | |
| | 3.0 | 4.3 | 58% | 30% | 0% | | | | | | |
| 0–3 mo | 3.5 | 5.0 | 68% | 48% | 26% | 0% | | | | | |
| 3–9 mo | 4.0 | 5.6 | 75% | 59% | 41% | 22% | 0% | | | | |
| 9 mo to 2y | 4.5 | 6.2 | 80% | 67% | 53% | 38% | 20% | 0% | | | |
| 2y | 5.0 | 7.0 | 84% | 74% | 62% | 50% | 35% | 19% | 0% | | |
| 4y | 5.5 | 7.6 | 86% | 78% | 68% | 57% | 45% | 32% | 17% | 0% | |
| 6y | 6.0 | 8.2 | 89% | 81% | 73% | 64% | 54% | 43% | 30% | 16% | 0% |

ID – Inside diameter, OD – Outside diameter

| Grade I | Grade II | Grade III | Grade IV |
|---|---|---|---|
| No obstruction<br>50% obstruction | 51% obstruction<br>70% obstruction | 71% obstruction<br>99% obstruction | No detectable lumen |

**FIG. 79.1** Myer-Cotton grading scale.

The entire airway should also be evaluated for the presence of inflammation because operating on an inflamed airway has a far lower success rate. Common signs of airway inflammation include cobblestoning of the mucosa of the laryngeal surface of the epiglottis, eversion of the laryngeal ventricles, edema of the subglottic mucosa, and loss of definition of tracheal rings due to tracheal mucosal edema.

## Esophagogastroduodenoscopy

Evaluation of the upper gastrointestinal tract can provide information that is crucial in decision making with regard to future surgery. Inflammation in the laryngotracheal complex can be caused by conditions of the upper gastrointestinal tract, resulting in an "active" (i.e., inflamed) larynx. Poor wound healing and scarring are more likely to occur in this setting. The two gastrointestinal conditions associated with laryngeal inflammation are eosinophilic esophagitis (EoE) and gastroesophageal reflux disease (GERD); the diagnosis of EoE is made on esophageal biopsy. Laryngeal inflammation may resolve with appropriate treatment of the underlying condition, permitting surgical reconstruction with a lower risk of complication.

## Swallowing and Voice Evaluations

Preoperative swallowing and voice evaluations can be crucial because both may alter an otherwise sound surgical plan.

If there is a suspicion of ongoing aspiration, if surgery will involve the glottis, or if surgery will repair a stenosis that may be preventing aspiration, then a swallowing evaluation should be pursued. The two most commonly used evaluations of swallowing are the videofluoroscopic swallow study (VSS) and FEES. These complimentary evaluations can assess ongoing aspiration with swallowing, as well as the likelihood of future aspiration.[5–7] The advantages of FEES are that the laryngeal protective mechanisms can be visualized by the surgeon, vocal fold motion can be documented, and the potential risk of aspiration can be assessed prior to airway surgery.

Another evaluation that may be useful in children who have a tracheotomy is dye testing. Through the use of green food coloring, aspiration in general, as well as specific causes of aspiration, can be assessed as follows: dye can be placed on the tongue to evaluate aspiration of saliva or secretions; a particular consistency of food can be dyed to assess for consistency-specific aspiration; and gastrostomy tube feeds can be dyed to assess aspiration of refluxed feeds. Aspiration is suspected if stained secretions or feeds are noted from the tracheotomy during feeding or at any time after feeding. Dye testing provides no value in the evaluation of aspiration in children with a grade IV (complete) stenosis. Information obtained from a swallowing evaluation becomes crucial in planning the operative procedure and in counseling the family about the potential risk of aspiration.

Because many airway reconstructive procedures involve a compromise between voice quality and airway improvement, preoperative voice evaluation has become increasingly important.[8–12] This evaluation provides key information regarding the impact of the initial surgery on voice, the potential impact of further surgery on voice, and the status of vocal cord mobility. In some cases, operative planning can be modified to offer a better balance between long-term voice and airway concerns. When vocal fold immobility is noted on the voice evaluation, the surgeon should search for the specific etiology of the immobility, as various conditions may appear similar on voice evaluation but may be treated differently (e.g., posterior glottic stenosis, vocal cord paralysis, and fixation of the cricoarytenoid joints). This investigation is best done during microlaryngoscopy and bronchoscopy. Counseling families about the impact of airway surgery on future voice quality and the options of voice therapy is also an important part of the overall process. A new indication for structural airway surgery is voice improvement rather than just airway improvement.

# Mitigating Factors

## Bacterial Colonization

Because of the prevalence of colonization of methicillin-resistant *Staphylococcus aureus* (MRSA) and *Pseudomonas aeruginosa* in our patients with complex aerodigestive problems (approximately 30%), we recommend screening for these bacteria by culturing the nares and tracheal aspirate. Both MRSA and *P. aeruginosa* have a predilection for cartilage and can lead to operative failure. Patients who are found to be positive are treated with perioperative and postoperative antibiotic therapy (Table 79.1). In our collective experience, this protocol decreases the risk of infection-related morbidity.[13]

**Table 79.1**

**Perioperative and Operative Antibiotic Protocol for Bacterial Colonization**

| Organism | Perioperative | Intraoperative | Postoperative |
|---|---|---|---|
| Methicillin-resistant *Staphylococcus aureus* | Bactrim DS: 6–12 mg/kg per day, 72 h before; Bactroban intranasal 72 h before | Vancomycin: 15 mg/kg 1 h before incision followed by q6h × 2 doses (maximum) | Bactrim DS: 6–12 mg/kg per day for 2 weeks;<br>Vancomycin 15 mg/kg per 24 hour × 48 h |
| *Pseudomonas aeruginosa* | Ciprodex: intratracheal 72 h before | Piperacillin/tazobactam: 100 mg/kg 1 h before incision followed by q6h dosing | Ciprodex: Begin 1 week after surgery through tracheal tube;<br>Piperacillin/tazobactam 100 mg/kg q6h for 1 week after surgery |

## Eosinophilic Esophagitis

EoE is an uncommon disorder that, if left untreated, may have a significant effect on the aerodigestive tract. Many patients who have EoE also have esophageal, laryngotracheal, and sinonasal complaints; however, some patients are asymptomatic.[14] The diagnosis is made by histologic examination of biopsies taken from the esophagus at the time of esophageal endoscopy. In patients who have active EoE, the laryngotracheal complex is often inflamed. Surgery in the presence of active EoE often elicits a brisk inflammatory response that can lead to graft failure and/or restenosis. If EoE is present, the authors recommend medical management followed by repeat endoscopy with biopsies. After biopsies demonstrate no active EoE, surgery may be performed. See Chapter 78 for a more detailed discussion on EoE and its treatment.

## Gastroesophageal Reflux Disease

The evaluation for GERD can include esophagoscopy with biopsies, esophagram, impedance probe,[15] and dual pH probe testing. Because of the potential impact of this condition on postoperative healing, the authors routinely administer prophylactic preoperative and postoperative therapy to patients undergoing airway reconstruction. Most patients are managed with a daily proton pump inhibitor and nighttime H2 blocker therapy. Patients continue the antireflux regimen for up to 1 year following successful reconstruction. Nonacidic reflux may also contribute to laryngeal inflammation and compromised healing. The authors believe that in some cases nonacidic reflux can cause damage in the reconstructed airway and potentially lead to operative failure. When medical treatment fails or nonacid reflux is suspected, a Nissen fundoplication or jejunal feeding should be considered before airway reconstruction.[16–18]

## Obstructive Sleep Apnea

Obstructive sleep apnea (OSA) can be difficult to diagnose and treat, and it can cause failure in an otherwise well-executed operative plan. In children who have multilevel airway obstruction, including a known fixed airway lesion above a tracheotomy, OSA may be difficult to identify, because the tracheotomy cannot be capped during a sleep study. In these cases, a two-stage airway reconstruction is often performed, leaving the tracheotomy in place, which allows for later assessment of OSA.

## Pulmonary Disease

Unrecognized or untreated pulmonary disease can increase the risk of operative failure. This broad classification of pathology encompasses numerous diseases that affect the upper and lower respiratory systems, including unrecognized but significant aspiration, bronchopulmonary dysplasia, tracheomalacia, bronchomalacia, cystic fibrosis, and reactive airway disease. Failure to identify any of these disease processes, even when the more commonly found SGS is identified and treated, can result in significant airway obstruction and operative failure. Collaboration with a pediatric pulmonologist is important not only in the diagnosis but also in both the short- and long-term management of these patients. When significant pulmonary disease is identified, it is crucial that surgery be delayed until it is treated.

## Patient Selection

Patient selection can significantly affect overall clinical outcome. Although the goal of creating an anatomically normal airway at the site of reconstruction may be achieved from a technical perspective, if a child remains dependent on a tracheotomy because of oxygen or ventilation requirements or suffers from chronic aspiration, then in a more global sense the operation has failed. A tracheotomy is not benign, and tracheotomy-related death or neurologic damage remains a risk for tracheotomy-dependent children. In a small number of cases the primary goal is not decannulation or avoidance of a tracheotomy. Alternatively, the goal may be to create a safer airway in the event of accidental decannulation, to improve or restore voice, or to decrease aspiration events.

# Optimization

Optimizing patient status before surgery plays a vital role in airway management and is crucial to the success of surgery. This point cannot be overemphasized. Many of our patients have multiple comorbidities that complicate treatment. Inadequate management of the aforementioned mitigating factors can have a negative impact on an otherwise well-conceived and well-executed surgical plan.

# Management of Airway Pathology

## Laryngomalacia

Laryngomalacia is the most common cause of stridor in newborns.[19] Symptoms are usually observed at birth or within the first few days of life. Stridor is generally mild but typically worsens with feeding, crying, and lying in a supine position. In 50% of patients, stridor worsens during the first 6 months of life. A subset of children with severe laryngomalacia (5%) may present with a spectrum of symptoms, including apnea, cyanosis, severe retractions, and failure to thrive. Many patients also suffer from clinically significant reflux. In extremely severe cases, cor pulmonale is seen. Although laryngomalacia usually resolves spontaneously by 1 year of age, severe disease necessitates surgical intervention.

Diagnosis is confirmed by awake flexible transnasal fiberoptic laryngoscopy. Characteristic findings include short aryepiglottic folds, with prolapse of the cuneiform cartilages. In some patients a tightly curled (Ω shaped) epiglottis is observed. Because of the Bernoulli effect, characteristic collapse of the supraglottic structures is seen on inspiration. Inflammation indicative of reflux laryngitis may also be seen.

Determining whether to intervene surgically is based more on the severity of symptoms than on the endoscopic appearance of the larynx. Patients with laryngomalacia rarely present with acute airway compromise. In the 5% who require surgical intervention, this may be planned within 1–2 weeks of presentation. Preoperative management of GER is recommended.

Supraglottoplasty, also referred to as *epiglottoplasty,* is currently the operative procedure of choice. This procedure is quick and effective and can be adapted to the infant's specific laryngeal pathology. Both aryepiglottic folds are divided, and one or both cuneiform cartilages may also be removed. Postoperative intubation is generally not required unless the child has some additional pathology; in such cases, overnight intubation may be necessary.

Following supraglottoplasty, we recommend that patients be observed overnight. In some children, obstruction persists postoperatively. Repeat fiberoptic laryngoscopy at the bedside is valuable in determining whether this can be attributed to laryngeal edema or persistent laryngomalacia that necessitates further surgery. Reflux management is helpful in minimizing laryngeal edema. Occasionally, although the postoperative appearance of the larynx is adequate, obstructive symptoms are ongoing. Such cases may have an underlying neurologic component, which becomes more evident with time. In neurologic variant laryngomalacia, supraglottoplasty often fails, thus requiring tracheotomy placement.

## Vocal Cord Paralysis

Vocal cord paralysis is the second most common cause of stridor in newborns and may be either congenital or acquired.[20] Congenital vocal cord paralysis generally manifests bilaterally. Although it is usually idiopathic, it is sometimes seen in children with central nervous system pathology (e.g., hydrocephalus and Chiari malformation of the brainstem). Most children with bilateral paralysis present with significant airway compromise, although with an excellent voice. They usually do not aspirate unless there is a significant Chiari II malformation. Acquired disease is generally, although not always, a unilateral condition arising from iatrogenic injury to the recurrent laryngeal nerve. Because of the length and course of the left recurrent nerve, this is far more likely to be damaged than the right recurrent laryngeal nerve. As such, acquired disease usually affects the left vocal cord. Risk factors for acquired paralysis include patent ductus arteriosus repair, the Norwood cardiac repair, and esophageal surgery, particularly TEF repair. In older children, thyroid surgery is an additional risk factor. Unlike children with bilateral vocal cord paralysis, most children with unilateral disease have an acceptable airway but a breathy voice. These children are at a slightly higher risk of aspiration.

The diagnosis of vocal cord paralysis is established with awake flexible transnasal fiberoptic laryngoscopy or stroboscopy. After paralysis has been confirmed, management depends on a number of factors. Children with acquired vocal cord paralysis (whether unilateral or bilateral) may experience spontaneous recovery several months after nerve injury; however, this occurs only if the nerve is stretched or crushed but is otherwise intact.

Children with unilateral paralysis can be initially managed with observation, medialization by temporary injection, or speech and voice therapy. Neonates with acquired unilateral vocal cord paralysis are managed based on their symptoms and comorbidities. Determining the appropriate option is based on a discussion with the patient's family, taking into account the need for restoration of normal voice and improvement of aspiration. Regardless of which option is chosen, these children should be observed for at least 1 year prior to any permanent intervention. If paralysis persists after this period of time and there is a functional deficit, long-term interventions, such as ansa-cervicalis reinnervation, permanent medialization laryngoplasty, or long-term injection medialization, are considered. These options are discussed with the family and are often influenced by the age of the child and the presence of comorbidities. Medialization laryngoplasty is best performed after puberty.

For patients with bilateral paralysis associated with an underlying disease process, successful treatment of that disease may reverse the paralysis; however, up to 90% of these infants ultimately require tracheotomy placement. Given that up to 50% of children with congenital idiopathic bilateral vocal cord paralysis have spontaneous resolution by 1 year of age, surgical intervention to achieve decannulation is almost always delayed until patients are older than 1 year of age. A more recent innovation to prevent the need for tracheotomy placement in neonates with bilateral cord paralysis is the introduction of the endoscopic anterior-posterior cricoid split.[21]

Several surgical options have been used for patients with bilateral paralysis, and no particular option offers a universally acceptable outcome. The aim of surgery is twofold: (1) to achieve an adequate decannulated airway while maintaining voice and (2) to prevent aspiration. Surgical options include laser cordotomy, partial or complete arytenoidectomy (endoscopic or open), vocal process lateralization (open or endoscopically guided), and posterior cricoid cartilage grafting. In a child with a tracheotomy, it is often prudent to maintain the tracheotomy to ensure an adequate airway prior to decannulation. In a nontracheotomized child, a single-stage surgical procedure can be carried out. Acquired bilateral vocal cord paralysis that does not resolve spontaneously is usually less responsive to treatment than idiopathic cord paralysis. In these cases, more than one operative intervention may be required to achieve decannulation. In patients who have undergone such interventions, postextubation stridor may respond to continuous positive airway pressure (CPAP) or high-flow nasal cannula. The postoperative risk of aspiration should be evaluated by a video swallow study before the child returns to a normal diet. During the initial postoperative weeks, some children have an increased risk of aspirating with certain textures, especially thin liquids.

## Laryngeal Webs

Laryngeal webs result from a failure of recanalization of the glottic airway in the early weeks of embryogenesis. In severe cases, as recanalization commences posteriorly and progresses anteriorly, complete laryngeal atresia may occur. In less severe cases a thin anterior glottic web may be the only remnant of the recanalization process. Glottic webs are associated with 22q11.2 deletion syndrome in 60% of cases.[22] The web is typically thickened anteriorly and thins out towards the posterior edge.

Although some anterior glottic webs are gossamer thin, most are thick and generally associated with a subglottic “sail” that compromises the subglottic lumen. Patients have varying degrees of glottic airway compromise, which usually manifests in an abnormal cry or respiratory distress. Thin webs may evade detection because neonatal intubation for airway distress may lyse the web.

Thick webs require open reconstruction with either reconstruction of the anterior commissure or placement of a laryngeal keel.[23] These webs have a high association with SGS, and usually a stenosis will need to be addressed concurrently. The presence of thick membranous webs requires placement of a tracheotomy in approximately 40% of patients, although early single-stage reconstruction may be performed in selected cases.

## Subglottic Stenosis

SGS can be either congenital or acquired. Congenital SGS in the neonate is defined as a lumen 4.0 mm in diameter or less at the level of the cricoid. SGS is thought to result from a failure of the laryngeal lumen to recanalize and is one of a continuum of embryologic failures that includes laryngeal atresia, stenosis, and webs. Congenital SGS is often associated with other congenital head and neck lesions and syndromes (e.g., a small larynx in a patient with Down syndrome). Acquired SGS is far more common and is typically a sequela of prolonged neonatal intubation, often with an inappropriately large endotracheal tube (one that does not permit an air leak at less than 20 cm of water pressure). Other cofactors for the development of acquired SGS include reflux and EoE.

Levels of SGS severity are graded according to the Myer-Cotton grading system (see Fig. 79.1). In its mildest form (no obstruction to 50% obstruction), congenital SGS appears as a normal cricoid with smaller than average diameter, usually elliptical in shape. Mild SGS may manifest in recurrent upper respiratory infections (often diagnosed as croup) in which minimal subglottic swelling precipitates airway obstruction. In a young child, the greatest obstruction is usually 2–3 mm below the true vocal cords. More severe cases may present with acute airway compromise at delivery. If endotracheal intubation is successful, the patient may require intervention before extubation. When intubation cannot be achieved, tracheotomy placement at the time of delivery may be life-saving. Important to note, infants typically have surprisingly few symptoms. Even those with grade III SGS (71%–99% obstruction) may not be symptomatic for weeks or months.

Children with mild acquired SGS may be asymptomatic or minimally symptomatic. Observation rather than intervention may thus be appropriate. This is often the case for children with grade I or II SGS. However, those with more severe SGS (grades III and IV) are often symptomatic, with either tracheotomy dependency or stridor and exercise intolerance.

Radiologic evaluation of an airway that is not intubated may provide the clinician clues about the site and length of the stenosis. Useful imaging modalities include inspiratory and expiratory lateral soft tissue neck films, fluoroscopy to demonstrate the dynamics of the trachea and larynx, and a chest x-ray. However, the single most important investigation is high-kilovoltage airway films. These films are taken not only to identify the classic “steepling” observed in patients with SGS but also to identify possible tracheal stenosis. The latter condition is generally caused by complete tracheal rings, which may predispose the patient to a life-threatening situation during rigid endoscopy or even during intubation.

Whether SGS is congenital or acquired, evaluation requires endoscopic assessment, which is considered the gold standard. Endoscopy is necessary for the diagnosis of laryngeal stenosis. Precise evaluation of the endolarynx should be carried out, including grading of the SGS. Stenosis caused by scarring, granulation tissue, submucosal thickening, or a congenitally abnormal cricoid can be differentiated from SGS with a normal cricoid, but endoscopic measurement with endotracheal tubes or bronchoscopes is required for an accurate evaluation.

In a patient with congenital SGS, the larynx will grow as the patient grows. As such, after initial management of SGS, the patient may not require further surgical intervention. However, if initial management requires intubation, the risk of developing an acquired SGS in addition to the underlying congenital SGS is considerable.

Unlike congenital SGS, acquired SGS is unlikely to resolve spontaneously and thus requires intervention. Reconstruction of the subglottic airway is a challenging procedure, and the patient's general condition should be optimized before surgery. In children with mild symptoms and a minor degree of SGS, endoscopic intervention may be effective. Endoscopic options include radial incisions (cold steel or laser) through the stenosis, laryngeal dilatation, the application of topical or injected steroids and topical mitomycin. More severe forms of SGS are better managed with open airway reconstruction. Laryngotracheal reconstruction using costal cartilage grafts placed through the split lamina of the cricoid cartilage is reliable and has withstood the test of time.[24,25] Costal cartilage grafts may be placed through the anterior lamina of the cricoid cartilage, the posterior lamina of the cricoid cartilage, or both. These procedures may be performed as a two-stage procedure, maintaining the tracheal tube and temporarily placing a suprastomal laryngeal stent above the tracheal tube. Alternatively, in selective cases a single-stage procedure may be performed, with removal of the tracheal tube on the day of surgery and with the child requiring intubation for 1–14 days.[26,27] Higher decannulation rates have been achieved with cricotracheal resection than with laryngotracheal reconstruction in the management of severe SGS.[28,29] However, cricotracheal resection is a technically demanding procedure that carries a significant risk of complications.

## Vascular Compression

Although vascular compression of the airway is not uncommon, most affected children are either asymptomatic or only minimally symptomatic. Forms of vascular compression affecting the trachea include innominate artery compression (most common), double aortic arch, and pulmonary artery sling. Although symptomatic vascular compression of the trachea or bronchi is rare, it is associated with marked symptoms, including biphasic stridor, retractions, a brassy cough, and “dying spells.” Symptoms tend to become worse when the child is distressed. Vascular rings that result from a retroesophageal subclavian artery and a ligamentum arteriosum are less likely to be associated with airway compromise. Bronchial compression by either the pulmonary arteries or aorta may be significant, but in the absence of associated major cardiac anomalies, it is typically a unilateral problem.

The diagnosis of airway compression is best established with rigid or flexible bronchoscopy or both procedures. Thoracic imaging is then useful in assessing the intrathoracic vasculature. Imaging modalities generally include high-resolution computed tomography (CT) with contrast enhancement and three-dimensional reconstruction, magnetic resonance imaging (MRI), magnetic resonance angiography (MRA), and echocardiography. In some cases, angiography is required.

In a neonate with acute airway compromise, intubation may be required to maintain the airway prior to definitive treatment. In some cases, CPAP offers a degree of temporary improvement because segmental tracheomalacia may be present in the region of the vascular compression. Prolonged intubation should be avoided because of the risk of forming an arterial fistula from erosion of an endotracheal tube into the area of compression. Similarly, although tracheotomy will establish an unobstructed airway, there is also an increased risk of an arterial fistula into the airway.

The surgical management of symptomatic vascular compression varies, depending on individual pathology. Strategies for managing innominate artery compression include thymectomy and aortopexy; however, if little thymus is present, an alternative procedure is reimplantation of the innominate artery more proximately on the aortic arch. A double aortic arch requires ligation of the smaller of the two arches, which is usually the left one. A pulmonary artery sling is transected at its origin, dissected free, and reimplanted into the pulmonary trunk anterior to the trachea. There is a high incidence of complete tracheal rings in children with a pulmonary artery sling, and these should be repaired at the same time.

Although alleviating vascular compression improves the airway, it takes time for the airway to completely normalize. This is a consequence of long-standing vascular compression having adversely affected the normal cartilaginous development of the compressed segment of trachea, with resultant cartilaginous malacia or stenosis. Until the airway normalizes, children who are persistently symptomatic may require stabilization with a tracheotomy. Tracheal stabilization with the use of intratracheal stents is alluring, but the incidence of complications is high. Placement of a temporary tracheotomy is therefore a more desirable alternative.[30]

## Posterior Laryngeal Clefts

Posterior laryngeal clefts result from a failure of the laryngotracheal groove to fuse during embryogenesis. In a widely used anatomic classification system, these clefts are divided into four subtypes associated with varying levels of severity; type I cleft is the least and type IV cleft the most severe.[31] Other associated anomalies are common and may be divided into those that affect the airway and those that do not. Associated airway anomalies include tracheomalacia (>80%) and TEF formation (20%). Nonairway associations include anogenital anomalies and GER. The most common syndrome in which posterior laryngeal clefting occurs is Opitz-Frias syndrome; hypertelorism and anogenital anomalies are other features of this syndrome.

Although aspiration is the hallmark clinical feature of this disorder, signs and symptoms may be nonspecific, making the diagnosis elusive. Symptoms may also include apnea, recurrent pneumonia, feeding difficulties, and airway obstruction.

VSS and FEES may suggest the risk of aspiration in children with clefts; however, definitive diagnosis requires rigid laryngoscopy and bronchoscopy, with the interarytenoid area being specifically probed to determine if a posterior laryngeal cleft is present.

Initial management decisions should consider whether the infant requires tracheotomy placement, gastrostomy tube placement, or Nissen fundoplication. Although none of these procedures is essential, each increases the likelihood of a successful cleft repair. Protection against aspiration is also crucial, and nasojejunal feeding may be a useful preventative measure. Surgical repair may be performed endoscopically for most type I and type II clefts, and some type III clefts; however, longer clefts that extend into the cervical or thoracic trachea require open repair. The transtracheal approach is advocated in that it provides unparalleled exposure of the cleft while protecting the recurrent laryngeal nerves. A two-layer closure is recommended, with the option of performing an interposition graft if warranted; a useful interposition graft is a free transfer of clavicular or tibial periosteum, or costal cartilage. Because all clefts are prone to anastomotic breakdown, repeat endoscopy and postoperative swallowing studies should be performed to evaluate for aspiration and to confirm a successful repair.[32,33] Despite successful repair, patients may experience continued problems with dysphagia.[34]

Recently there has been an increasing emphasis placed on type I clefts and associated deep interarytenoid notches. Endoscopic repair of minor clefts has become far more common in children who are diagnosed because of a high index of suspicion or evidence of recurrent or chronic aspiration.[35,36] This suggests that in such patients, type I clefts may be more of a functional diagnosis than an anatomic diagnosis.

## Tracheomalacia

Tracheomalacia is the most common congenital tracheal anomaly. Most children are either asymptomatic or minimally symptomatic, and most cases involve posterior malacia of the trachealis, with associated broad tracheal rings. Commonly associated abnormalities include laryngeal clefts, TEF, and bronchomalacia. Presenting symptoms include a brassy cough, wheezing, respiratory distress when agitated, and “dying spells.” Diagnosis is established with rigid or flexible bronchoscopy, while maintaining spontaneous respiration. The key diagnostic elements include: (1) ascertaining the severity of the malacia; (2) ascertaining the location of the malacia, particularly the possible presence of associated bronchomalacia; and (3) determining whether positive pressure support improves the malacia.

Although mild tracheomalacia is watched expectantly and anticipated to improve with time, more severe symptoms warrant intervention.[37] The most common intervention is tracheotomy placement, with the tip of the tracheotomy tube bypassing the malacic segment. Positive pressure support delivered through the tracheotomy tube assists with the management of associated bronchomalacia. Although there is currently no definitive surgical approach to repair tracheomalacia, this is an area of active research.

## Complete Tracheal Rings

Complete tracheal rings are a rare but life-threatening anomaly that presents with progressive worsening of respiratory function over the first few months of life, stridor, retractions, and marked exacerbation of symptoms during intercurrent upper respiratory tract infections. Children with distal tracheal stenosis usually have a characteristic biphasic wet-sounding breathing pattern that transiently clears with coughing; this pattern is referred to as “washing machine breathing.” The risk of respiratory failure increases with age.

An initial high-kilovolt airway film may indicate tracheal narrowing; however, the diagnosis is established with rigid bronchoscopy. This should be performed with utmost caution, using the smallest possible telescopes, as any airway edema in the region of the stenosis may turn a narrow airway into an extremely critical airway. If the stenosis is severe, the stenotic airway should not be instrumented, even with the smallest telescope. The initial bronchoscopic view is often sufficient to establish the diagnosis, thereby avoiding the risk of airway edema. Because 50% of children have a tracheal inner diameter of approximately 2 mm at the time of diagnosis, the standard interventions for managing a compromised airway are not applicable. More specifically, the smallest endotracheal tube has an outer diameter of 2.9 mm, and the smallest tracheotomy tube has an outer diameter of 3.9 mm; hence the stenotic segment cannot be intubated. This may leave extracorporeal membrane oxygenation (ECMO) as the only viable alternative for stabilizing the child. This situation is best avoided by performing bronchoscopy with the highest level of care. More than 80% of children with complete tracheal rings have other congenital anomalies, which are generally cardiovascular. As such, investigation should include a contrast-enhanced high-resolution CT scan of the chest and an echocardiogram. Specifically, a pulmonary artery sling should be excluded because this is a common association and, if present, should be repaired concurrent with the tracheal repair. Most children with complete tracheal rings require tracheal reconstruction.[38] The recommended surgical technique is the slide tracheoplasty.[39–41] This approach yields significantly better results than any other form of tracheal reconstruction and is applicable to all anatomic variants of complete tracheal rings.

# Sudden Infant Death Syndrome and Apparent Life-Threatening Events

*Andrea Coverstone MD, James Kemp MD*

Infants experiencing an apparent life-threatening event (ALTE) and premature infants with apnea may later die suddenly and unexpectedly, with a diagnosis of sudden infant death syndrome (SIDS). However, because about 80% of victims who died suddenly and unexpectedly were born at term and were never known to be apneic until they died, discussing ALTE, apnea of prematurity (AOP), and SIDS together has become controversial, particularly when the issue of apnea monitoring is raised.

The American Academy of Pediatrics has recently promulgated a new category for this discussion—BRUE, Brief Resolved Unexplained Event. This new designation attempts to address the appropriate clinical approach to young infants coming to emergency departments with a history of events that, far more often than not, prove to be benign, and may be properly managed by reassuring parents and caregivers.

# Acute Life-Threatening Events (ALTE) and BRUE

## Epidemiology

The term apparent life-threatening event (ALTE) was first coined following the 1986 National Institute of Health Consensus Conference on Infant Apnea. The intention at the time was to replace the term "near-miss sudden infant death syndrome." ALTE is defined as "an episode that is frightening to the observer that is characterized by some combination of apnea (central or occasionally obstructive), color change (usually cyanotic or pallid but occasionally erythematous or plethoric), marked change in muscle tone (usually marked limpness), or choking or gagging."[1]

In 2016, the American Academy of Pediatrics (AAP) released a clinical practice guideline with the objective of replacing the term ALTE with a new term: BRUE.[2] This guideline was published to allow the clinician a practical approach to the evaluation of a child with the features of an ALTE who is considered low risk. BRUE was specifically defined as an "event occurring in an infant younger than 1 year" who is reported to have a "sudden, brief, and now resolved episode of one or more of the following: (1) cyanosis or pallor; (2) absent, decreased, or irregular breathing; (3) marked change in tone (hypertonia or hypotonia); and (4) altered level of responsiveness." A BRUE is distinguished from an ALTE in that it is defined as both brief and resolved (Table 80.1). Therefore children who have not returned to their baseline state of health would not fit into this category. By providing a more specific definition of these events, it is anticipated that clinicians will avoid overuse of medical interventions and testing in the group that is considered low risk. In addition to clarifying what an event entails, the term BRUE is favored by the AAP over ALTE, because the term "life-threatening" is often misleading and has the potential to reinforce caregivers' perceptions that the event was, in fact, life-threatening, making it more challenging to provide reassurance when often that is all that is needed.

**Table 80.1**

## BRUE Definition and Factors for Inclusion and Exclusion

| | Includes | Excludes |
|---|---|---|
| Brief Resolved | Duration <1 min; typically 20–30 s<br>Patient returned to his or her baseline state of health after the event<br>Normal vital signs<br>Normal appearance | Duration ≥1 min<br>At the time of medical evaluation:<br>Fever or recent fever<br>Tachypnea, bradypnea, apnea<br>Tachycardia or bradycardia<br>Hypotension, hypertension, or hemodynamic instability<br>Mental status changes, somnolence, lethargy<br>Hypotonia or hypertonia<br>Vomiting<br>Bruising, petechiae, or other signs of injury/trauma<br>Abnormal weight, growth, or head circumference<br>Noisy breathing (stridor, stertor, wheezing)<br>Repeat event(s) |
| Unexplained | Not explained by an identifiable medical condition | Event consistent with GER, swallow dysfunction, nasal congestion, etc.<br>History or physical examination concerning for child abuse, congenital airway abnormality, etc. |
| Event Characterization | | |
| *Cyanosis or pallor* | Central cyanosis: blue or purple coloration of face, gums, trunk<br>Central pallor: pale coloration of face or trunk | Acrocyanosis or perioral cyanosis<br>Rubor |
| *Absent, decreased, or irregular breathing* | Central apnea<br>Obstructive apnea<br>Mixed obstructive apnea | Periodic breathing of the newborn<br>Breath-holding spell |
| *Marked change in tone (hypertonia or hypotonia)* | Hypertonia<br>Hypotonia | Hypertonia associated with crying, choking, or gagging due to GER or feeding problems<br>Tone changes associated with breath holding spell<br>Tonic eye deviation or nystagmus<br>Tonic-clonic seizure activity<br>Infantile spasms |
| *Altered responsiveness* | Loss of consciousness<br>Mental status change<br>Lethargy<br>Somnolence<br>Postictal phase | Loss of consciousness associated with breath holding spell |

From Tieder JS, Bonkowsky JL, Etzel RA, et al. Clinical practice guideline: Brief Resolved Unexplained Events (Formerly Apparent Life-Threatening Events) and Evaluation of Lower-Risk Infants. *Pediatrics*. 2016;137(5):e20160590.

The incidence of ALTE in the population worldwide is estimated between 0.6 and 4.1 per 1000 live births[3–5]; however, the true incidence of ALTEs is unknown, especially given that the International Classification of Disease (ICD) code for ALTE was not introduced until 2012.[3] It is estimated that ALTE accounts for 0.6%–1.7% of emergency department visits for children younger than 1 year.[6,7] The usefulness of the BRUE designation and its impact on ALTE statistics remains to be seen.

## Diagnosis and Differential Diagnosis

As described above, BRUE refers to an event (Table 80.1) with specific parameters.[2] BRUE should be diagnosed only when there is no explanation for a qualifying event after conducting an appropriate history and physical examination.

When evaluating the child who presents for medical attention following an event, a thorough physical examination and history is required to determine the risk of severe sequelae, as management guidelines for BRUE pertain only to those individuals who meet lower risk criteria, which are as follows:

- Age more than 60 days
- Prematurity: gestational age ≥32 weeks and postconceptional age ≥45 weeks
- First BRUE (no previous BRUE ever and not occurring in clusters)
- Duration of event less than 1 minute
- No cardiopulmonary resuscitation (CPR) required by trained medical provider
- No concerning historical features
- No concerning physical examination findings

The differential diagnosis for a child presenting with an apparent life-threatening event is shown in Box 80.1.

**Box 80.1**

### Selected Causes in the Differential Diagnosis of an Apparent Life-Threatening Event

Respiratory syncytial virus, pertussis
Sepsis with apnea
Syndromes compromising the upper airway (e.g., Pierre Robin sequence)
Breath-holding spells
Seizures
Intracranial hemorrhages (e.g., caused by vascular malformations, child abuse, vitamin K deficiency)
Exaggerated laryngeal chemoreflex with or without gastroesophageal reflux
Drugs (e.g., phenothiazines, over-the-counter cold remedies)*
Tachyarrhythmias (e.g., Wolfe-Parkinson-White syndrome, prolonged QT syndrome)
Inborn errors of metabolism (e.g., MCAD deficiencies)
Hypoventilation during bed sharing or because nose and mouth become covered with bedding

## Etiology and Pathology/Pathogenesis

We will now discuss potential explanations for ALTE as that term is currently used. Box 80.1 outlines considerations when the findings of hypotonia, cyanosis, and possible apnea persist or recur, thus exceeding the criteria for a BRUE.

It is our experience, and the published experience of others linking GER to ALTE,[8] that the history in ALTE infants often suggests apnea after choking. It seems likely that infants whose ALTE resembles apnea after choking have an exaggerated laryngeal chemoreflex. For this reason, we will discuss Laryngeal ChemoReflex Apnea (LCRA) in detail (Fig. 80.1).

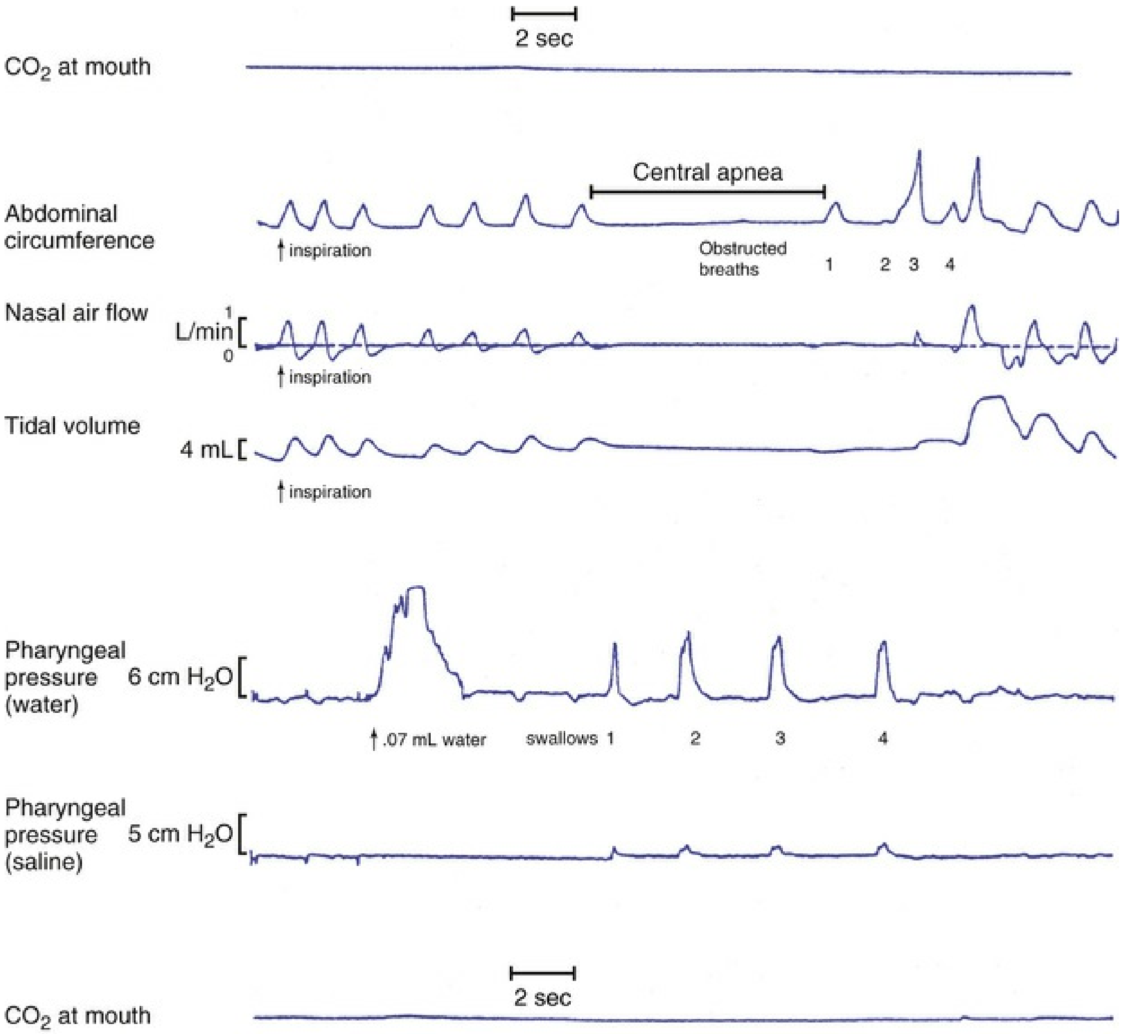

**FIG. 80.1** Sequence of response representing laryngeal chemoreflex apnea in an infant. Upward deflections on pharyngeal pressure tracing reflect swallows. Application of less than 0.1 mL of water onto the larynx leads to swallows and central apnea, followed by obstructive apnea and restoration of eupnea after water has been cleared by swallows. (From Davies AM, Koenig JS, Thach BT. Upper airway chemoreflex responses to saline and water in preterm infants. *J Appl Physiol.* 1988;64:1412-1420.)

The larynx is a complex structure enriched with hundreds of nonmyelinated sensory nerve endings, including chemoreceptors and mechanoreceptors involved in maintaining upper airway patency. Laryngeal mucosal chemoreceptors function as irritant receptors, water receptors, and C fiber endings.[9] These nerve endings are most numerous in the mucosal epithelium of the epiglottis, aryepiglottic folds, and interarytenoid space.[10] Water receptors respond to either reduced osmolarity or reduced chloride ion concentration. C fibers are stimulated by noxious agents, such as temperature, ammonium, capsaicin, and $H^+$ ions. Stimulation of these unmyelinated nerve fibers arising in the laryngeal epithelium and traveling in the superior laryngeal nerve cause prolonged apnea, bradycardia, and marked increases in central venous and arterial blood pressure in experimental animals. Thus, both animals and humans can develop laryngeal chemoreflex apnea.

Any liquid in contact with the laryngeal mucosa will trigger a more or less brisk LCRA. The sequence of response after single-fiber stimulation of these nerves is dramatic and is most marked in younger animals (e.g., piglets, lambs, and puppies). Apnea beginning within 0.25 seconds of the stimulus may last 20–90 seconds and may be fatal in the laboratory.[11,12] Saline elicits little or no response, whereas water and cow's milk elicit a dramatic LCRA.[11–13]

As in experimental animals, among human preterm infants, water is more potent than normal saline in eliciting severe LCRA.[13,14] In infants, should swallowing be delayed or fail to occur, the apneic phase of the laryngeal chemoreflex can be prolonged, extending over 20 seconds and causing hypoxemia. The duration of the apneic phase of the laryngeal chemoreflex (LCR) seems to be inversely proportional to postnatal age.[12] Taken together, these findings suggest that in immature subjects, airway protection from aspiration takes precedence over ventilation in some circumstances when even small quantities of fluids (~0.1 mL), including water, come in contact with the larynx.

Human infants attempt to clear fluid that elicits LCRA by laryngeal closure and swallowing during a central apnea (see Fig. 80.1).[13] After the central apnea, any breaths attempted are obstructed so long as upper airway closure persists. When swallowing clears the fluid, the upper airway is opened with a return to eupneic breathing. The LCR sequence in more mature infants and experimental animals does not involve prolonged apnea, and is as follows: cough, swallowing, and arousal if asleep.[15] The cough-swallow-arousal sequence is much less common when elicited during sleep in immature subjects.[10]

With maturation in older infants and older experimental animals, apnea occurs as part of the laryngeal chemoreflex, but it is shorter than in preterm infants and newborn animals. Maturation is associated with reduction in central respiratory inhibition. Cough and arousal from sleep are also more likely to occur among mature subjects when water, acid, or milk come in contact with the larynx.[10] Nevertheless, in susceptible infants, delays in maturational influences could put them at risk for prolonged apnea as part of the laryngeal chemoreflex.[16]

The role of gastroesophageal reflux (GER) in eliciting apnea through the LCR and therefore as a cause of ALTE or BRUE is controversial. Indeed, the new guidelines defining BRUE explicitly state that any event consistent with GER is *not* a BRUE, perhaps because GER in and of itself may be associated with a changed respiratory pattern.[2] As noted above, in animals and infants, milk and water can have a profound response from LCR. Stimulation need not be acidic to elicit a LCRA.[9] There are no distal esophageal receptors known to elicit apnea; therefore reflux must be to the level of the pharynx to stimulate LCRA. Reflux to the level of the larynx may occur in 60%–70% of episodes of GER.[17] The temporal sequence of GER eliciting a subsequent apnea and potential pathogenesis in term infants has been demonstrated, but the association among preterm infants is less clear, perhaps because the high background rate of central apneas in preterm infants makes establishing a link to antecedent GER events more challenging.[17–20] Therefore GER may be one explanation for ALTE, particularly in select term and premature infants, however, proving the association is difficult and, moreover, reflux may occur in the absence of any abnormal respiratory patterns.

## Clinical Features of an Apparent Life-Threatening Event

### Symptoms

Most infants who come to medical attention following an ALTE are asymptomatic at the time of presentation.[7] The history should attempt to provide a clear understanding of the timing and nature of the event as well as pertinent past medical history, family history, environmental exposures, and social history. The attending physician supervising the evaluation should make every effort to obtain the history himself or herself, including the duration of the event, time of day, adequacy of lighting, infant's position within his or her surroundings, and whether the episode began while awake or asleep. The infant's color, tone, activity, and movements at the time of event (e.g., repetitive motions) must be noted. Was blood or pink froth coming from the infant's mouth or nose, for instance, or did the caregiver notice any other unusual findings? Were any measures taken to stop the event (stimulating the infant through touching or blowing on the face) and did the infant require resuscitation (i.e., CPR)? Who was present and witnessed the event and who was the responsible caregiver at the time that this occurred? The appropriateness of the caregivers' concern should be noted. Any glaring inconsistencies in the history should raise suspicion for nonaccidental trauma or attention-seeking behavior. Beyond the event itself, a thorough medical and family history should be obtained. Has the infant been growing and developing normally? Is there a history of prematurity, prior hospitalization, GE reflux, prior injury, snoring, or noisy breathing? Was the infant in the early stages of a respiratory illness, or was he or she having coughing paroxysms? Family history of seizures, arrhythmias, sudden death, or serious illness with coma among young people must be ascertained. A thorough list of pertinent questions to ask when taking a history for an ALTE or BRUE is available in the BRUE guidelines.[2]

## Physical Findings

Just as the majority of infants are asymptomatic at presentation, physical exam findings are often normal. Nevertheless, a thorough physical examination is essential in detecting a possible etiology for the event, and suggesting specific needs for further diagnostic evaluation. As with any disease presentation, accurate vital signs are an essential initial assessment. Fever, tachypnea, hypotension, or hypoxemia should clue the clinician into an underlying illness such as focal infection, generalized sepsis, or underlying cardiovascular or respiratory disease. Growth parameters can also be clues, with poor weight gain since birth suggestive of chronic underlying disease, and large head circumference suggesting a neurological disorder or bleeding related to head trauma. A thorough neurological examination should consider the infant's level of responsiveness and alertness as well as tone, symmetry of reflexes and movement, pupillary responses, and size; it should also include a funduscopic exam for retinal hemorrhages. A limb that does not move spontaneously or one that is deformed, bruised, swollen, or painful when palpated suggests an underlying fracture and possible child abuse. Nasal congestion, coryza, cough, and other abnormal respiratory findings (crackles, wheezes, tachypnea, stridor, or retractions) might suggest an upper or lower respiratory tract infection. A hyperdynamic precordium, cardiac murmurs, gallop rhythms, or heart rhythm irregularities warrant further investigation for an underlying congenital or infectious cardiac disorder such as cardiomyopathy or myocarditis. Abdominal distension or organomegaly could be clues to infection or a metabolic disorder. Infants younger than 2 months of age should be considered at risk for bacteremic sepsis when they present with apnea or hypotonia and should be treated accordingly.

## Management and Treatment of Apparent Life-Threatening Event

A systematic review for the management of ALTEs was published in 2013 that attempted to address some of the challenges of the clinical management of patients who experience such an event.[21] The challenges increase when trying to address the patient who is asymptomatic by the time of presentation to the medical team. While events called ALTE are ultimately benign, they may be an initial presentation of a significant underlying disorder. Trying to determine which child deserves a more extensive evaluation and what that evaluation may entail, including diagnostic testing and need for hospitalization, is not only challenging but fraught with controversy. Indeed, some institutions have developed clinical decision rules to determine which infants may be safely discharged home from the ER following an ALTE.[22,23] The newer BRUE guidelines attempt to further address these issues and outline management recommendations based on available research to apply to those infants deemed low risk. The guidelines were developed by a multidisciplinary subcommittee of the AAP composed of a group of experts from various fields of medicine, epidemiologists, methodologists, and parent representatives. They performed an extensive review of the literature related to ALTEs from 1970 through 2014 to develop their definition and recommendations.[2] The authors recognized that the strength of their recommendations for low-risk infants is moderate to weak because of lack of high-quality evidence and studies. It is essential to understand that the guidelines for BRUE only apply to low-risk infants who have returned to baseline and any abnormal physical examination findings or history should warrant further investigation.

Management guidelines for higher risk infants have not yet been established but the available studies to date would recommend a tailored approach based on the findings from the history and physical examination (for further reading, we recommend reviewing the tables within Tieder et al., *Pediatrics* 2016 outlining the historical features to be considered in the evaluation of a potential BRUE). That is, while there are many laboratory studies and diagnostic tests that could be performed to determine the etiology of the event, only certain tests may be necessary or appropriate in individual cases.

## Imaging and Laboratory Findings

The 2016 guidelines for BRUE suggest minimal testing for those infants who meet the criteria for low risk. These recommendations advise against the routine use of chest radiographs, blood gases, polysomnograms, echocardiograms, neuroimaging, and blood evaluations for culture, white blood cell count, or metabolic disorders. They do recommend that caregivers be offered resources for CPR training and given education on BRUEs. Furthermore, recommendations and testing should be done through a shared decision-making platform between medical provider and caregiver.[2]

The following tests may be informative when the criteria for a BRUE are exceeded, for example, recurrent events over a short period of time, abnormal physical findings, or worrisome history. Initial laboratory evaluation may include measurement of hemoglobin and white blood cell count with differential cell count; culture of blood and urine; nasal swabs for respiratory syncytial virus (RSV) and pertussis; a chest radiograph; and serum glucose, sodium, potassium, chloride, and bicarbonate. The child who has a concerning history and is not back to baseline should be admitted to a unit where cardiorespiratory monitoring is available so that abnormalities in cardiac or respiratory rate can be recorded. If the infant continues to be limp, or if apnea recurs, one should measure arterial blood gases, serum lactate, and ammonia, and screen the urine for abnormal levels of amino and organic acids, and drugs.[24] In children who continue to appear ill or who have altered mental status with no other cause detected, video electroencephalography (EEG) should be conducted and imaging of the central nervous system by computed tomography or, preferably, magnetic resonance imaging, should be performed.[25]

The clinical approach to an ALTE should, of course, be based on one's assessment of the validity of the caregivers' observations: “benign physiological events in babies may sometimes cause an overreaction by parents, particularly those who are anxious, are attention-seeking, or suffer a personality disorder.”[26,27] On the other hand, one's approach should also be informed by the knowledge that 89% of infants with documented prolonged apnea, bradycardia, and marked hypoxemia when subsequently hospitalized for an ALTE had appeared well in the emergency department (Fig. 80.2).[7]

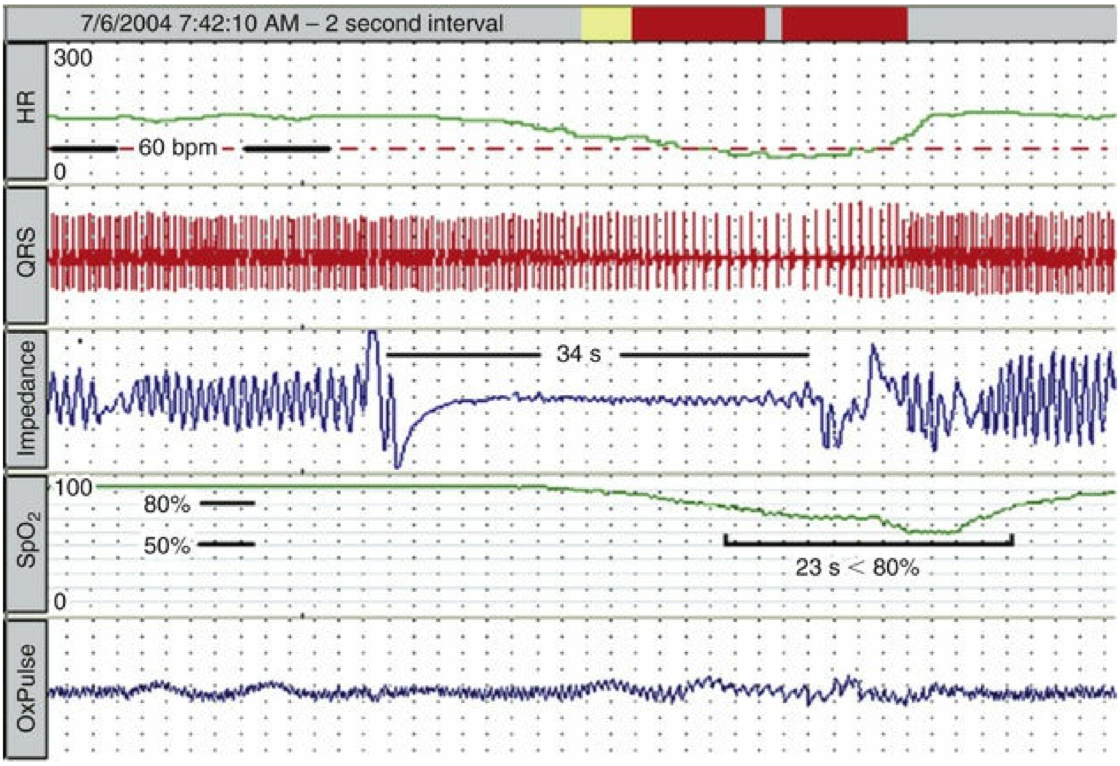

**FIG. 80.2** Recording from an infant hospitalized with an apparent life-threatening event. Representative example of the most common event classified as an extreme event. Note the 34-second central apnea with the associated desaturation below the level of 80%. The apparent small respiratory movements on the impedance channel during the apnea correspond to cardiogenic artifacts. *HR,* Heart rate; *QRS,* QRS wave of the electrocardiogram; *impedance,* respiratory movements detected by transthoracic impedance; *oxpulse,* plethysmographic wave obtained from the pulse oximeter. (From Al-Kindy HA, Gelinas J, Hatsakis G, Cote A. Risk factors for extreme events in infants hospitalized for apparent life-threatening events. *J Pediatr*. 2009;154:322-327.)

## Prevention: Home Apnea Monitors and Feeding Infants With Exaggerated Laryngeal ChemoReflex Apnea

Because the pathophysiology and underlying causes of ALTEs or BRUEs are usually difficult to identify, how to prevent these events is not known. That said, much concern regarding BRUE and ALTE arises from the worry that they are a signal of an underlying condition or an indication of risk for a future SIDS event. Therefore these children are often discharged home with apnea monitors in the hope of preventing SIDS. Home monitors are often prescribed by practicing physicians when a child is deemed at risk for a cardiorespiratory event. In a retrospective review of 88 infants prescribed home monitors at a tertiary hospital, indications for monitoring included family history of SIDS in 21%, apnea of prematurity in 25%, history of previous ALTE in 21% and a choking episode in 15%.[28]

The CHIME (Collaborative Home Infant Monitoring Evaluation) study was an NIH-funded study developed in order to determine whether home monitors were effective in identifying episodes of apnea or bradycardia that were potentially threatening to an infant's health.[29] It enrolled a total of 1079 infants between 1994 and 1998, and included a group of healthy term infants, preterm infants, infants who had experienced an ALTE, and infants whose siblings died from SIDS. Extreme and conventional events were determined based on degree and duration of bradycardia and apnea. The CHIME monitor included both EKG and pulse oximetry recordings as well as Respiratory Inductance Plethysmography (RIP) bands. The RIP bands allowed the researchers to evaluate episodes of apnea as obstructive or not and found that 70% of “extreme” events and 50% of “conventional events” were associated with obstructed breaths. By using RIP bands, they were able to show that apnea identified by impedance cardiorespiratory monitoring was concordant with that found by RIP. The authors concluded that events, in general, were common, including in the healthy term infants. Extreme events, defined as apneas ≥30 seconds and heart rate less than 50 bpm (≥44 weeks PCA) or 60 bpm (<44 weeks PCA) for at least 10 seconds were more likely in preterm infants, and tended to recur within 6 weeks. The CHIME study did not detect an association between extreme events and death or neurologic injury, with only 6 deaths occurring during the study, and it did not address whether use of monitors would decrease SIDS rates. In a retrospective review of a similar, smaller cohort of infants, 36% of infants had a significant event on home monitoring, which occurred most often within the first month, and more so the first week, of monitoring.[30] This retrospective study also found that preterm infants were more likely to have events than those with prior ALTE, a SIDS sibling, or infants monitored due to parental anxiety. An event during a hospitalization also increased the likelihood of finding an event on home monitoring (see Fig. 80.2).

The American Academy of Pediatrics' (AAP) last review and guidelines for the use of home monitors was published in 2003.[31] The AAP recommends monitoring in two specific circumstances: (1) it "may be warranted" in selected premature infants until "43 weeks postmenstrual age," or until "extreme episodes" of apnea, bradycardia, and hypoxemia stop; (2) infants who are usually supported at home by mechanical ventilation through a tracheotomy. Routine monitoring is not recommended by the AAP for infants with an ALTE or among siblings of SIDS victims. In a list of instructions, the AAP states: (1) "Home cardiorespiratory monitoring should not be prescribed to prevent SIDS"; (2) "Parents should be advised that…monitoring has not been proven to prevent sudden unexpected deaths…"[31] The AAP's recommendations reflect an accurate interpretation of published reports but also reflect compromises that are believed by some to be too generous toward or too restrictive of monitoring.[32]

A 2011 systematic review of the reduced rates of SIDS identified 11 prospective studies, but only one provided high-level evidence.[33] The majority of studies reviewed were cohort studies from the 1980s. Many of these studies were flawed in their methodology or description of study design, and the type of home monitoring device varied among the studies and even within a single study. A total of 2210 infants had been studied over an average of 5.5 months with a rate of SIDS deaths of 5.0 deaths per 1000 (95% CI 1.4–11.0). While the review concludes that there is little evidence that home monitoring may prevent SIDS, the authors go on to say that "the lack of high-level evidence of effectiveness of home monitoring does not prove that it is ineffective. Indeed, the lack of evidence may be more of a reflection of the difficulty in designing an appropriate and rigorous study in this sensitive area, where the well-being of any child enrolled must be given much higher priority than the more abstract needs of researchers."

In our opinion, approaches to monitoring that are dogmatic, either pro or con, and not sympathetic to parents' concerns, should not be the norm. Thus, although it is the official recommendation of the AAP that ALTE patients not be monitored, this recommendation remains controversial, and home monitoring appears to be a common practice.

# Apnea in Premature Infants

## Diagnosis and Differential Diagnosis

During their initial hospitalization, 50%–100% of premature infants born weighing less than 1500 g will require mechanical or pharmacological interventions because of apnea.[34,35] Apnea of prematurity (AOP) is defined as cessation of airflow for 10–20 seconds or longer. Shorter pauses in respiration associated with falls in $\mathrm{SpO_2}$% (e.g., to <90%) or in heart rate (e.g., to <100 beats/min) are also seen as important episodes of apnea in most neonatal intensive care units (NICUs). However, if apnea is less than 10 seconds, there is little consensus about the amount of reduction in $\mathrm{SpO_2}$% that is worrisome.[34,36–38]

Other possibilities in the differential diagnosis of AOP besides immaturity of ventilatory control include: intracranial hemorrhage, sedation crossing the placenta, sepsis with or without meningitis, heat or cold stress,[39] a patent ductus arteriosus, hypoglycemia, electrolyte abnormalities (particularly hyponatremia), anemia, necrotizing enterocolitis, feeding-related apnea,[40] heart block or heart failure lowering cerebral perfusion, and excessive sedation given to the infant directly.

The majority of apnea among premature infants is “idiopathic,” and attributed to immaturity of ventilatory control.

## Pathogenesis of Apnea of Prematurity

Ventilatory control among premature infants is sufficiently unstable that apnea, even prolonged, is provoked by problems (e.g., hyponatremia, heart failure) that would not be sufficient explanations beyond term postmenstrual age (PMA). Thus, the primary instability of ventilatory pattern and drive among premature infants, even when they are "well," is important.[38]

It is simplistic to state that most apnea among premature infants is central, although most episodes can be prevented with stimulants whose primary action is central. Indeed, it is probable that the majority of apneic events in premature infants have both obstructive and central components (i.e., they are mixed).[41] Furthermore, it seems likely that all three types of apnea described in preterm infants—central, obstructive, and mixed—occur when the frequency of output from the respiratory controller is at a low ebb, "suggesting that all 3 patterns had one common underlying mechanism."[38]

There is little recent published work that describes the prevalence of the various types of apnea (central, obstructive, or mixed) or the impact of sleep state, or that explores critically the continued relevance of what has become "cribside" dogma.[42] Moreover, clinical rules have often been based on few observations; for example, the dogma that apnea is much more common in active than in quiet sleep is based on studies done on nine term infants.[43] With many smaller and more premature infants surviving, since the introduction of artificial surfactant over 25 years ago, these dicta should be reexplored.

It was observed in the 1980s that the majority of central apneic episodes were either preceded or followed by evidence of upper airway obstruction.[44,45] During apnea in premature infants, respiratory effort often continues, or resumes, before airflow returns, with phasic contraction of the diaphragm (electromyogram) associated with generation of progressively more negative intrathoracic pressures ($P_{\text{esoph}}$). Near the end of a typical mixed apnea, genioglossus contraction (submental electromyogram) opens the airway and flow resumes.[46] It was thus recognized that apneic episodes in premature neonates could also appear on recordings to be bradycardia with desaturation, because impedance chest movement monitors would correctly indicate that respiratory efforts continued.[47]

During quiet sleep, premature neonates with frequent apnea are less able than nonapneic controls to compensate for progressive increases in upper airway resistance. Neonates with apnea have much shorter and weaker inspiratory efforts in response to end-expiratory occlusion. Premature neonates with apnea also have a higher $Pa_{CO_2}$ (~9 mm Hg higher) and a much flatter ventilatory response to breathing 4% $CO_2$ ($V_E$/min/kg) compared to controls.[48,49] In addition, infants, in general, have a flatter $CO_2$ response when breathing progressively more hypoxic gas mixtures.[50]

A series of explanations for the most common type of apnea among premature infants—mixed apnea—can be constructed from these classic studies:

1. Upper airway obstruction, for which the infant has shorter and weaker "load compensation," is preceded by brief central apnea, or leads to longer central apnea.
2. Infants with a lower minute volume response to increasing $CO_2$ become progressively more hypercarbic and hypoxemic.
3. The development of hypoxemia further blunts $CO_2$ response, and the increasing $CO_2$ makes the activities of the diaphragm and genioglossus asynchronous,[51] perpetuating the cycle of obstructive and central (i.e., mixed) apneas.

Other "classic" studies from the mid-1980s suggested additional physiologic mechanisms to explain why premature infants might be more at risk for mixed apnea and its complications during active sleep:

1. The inspiratory "load" for which premature infants are unable to "compensate" is due to upper airway narrowing,[42,43] which usually occurs at the pharynx.[41]
2. Loss of intercostal tone[52] during active sleep would increase wasted "distortional" work[53] during the paradoxical breathing caused by pharyngeal airway narrowing.[41,54]
3. Loss of intercostal tone would also diminish functional residual capacity and thus worsen hypoxemia during compromised breathing.[52,55]

Furthermore, the LCRA, described above, may also play a role in AOP. Swallowing interrupts LCRA. Premature infants swallow more frequently during apnea than during eupneic breathing. This suggests that exaggerated LCRA, such as that caused by spontaneous pooling of saliva, may explain some apneic episodes.[56] LCRA is, in fact, mixed apnea, and similar to the most frequent type of AOP.

Although it may be simplistic to describe AOP as "primarily central," inadequate responses to upper airway obstruction do reflect a significant "central immaturity" among premature infants. Other evidence of the "central immaturity" of younger infants is the marked increase in periodic breathing particularly during active sleep.[43] After the onset of periodic breathing, transient upper airway obstruction at the pharynx is common during the first inspiratory effort after the apneic pause. Thus, excessive periodic breathing, which is considered pathognomonic for "central immaturity" of respiratory control, frequently has both central and obstructive (i.e., mixed) apnea components.

During epochs of periodic breathing, preterm infants have falls in $SpO_2$% and are widely believed to be more susceptible to prolonged apneas (Fig. 80.3). A recent longitudinal study of 24 infants born between 27 and 36 weeks gestation showed that all but one had periodic breathing during 2–3 hour recordings during naps.[57] The infants were 2, 4, and 6 months postterm corrected age. For most infants, the periodic breathing runs were short and benign, though falls in $SpO_2$% and cerebral tissue oxygenation index were often statistically significant. Three infants had large and sustained falls in heart rate, $SpO_2$% (to <80%), and cerebral oxygenation index.[57] Their susceptibility to periodic breathing may be enhanced by the fact that their $PaCO_2$ during eupneic breathing may be only 1.3 mm Hg above their apneic threshold.[58] Thus any ventilatory overshoot after a periodic apnea makes preterms particularly vulnerable to resuming apnea. In this regard, evidence from lambs induced to have periodic breathing suggests that increases in lung volume from adding CPAP served to reduce the overshoot, or "loop gain," after a periodic apnea, followed by shortened epochs of periodic breathing.[59]

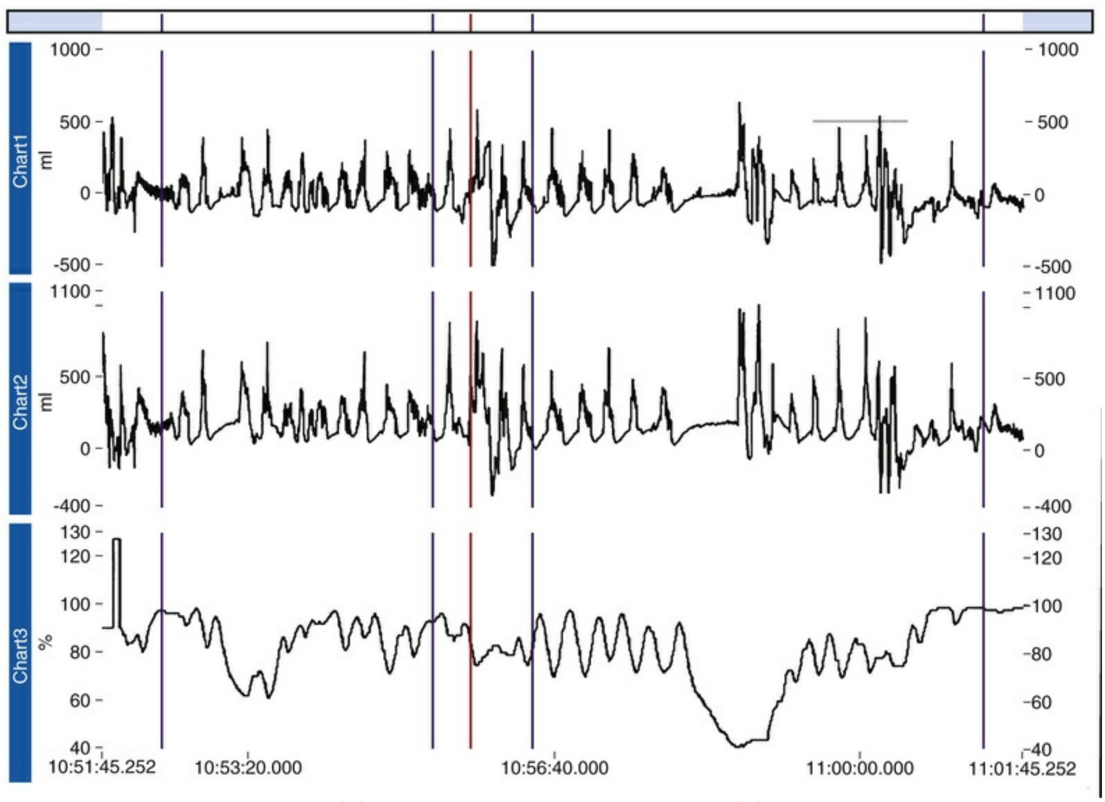

**FIG. 80.3** A 10-minute recording in a 26-week premature infant at 36 weeks postmenstrual age. Upper two tracings are respiratory inductance plethysmography (RIP) from rib cage and abdominal belts. The pattern seen during the first 6 minutes is typical for periodic breathing. Lower tracing shows oscillations in $SpO_2$% with periodic breathing/periodic apnea. Fall in $SpO_2$% to 46% is associated with a 38-second central apnea recorded by the RIP belts. (Data from the Prematurity and Respiratory Outcomes Program (PROP) Study.)

Premature infants also have more active sleep than quiet sleep, with the attendant irregularity in tidal volume ($V_T$) and ventilatory frequency ($V_f$), and increases in both prolonged apnea and periodic apnea/breathing. In the episodes of apnea when obstruction is not found (<50%), irregularities in respiratory pattern ($V_f$, $V_T$, periodic breathing) often explain a propensity for apnea that is "primarily central."

## Prognosis of Apnea of Prematurity

The natural history of AOP is unclear because interventions to treat it, and thus alter its natural history, have been tried ever since it was first described.

Apneic pauses longer than 5 seconds are common on the first day of life among premature infants without respiratory distress syndrome and can increase to 25 per day by the third day.[60] During a 5-year period (1989–1994), one NICU discharged 457 infants born at 24–28 weeks PMA.[35] All infants enrolled in the study had been treated because all had apnea lasting longer than 20 seconds. In general, infants born earlier had apnea and bradycardia events that persisted until an older PMA. In the study by Eichenwald and coworkers,[35] apnea was diagnosed when chest wall movement was not detected by impedance monitoring. The last events to disappear with maturation were bradycardia episodes without associated central apnea. As noted earlier and as recognized by the Eichenwald et al., the explanation may be that obstructive apneic episodes with bradycardia continued until the age that the bradycardia episodes ceased. Another study using transthoracic impedance but incorporating motion-artifact resistant oximetry has led to similarly plausible speculation.[61] Finally, evidence for persistent propensity for undetected mixed apneas is also suggested by detailed descriptions of maturation of upper airway–stabilizing mechanisms.[62] There seems to be a growth- and age-dependent threshold for improvement in upper airway stability beginning at about 36 weeks PMA.

One group of preterm infants whose ventilatory and general "autonomic instability" may not be appreciated are so-called late preterm infants, born at 33 or 34–37 weeks PMA. The majority (75%) of preterm births in the United States each year are in this group, and over 400,000 infants are born at 33–37 weeks annually.[63] Most attention in diagnosing and treating apnea of prematurity is directed to infants born less than 32 or less than 28 weeks PMA.[35,64,65] However, compared to term infants in the CHIME study (Collaborative Home Infant Monitoring Evaluation),[29] late preterm infants had a relative risk less than 5 for "extreme" apnea lasting longer than 30 seconds, or bradycardia (see Fig. 80.2). Further, in our experience, late preterm infants not infrequently return to hospital with, for example, excessive periodic breathing, hypoxemia, and apnea at 40 weeks PMA or older, and clinicians seem surprised at the severity of their ventilatory instability. It is clear that postnatal maturation of ventilatory control among very preterm infants is not the same as infants of the same PMA but born at term.[65] Whether and how much this delay in maturation occurs in late preterm infants is not clear. But concerns are growing about respiratory morbidity and about neurodevelopmental milestones in late preterms, particularly with regards to mathematics and reading skills.[66] This has led to trials of interventions such as betamethasone[67] during late preterm labor (34–37 weeks) to begin to address a series of problems that are common and that were underappreciated until recently. Studies are also needed to clarify whether the ventilatory control problems of some late preterm infants, as in the CHIME study, contribute to neurodevelopmental complications.

## Management and Treatment for Apnea of Prematurity

The first-line treatment for AOP remains methylxanthines,[68] with approximately 75% of premature infants responding. Caffeine has replaced theophylline as the methylxanthine of choice because it is as effective and less likely than theophylline to cause tachycardia or poor feeding.[69] Caffeine is thought to act by blocking brainstem inhibitory adenosine $A_1$ receptors, leading to increased respiratory neural output.[47]

Pulmonologists should also know that much enthusiasm has developed recently for the early introduction of caffeine for prematures weighing 500–1250 g, even before apnea of prematurity necessitates increased ventilatory support. It is not clear why, but subjects started on caffeine within the first 10 days of life in a randomized, controlled trial involving 2006 infants had: (1) shorter need for supplemental $O_2$ and CPAP[70]; and (2) less neurodevelopmental disability at 18–21 months postterm corrected age.[71] Caffeine was begun before chronic lung disease had developed, and continued until apnea, if it developed, had resolved. How caffeine given more or less prophylactically might reduce the incidence of chronic lung disease is not clear.[72,73] Studies in animal models suggest that its effect may be through adenosine receptors both on lung inflammatory cells and on airway smooth muscle that determine the responses to inflammation[74] or through prevention of the functional, structural, and inflammatory changes induced by hyperoxia.[75] Furthermore, although it reduces apnea frequency and, presumably, the associated hypoxemia, whether these effects on ventilatory stability provide the explanation for caffeine's apparent impact on neurodevelopmental outcome was not addressed in the large randomized trial.[72] The longer-term effects of caffeine on oxygenation are suggested by a study showing that earlier cessation of caffeine treatment according to nursery protocol was associated with longer periods of intermittent hypoxemia at 35 and 36 weeks PMA than if caffeine was continued longer until clinical concerns regarding apnea had resolved.[76]

Infants who fail to respond to methylxanthines will often respond to nasal continuous positive airway pressure (NCPAP) or nasal intermittent positive pressure ventilation.[77] However, concerns about toxicity from high-dose methylxanthines and mucosal injury from NCPAP have led to widespread enthusiasm for early use of high-flow nasal cannulas. High-flow nasal cannulas use adequately warmed and humidified air to deliver distending pressures that are presumably comparable to NCPAP, and are often used at flow rates of 2.5 L/min, or more.[78] These catheters have been shown to be as effective as NCPAP in reducing apnea, bradycardia, and episodes of desaturation. High-flow cannulas appear to stave off intubation both by stabilizing respiratory mechanics and treating AOP.[79] Potential explanations for the efficacy of high-flow therapy in treating AOP have not been tested empirically, despite its frequent use for this purpose.[80] However, it seems plausible that distending pressures from the high-flow catheters might mitigate the obstructive component of a typical preterm's mixed apnea (Fig. 80.4). Also, continued flow *per se* might stimulate laryngeal flow receptors[9] and, in effect, feed forward to stimulate continued respiratory effort.[81]

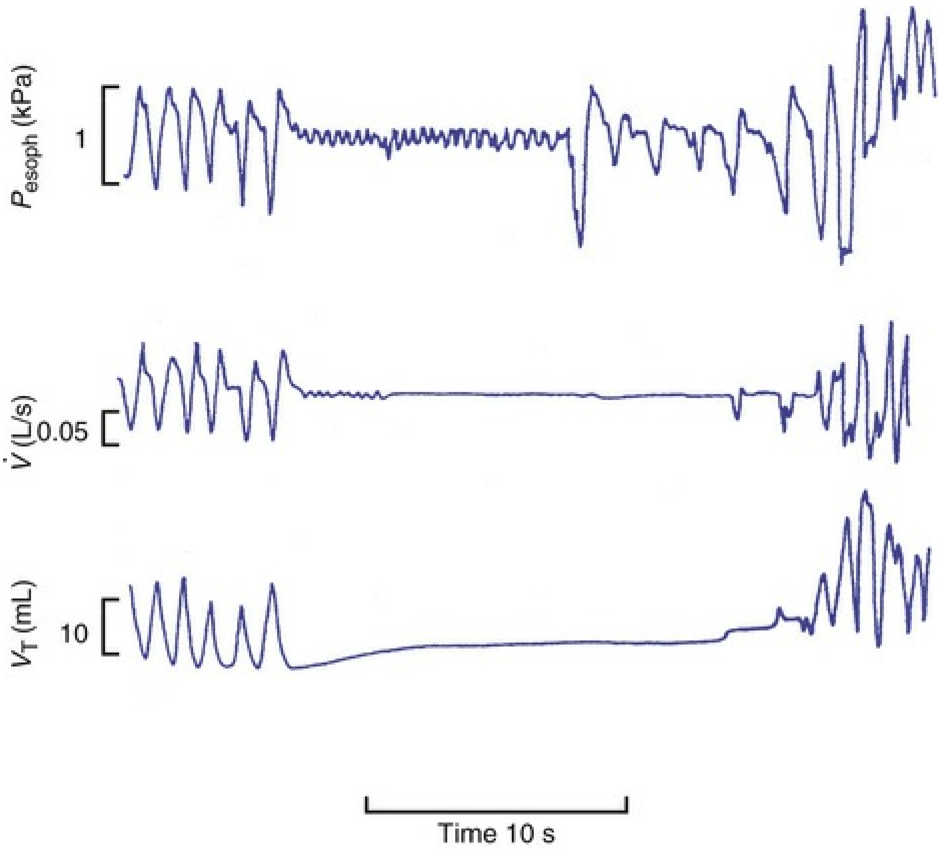

**FIG. 80.4** Spontaneous apnea in a premature infant. Esophageal pressure tracing, with cardiogenic artifact, demonstrates first central apnea, then respiratory efforts. Flow and volume tracings show that the first four or five efforts after central apnea are obstructed. Such mixed apneas are the most common type of apnea of prematurity. $P_{esoph}$, Intrathoracic pressure; $V_T$, tidal volume; $\dot{V}$, airflow. (From Milner AD, Greenough A. The role of the upper airway in neonatal apnea. *Semin Neonatol*. 2004;9:213-220.)

Another older intervention for apnea, blood transfusion, remains controversial.[82] The long-term effect of transfusion therapy on reducing AOP is not clear. However, it has recently been shown that infants have more apnea when their hematocrit is lower, and apnea is less frequent for 3 days after a transfusion.[83]

Pediatric pulmonologists who are not based in NICUs should be reminded that premature infants are at much greater risk for serious apnea after general anesthesia.[84] After anesthesia, increased frequency of apnea and bradycardia can continue to beyond 46 weeks PMA, particularly among infants who required prolonged ventilatory support just after birth, or who have significant residual lung injury. Pulmonologists should be aware of the policies of local pediatric anesthesiologists with respect to perioperative monitoring, even for semielective surgery such as herniorrhaphy. A systematic review from Copenhagen emphasized that "Grade 1 evidence (randomized, controlled trial) exists for recommending regional versus general anesthesia when possible, and for the efficacy of prophylactic caffeine (10 mg/kg IV) on the day of surgery for preterms less than 44 weeks PMA."[85] The Danish authors recommend at least 12 hours of nurse-supervised, postanesthesia monitoring using ECG and oximetry for: (1) all preterms less than 46 weeks PMA; (2) for infants 46–60 weeks PMA with a hematocrit less than 30%, and, (3) those 46–60 weeks PMA with "co-morbidities" including chronic lung disease, a history of apnea, or CNS abnormalities. Six hours of recovery room monitoring is otherwise recommended for preterms 46–60 weeks PMA.[85] A recent study by the Pediatric Sedation Research Consortium involving over 57,000 patients receiving sedation showed that former preterm infants are at a small but significant risk for airway obstruction, lower $SpO_2$%, and other complications, and that risk that can extend into adulthood.[86]

## Monitoring Premature Infants at Home

Studies evaluating compliance with apnea monitor use suggest high rates of compliance among infants with AOP, particularly during the first month at home.[87] Abuses because of self-interest among those prescribing monitors notwithstanding,[32,88] the promise or potential of monitors, when used to prevent deaths among "nursery graduates," should not be discounted. Infants born at 24–36 weeks PMA are 2.1–3.3 times as likely to die of SIDS as infants born at greater than 37 weeks.[89]

The issue of monitor use is quite complex, however. In their review of more than 37,000 deaths and 3.8 million linked births, Malloy and Hoffman showed that, depending on the estimated gestational age, the age of SIDS deaths among premature infants was, on average, 44.2 weeks to 47.8 weeks PMA (range, 32–85 weeks).[89] On the basis of these data and those of the CHIME study,[29] wherein "extreme" apneic spells among premature infants "disappeared once the infants were 43 weeks postconceptional age," one editorial writer declared that the usefulness of prescribing monitors to detect extreme apneic spells and to prevent sudden death among premature infants and the "physiological basis for such a practice are more in doubt than ever."[32] However, because infants who have died were certainly apneic at least once, another possible scenario is that the time course of dangerous apnea activity among those premature infants dying is different from those having apnea and not dying. The vexing problem remains whether it is possible to select candidates who will benefit most from monitoring. Monitoring for apnea in preterm infants must continue to be part of this discussion. Malloy has shown that the adjusted odds ratio for deaths called SIDS for infants born between 24 and 28 weeks was 2.57, even given the propensity for attributing their deaths to causes related to complications of prematurity.[90]

For the time being, we are in agreement with the AAP recommendations for monitoring premature infants having apnea until they are 43 weeks PMA.[32,91] Because the average time course until cessation of apnea among those infants dying must be different from that for the premature infants in the CHIME study, monitoring infants past 43 weeks PMA who have frequent apnea lasting longer than 20 seconds, especially with reductions in heart rate, also seems prudent.

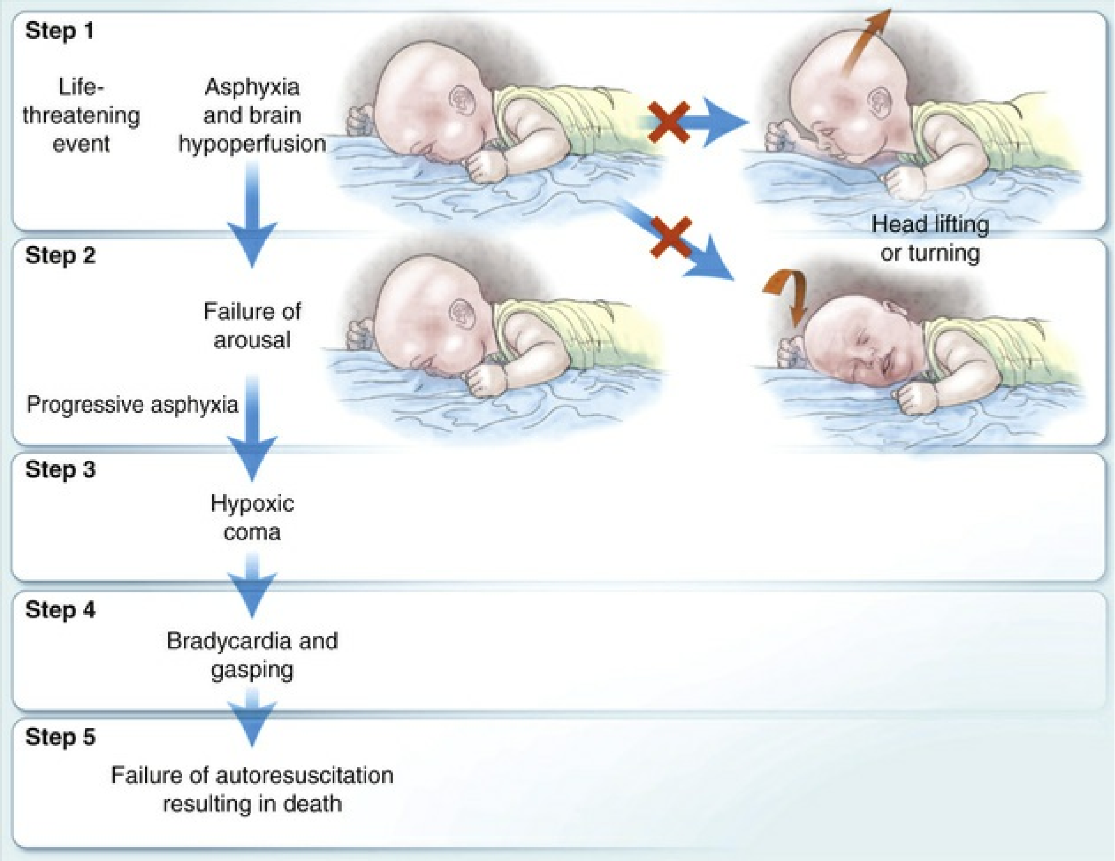
# Sudden Infant Death Syndrome

## Pathogenesis: Triple Risk Model

The definition for SIDS during the first 20 years after the syndrome was recognized was "the sudden death of an infant or young child, which is unexpected by history, and in which a thorough postmortem examination fails to demonstrate an adequate cause of death."[92] Because of the recognition of risk factors related to sleep practices, the definition was broadened in 1991 to "the sudden death of an infant under one year of age which remains unexplained after a thorough case investigation, including performance of a complete autopsy, *examination of the death scene,* and review of the clinical history."[93,94] For a complete discussion of issues surrounding the definition of SIDS,[95] categorization when investigations are incomplete, and the importance of alternative definitions with subtle changes in emphasis, the reader can refer to reviews by Rognum and by Krous and coworkers.[94,96]

In this regard, it is important to recall that the “SIDS era” arose from the recognition in the late 1960s that most sudden infant deaths occurred without sufficient pathologic findings to explain them.[97,98] Explanations were lacking beyond otitis media, or mild interstitial pneumonia, found at autopsy. This fundamental insight led to much research into reflexes, ventilatory control, and brainstem neurochemistry to clarify what was defined as “unexplained” by conventional histopathology.

While serving to stimulate new thinking about why infants die, the definition just cited requiring a scene investigation has led to nosologic uncertainty, and much controversy, with one author decrying the “disappearance” of deaths labeled SIDS as a large step backward in studies of unexpected infant mortality.[99] Accepting an explanation for some deaths from a group defined because they “remain unexplained” presents an obvious conundrum. For example, once empirical data became available that suggested how infants diagnosed as having died from SIDS might have subtly suffocated while face down on soft bedding,[100–104] it was claimed that these deaths were not due to SIDS (a mystery) as they were originally diagnosed, but, in fact, due to suffocation (Fig. 80.5).[105] The diagnostic shifting described[106] is understandable in the context of a definition that, while useful in stimulating research, assured a nosologic conundrum if progress was made and some of the deaths became explicable.



Step 1
Life-threatening event
Asphyxia and brain hypoperfusion
Head lifting or turning
Step 2
Failure of arousal
Progressive asphyxia
Step 3
Hypoxic coma
Step 4
Bradycardia and gasping
Step 5
Failure of autoresuscitation resulting in death

**FIG. 80.5** Five steps in the putative terminal respiratory pathway associated with the sudden infant death syndrome. Death results from one or more failures in protective mechanisms against a life-threatening event during sleep in the vulnerable infant during a critical period. In particular, infants unaccustomed to prone sleep are at an 18-fold increased risk for sudden death when placed prone. (Reprinted from Kinney HC, Thach BT. The sudden infant death syndrome. *N Engl J Med*. 2009;361:795-805, Copyright Massachusetts Medical Society.)

A framework that, in our opinion, has stood the test of time as a way to study sudden unexpected infant deaths is the triple-risk model (Fig. 80.6).[107] Susceptible infants at a vulnerable physiologic and developmental stage are exposed to more-or-less potent environmental stressors that lead to death. In a given infant or group of infants the relative importance of each influence may vary. Investigations into sleep practices over the past 20 years have increased the understanding of exogenous stressors.[108,109] Some would argue that these deaths should not be categorized as SIDS because they have had partial, new explanations,[102] even though the triple-risk model for SIDS encompasses them perfectly.

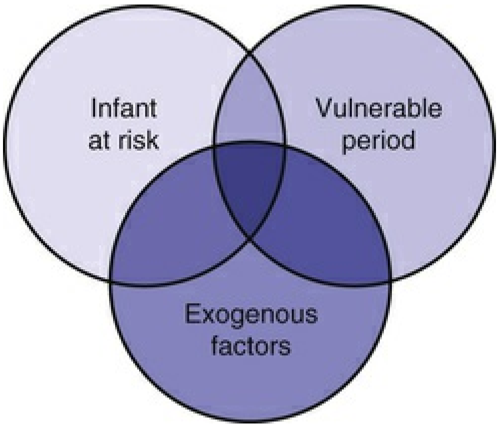


**FIG. 80.6** The triple-risk model, developed to address the problem of SIDS. It emphasizes the likelihood that most deaths have several partial explanations, within a causal sequence. It remains relevant when death scene investigations have caused diagnostic shifting among the diagnoses of SIDS, unexpected suffocation, and cause of death undetermined. (From Filiano JJ, Kinney HC. A perspective on neuropathologic findings in victims of the sudden infant death syndrome. The triple risk model. *Biol Neonate*. 1994;65:194-197.)

Although theoretically problematic, practical approaches to understanding related types of sudden unexpected infant deaths are possible under the rubric of SIDS. It is essential, however, to realize that there is little to be gained by an exclusionary definition of "true SIDS."[94,96]

Within the triple-risk model, for a given infant it is more helpful to think of a causal sequence. For example, we might consider a hypothetical infant with a sluggish arousal response to sleep environment threats while prone[107,110] who comes to lie prone on bedding that covers the nose and mouth.[111–113] The infant also has a respiratory infection[114] and is at a vulnerable age when the skills at gaining access to fresh air are poor.[110] Perhaps the infant has come to lie in the prone position for the first time, without the requisite learned skills to be safe prone.[110,111,115,116] In a given infant, each of these variables could be critical antecedents before autoresuscitation failure and sudden death. Moreover, amelioration of one or more of the risk factors present in this example would reduce the risk for death. The success of supine sleep interventions in many countries suggests that the prone position is critical at several junctures in a hypothetical causal sequence, at least among infants sleeping alone.[113,117–119]

## Potentially Lethal Mechanisms Linked to Sleep Position and Sleep Environment

The section addressing lethal physiology linked to prone sleep position in the eighth edition of this text described potential rebreathing of air exhaled by the infant and thermal stress in much detail. It summarized the epidemiologic and physiologic research supporting an interaction between sleep position and a sleep environment containing loose blankets and soft sleep surfaces leading to rebreathing that can be lethal and to thermal stress. If an infant's nose and mouth are encumbered at all, rebreathing of air depleted of $O_2$ and polluted with $CO_2$ will occur. Whether this is lethal depends on the severity of limitation of access to room air imposed by the sleep environment and the infant's susceptibilities.[106,107] When rebreathing occurs, which it does when an infant's airway is at all encumbered, the challenge is to understand when rebreathing can be or is likely to be lethal.[103]

The physiology of the mechanism(s) of death remains somewhat obscure when infants are exposed to putative thermal stress that does not cause cellular injury akin to that occurring with heat stroke.[120] Infants have been shown to thermoregulate effectively and predictably when exposed to sleep environments predicted to cause dangerous thermal stress and linked to increased risk of death.[121] Relative thermal stress, compared to sleeping alone, occurs when infants bedshare,[120] but infants dying while bed sharing do not have postmortem changes of heat injury, nor has the impact of comparable levels of thermal stress on ventilatory pattern and other homeostatic mechanisms been established.

## Epidemiology

The 50% fall in the number of deaths attributed to SIDS from the early 1990s through 2004 has been justly labeled “a success story for epidemiology."[122] Interventions in many countries motivated by the apparent causal association between prone sleep and SIDS seemed highly successful. After 2004, however, though deaths called SIDS were fewer, total sudden unexpected deaths have continued at a rate near 1.0 per 1000 live births (Fig. 80.7). As pointed out above, uncertainty continues regarding which deaths are unexplained—SIDS—and which might be attributed, at least in part, to subtle or not-so-subtle asphyxia of a susceptible infant.

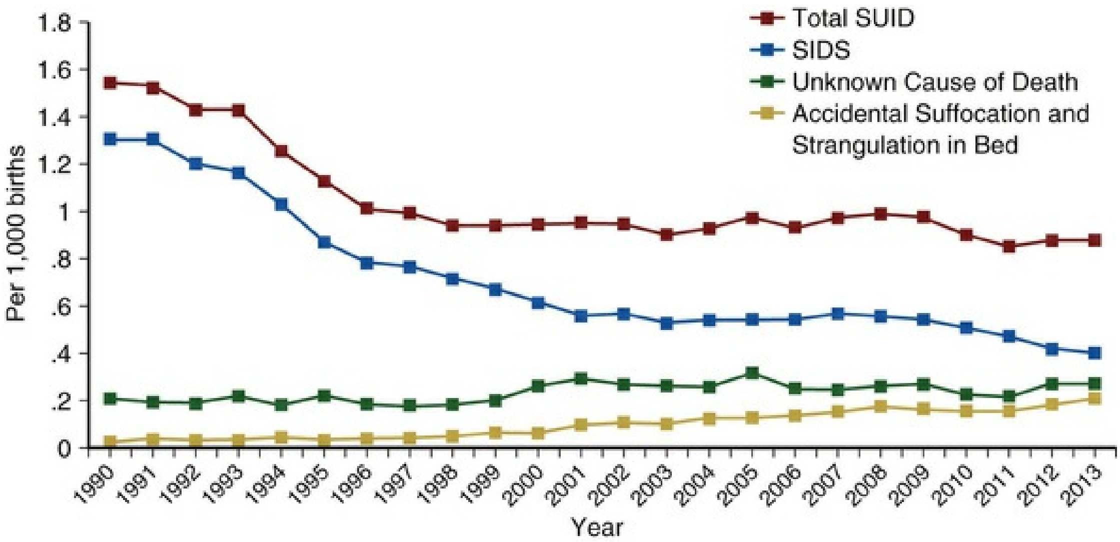

**FIG. 80.7** US rates of SIDS and other sleep-related causes of infant death (1990–2013). A graph showing the rates of SIDS and other sleep-related causes of death from 1990 to 2013. Total SUID deaths declined from ~1.5 in 1990 to 1 in 2013. Total SIDS deaths declined from ~1.3 in 1990 to ~0.5 in 2013. Deaths from unknown causes held steady between 1990 and 2013 at a rate of ~0.2. Deaths from accidental suffocation and strangulation in bed rose from ~0 in 1990 to ~0.2 in 2014. (From Fast Facts about SIDS. NIH Child Health and Human Development Safe to Sleep Public Education Campaign. https://www.nichd.nih.gov/sts/about/SIDS/Pages/fastfacts.aspx.)

Three recent important papers address newer issues pertinent to the apparent but sometimes confusing decline in unexpected infant deaths in the 1990s and early in this century. The first considers the decline in SIDS deaths over the last 25 years.[123] Causes for postneonatal infant mortality between 1983 and 2012 were analyzed for over 947,000 deaths in the United States. Goldstein et al. make the case that falls in numbers of deaths attributed to SIDS must be understood relative to trends for overall postneonatal mortality. Before the practice of Back-to-Sleep, SIDS rates were already falling at a rate similar to all postneonatal mortality (Fig. 80.8). Deaths labeled SIDS fell at a faster rate than all postneonatal mortality from 1994 to 1996, 1998 to 2001, and in 2012—that is, for only 8 of nearly 20 years of Back-to-Sleep. The authors argue that though Back-to-Sleep was successful, the success should be more completely described within populations of infants becoming less likely to die from all causes, perhaps because of reductions in "intrinsic factors" for SIDS and for deaths from other causes. Among reductions they cite are less smoking during pregnancy and fewer mothers never breastfeeding.

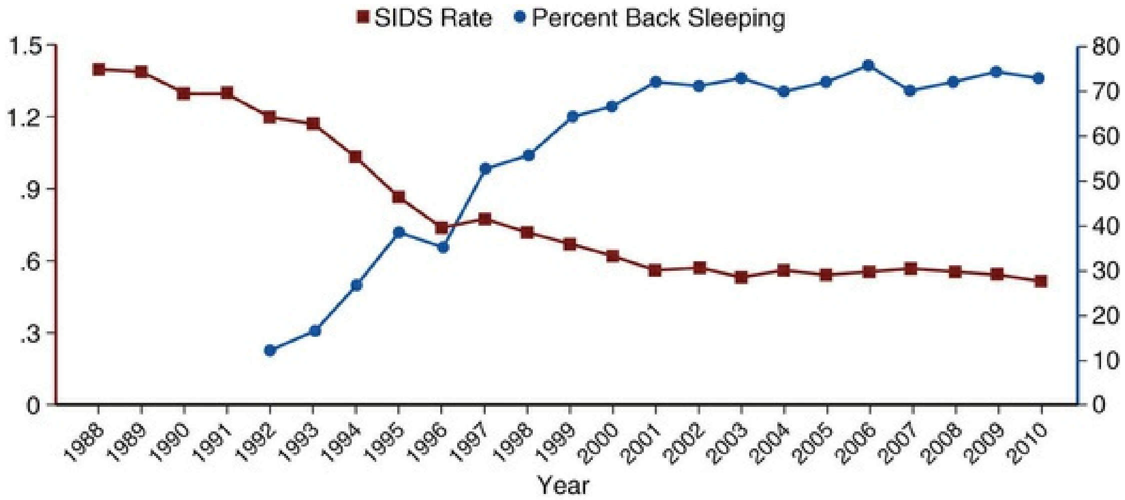

**FIG. 80.8** US SIDS rate and sleep position, 1988–2010 (deaths per 1000 live births). A line graph showing the US SIDS rates and the percent of infants on the back sleep position from 1988 to 2010. The SIDS rate decreased steadily from a rate of approximately 1.4 in 1988 to approximately 0.5 in 2010. The percent of infants being put to sleep in the back sleeping position increased from approximately 15% in 1998 to approximately 72% in 2010. (From Progress in Reducing SIDS. NIH Child Health and Human Development Safe to Sleep Public Education Campaign. https://www.nichd.nih.gov/sts/about/SIDS/Pages/progress.aspx.)

The second paper describes attempts to circumvent confusion arising from diagnostic shifting among SIDS, cause of death undetermined, and subtle asphyxia.[124] A system for evaluating cases within a standardized registry at the Centers for Disease Control and Prevention was applied to 436 infant deaths occurring in 9 participating states in 2011 (~13% of all sudden unexpected deaths in the United States).[125] The authors tabulated whether the deaths were believed to be unexplained (SIDS, cause undetermined) or possibly explained by asphyxia, whether thorough postmortem investigations including an investigation of the death were done, and whether unsafe sleep practices and obvious compromise of the infants' external airway were described.[124] This recently developed centralized case registry from the CDC, at first glance, would suggest a bias in favor of the idea that most infant deaths can be explained by some degree of asphyxia. However, as the authors claim, they want to quantify how frequently this occurs and recognize "…how suffocation or asphyxiation may contribute to death…" by better describing the completeness of the information on which these decisions are or should be based.

The third recent important paper reviews the well-known impact of being born prematurely on rates of SIDS and related sudden unexpected infant deaths,[90] taking into consideration diagnostic shifting due to scene investigations and interventions to promote nonprone, safe sleep. The focus was on comparing very preterm infants (24–28 weeks PMA) to those born at term. For the years 2005–2007, the SIDS mortality rate for preterm infants was higher than for term infants (1.23 vs. 0.37 per 1000 live births). The odds ratio for SIDS among preterm infants was 2.57 when adjusted for age. The postnatal age of preterm victims was greater (17.9 vs. 12.8 weeks), but the postconception age was younger (44.2 vs. 52.7 weeks). This suggests that the developmental processes leading to vulnerability occurred earlier in preterm infants.

## Newer Approaches to the Pathology and Physiology of Sudden Infant Death Syndrome

By definition, conventional gross or microscopic necropsy materials do not explain a SIDS death. Consequently, studies of its pathology have usually described subtle quantitative abnormalities in groups of SIDS victims that distinguish them from controls dying of identified causes.[96,126] Alternatively, investigations relying on novel techniques that have been developed since SIDS was defined have been used to begin to understand lethal mechanisms that work quickly and do not yield abnormalities visible with light microscopy (e.g., autoradiography of neuroligands or markers for apoptosis, or analysis of gene polymorphisms seen more frequently among some children dying suddenly and unexpectedly). Studies of specimens from SIDS victims using the newest techniques have attempted to piece together its pathophysiology, rather than attempting to describe findings that are, by consensus, sufficient to explain death.

Thus, in general, when infants die suddenly and unexpectedly, perhaps 1 in 6 of the deaths will be explained by postmortem findings or tests done on autopsy specimens.[127] However, when infants die without forewarning in the first week of life—SUEND, or sudden, unexpected early neonatal death—conventional postmortem investigations may more often yield diagnostic findings. In a study from London, UK, there were 55 SUEND from 1996 to 2005. Over half (58%) were explained by autopsy, primarily by congenital heart disease, acute infections, and fatty acid oxidation deficiencies.[128]

Epidemiologic findings have always influenced studies of SIDS pathology. In particular, it has been recognized for the past 25 years that many deaths diagnosed as SIDS have involved sleep practices that increase risk for death (see Fig. 80.8).[117] For this reason, pathogenetic models based on dysfunctional responses to stressors arising from sleep practices will be the focus of our review of newer approaches to pathology. In these models, the ultrastructural uniqueness of SIDS victims could cause abnormalities of ventilation, ventilatory control, or airway protection.

## Programmed Cell Death Within the Central Nervous System

In earlier studies, markers of apoptosis, triggered presumably by CNS hypoxia within the previous 48 hours, have been demonstrated in 80% of 29 SIDS victims, and 0 controls.[129] A detailed review of this topic has recently been published.[130] It outlines how "pathologic apoptotic activity" might lead to abnormalities in the dorsal motor nuclei of the vagus, which are believed to play an important role in the "efferent autonomic control of cardiorespiratory mechanisms." The model asserts that intermittent hypoxia and, in particular, intermittent hypercapnic hypoxia, causes apoptosis of neurons trafficking in important neurotransmitters (described below), and that the changes in neurotransmitter function are secondary to apoptosis induced by hypercapnic hypoxia. Thus, although most research into the role of neurotransmitters in sudden unexpected infant death has focused on ventral nuclei, apoptosis in victims has been more prominent in dorsal sites. The model outlined[130] may be particularly relevant to increased risk for death linked to nicotine exposure.

## Neural Receptors and Sudden Infant Death Syndrome

Extensive investigations using carefully chosen controls seem to have established that specific receptors within the CNS are reduced in number among SIDS victims. These receptors are needed for the excitatory function of serotonergic networks within the brainstem, across sleep and wake cycles.

During the past 30 years, Kinney and colleagues[107] have compared the brainstems of SIDS victims to brainstems from infants dying acutely from a known cause, or from chronic diseases causing hypoxia. Their approaches show that attempts to explain abnormal function, rather than only histologic neuropathology, are critical to understanding SIDS. Highlights of their work, for our purposes, can be summarized as follows:

1. These authors believe that structures in the human brainstem are "anatomically homologous" to chemosensitive areas in animals,[131] and two SIDS victims they studied had hypoplasia of the arcuate nucleus, a prime

"candidate" site for human brainstem chemosensitivity.

2. SIDS victims have less functional activity of receptors binding radiolabeled cholinergic transmitters within the arcuate nucleus in vitro, compared with acute and chronic controls.[132]
3. Serotonin binding by serotonin receptors in the brainstems of SIDS victims compared with controls is reduced not only in the arcuate nucleus but also in four other brainstem structures derived from the embryonic "rhombic lip" and the intermediate reticular zone.[133] In SIDS, it appears that the abnormal receptor binding patterns in the arcuate nucleus and other nuclei of the medullary serotonergic system are different than in infants who died of hypoxia of known etiology. This suggests that hypoxia alone does not cause the aberrant serotonin binding patterns in SIDS infants, but that other genetic or environmental exposures during development unique to SIDS are responsible for the aberrant patterns.[134]
4. The differences they describe occur within a serotonergic neural network involved with arousal, respiratory patterns, thermoregulation, chemoreception, and upper airway patency.[135] These findings are particularly relevant to asphyxia and hypercarbia that might occur but not be sensed by infants dying prone or supine with their nose and mouth covered.
5. There is a growing body of evidence that the medullary serotonergic system has neurons that are present as early as 7 weeks postconception, and that the nuclei comprising the system are fully developed by 20 weeks.[134] The activity of receptors binding serotonin seems to be developmentally regulated, at least between 35 and 70 weeks after conception.[133]
6. The serotonergic neurons and receptors of this system are vulnerable to in utero exposure to nicotine and alcohol, with markedly decreased serotonin binding in the arcuate nucleus in babies who were exposed.[136]

Two recent publications by Kinney and colleagues have explored the potential forensic applications of their findings regarding serotonergic networks. The first was based on the theory that a deficiency of medullary serotonin (5-HT) leads to 5-HT level abnormalities in SIDS cases and the fact that extrasynaptic 5-HT is deposited in the cerebrospinal fluid (CSF).[137] They measured 5-HT metabolites (5-hydroxy indoleacetic acid and homovanillic acid) in the CSF of 59 SIDS victims and 29 infants dying of other causes. There were no differences and they concluded that 5-HT metabolites measured in the CSF are not acceptable "forensic biomarkers" for SIDS. In a second study, they used a scoring system for potential asphyxial exposure at the time of death to separate their subjects into two primary groups.[138] They compared parameters of brainstem neurotransmitter function in 15 infants whose sudden and unexpected death was not thought to be asphyxia-related to 35 for whom asphyxia was at least implicated because of prone sleep on an unsafe sleep surface or sharing a sleep surface. Methods were those used by Kinney et al. between 1998 and 2008, and included autoradiography, high-performance liquid chromatography, and Western blots. Among other results, they quantified GABA receptor density, serotonin and its receptors, and a key protein regulating serotonin synthesis (14-3-3 isoform). The results from the two groups were not different in these four parameters, suggesting that the difference among SIDS victims in serotonergic network function is primary, and not an epiphenomenon of asphyxial exposure just before death.

In any event, it seems apparent, with respect to key receptor networks, that SIDS victims have the substrate for underlying susceptibilities that change with development. Taken together, these findings complete a triple-risk model (see Fig. 80.6) that might include exogenous stressors within the sleep environment.

## Fatty Acid Oxidation Deficiencies and the Contribution of Genetic Diseases of Metabolism to Sudden Infant Death Syndrome

The last two topics in our discussion of new pathology do not primarily involve respiration. However, a pulmonologist dealing with the sudden death of an infant will need a working familiarity with them.

Under the wide umbrella of SIDS and related causes of death, there has been much interest in heritable diseases affecting energy metabolism.[94] It is not clear whether the diseases are similar to SIDS in that they can be lethal in 2 hours or less in previously healthy infants, or whether the age of death from inherited metabolic disease overlaps classic SIDS ages (peak rate at 3 months, 95% of deaths by age 6 months).[139]

The epidemiologic features of sudden deaths due to inborn errors of energy metabolism are not well established. Furthermore, although techniques such as tandem mass spectroscopy can be used on neonatal blood spots to screen for many inborn errors, the ratios of false positive to true positive may be 8 : 1 or greater. It is unclear whether the public health resources exist to address with new parents the problems of false-positive tests, or unpredictable prognosis of many diseases.[140] Nevertheless, it is certain that some deaths once called SIDS, or attributed to parental neglect, can be explained by deranged energy metabolism. We will discuss two important examples.

During significant fasting, beta oxidation of fatty acids occurs in mitochondria to provide energy substrates as alternatives to dietary sources of energy. There are 11 proteins controlling the 20 steps leading to beta oxidation, and, ultimately, the tricarboxylic acid cycle and flavoprotein electron transport cycle.[141] Disorders may disrupt any step in the process, from substrate uptake to actual beta oxidation, and have their primary effects on the liver, the CNS, or the heart. The disorders are manifest during fasting, either very shortly after birth, or, in particular, associated with anorexia caused by a viral illness.

The most well-known defects are those causing pediatric cardiomyopathies. Newborns need the relevant enzyme, VLCAD (very long chain acyl-CoA dehydrogenase) to meet the extreme demands on their heart during the transition to extrauterine life. Infants with VLCAD deficiency may die suddenly but usually present in heart failure with a cardiomyopathy that is often familial and that responds to low-fat diets and avoidance of fasting.[142]

Altogether, recognized disorders of fatty acid beta oxidation are more common (1 : 10,000 live births) than phenylketonuria (1 : 15,000). The most common inborn error of beta oxidation is a deficiency in medium-chain acyl-CoA dehydrogenase (MCAD). After periods of inadequate oral intake, infants present with hypoglycemia, neonatal apnea, and, in as many as one-third of cases, sudden death.[143] However, their most frequent presentation is profound encephalopathy with cerebral edema, hypoketotic hypoglycemia, elevation of liver transaminases, and hyperammonemia. Because MCAD deficiency was not recognized until the early 1980s, it is probable, in retrospect, that some cases of Reye syndrome were crises occurring in children with MCAD deficiency.[141,144]

In a recent investigation of the potential importance of abnormalities of energy metabolism, tandem mass spectroscopy was performed on blood and bile samples from 410 autopsies on children dying suddenly and unexpectedly at younger than 1 year of age.[145] The autopsies were done at Great Ormond Street Hospital, between 1996 and 2009, and included autopsies done on behalf of the coroner. The authors concluded, reasonably, that about 2% of deaths had an underlying metabolic cause, a percentage consistent with earlier studies from the United States. The most common abnormalities based on acylcarnitine profiles were MCAD and VLCAD deficiencies.

Details about age at death, sleep practices, and prevalence of other SIDS risk factors have not been provided in the largest published series of infants with beta-oxidation defects, although there may be some age overlap with SIDS. Two of three infants with MCAD or VLCAD deficiencies from Oregon died within the first 48 hours of life, and two of three were sharing a bed when found dead.[146]

## Prolonged Electrocardiogram QT Intervals and Lethal Cardiac Arrhythmias

Schwartz and coworkers in Italy have been the most consistent proponents of the theory that cardiac arrhythmias can be lethal in SIDS victims with normal cardiac autopsy results. Arguments against this theory were as difficult to envision as were even partial proofs in empirical, population-based studies. Nevertheless, by recording more than 33,000 electrocardiograms on days 3 or 4 of life, Schwartz and coworkers reported that the mean corrected QT ($QT_C$) interval was longer in the 24 infants eventually dying of SIDS (435 ± 45 vs. 400 ± 20 ms) than in survivors.[147] None of the thousands of survivors had $QT_C$ intervals greater than 440 ms, but 12 of 24 SIDS victims did. The prolonged $QT_C$ interval is believed to be fatal because of an associated malignant arrhythmia (torsade de pointes).

In 2001, Ackerman and coworkers showed that 2 of 93 infants diagnosed as SIDS in Arkansas had mutations causing cardiac sodium channel dysfunction, as compared with none of 400 controls.[148] The mutation in the SCN5A sodium channel they studied is estimated to cause up to 10% of cases of long $QT_C$ interval syndrome.

A recent review summarized current understanding of the importance of "inheritable monogenic arrhythmia syndromes" as causes of sudden unexpected deaths in infancy.[149] The review considered children younger than 1 year and older than 1 year of age separately. The review asserted that $Na^+$ and $K^+$ channel malfunctions, and related channelopathies may have been present in as many as 14% of deaths called SIDS between 2006 and 2014. The authors suggest that fever, or overheating, may be the environmental triggers within the familiar Triple Risk Model context that proves lethal for an infant genetically vulnerable to fatal arrhythmias.

The theories of Schwartz and coworkers, and the findings of subsequent investigators now seem well established as causes for a percentage (~2%–5%) of deaths that might meet the criteria for SIDS. The impact of potent SIDS risk factors (e.g., prone sleep, maternal smoking) on the risk for lethal outcomes in infants who are homozygous, or even heterozygous for mutations in, for example, cardiac sodium channels, has not been calculated,[150] so it is not yet possible to use this information to understand how it fits into the classic epidemiology of sudden death in infancy.

Also, it is becoming less clear where the pathologic investigation of SIDS or other sudden unexpected infant deaths should stop,[94,151] as more causes for sudden death are discovered that were not known when SIDS was defined. Should molecular genetic mechanisms be pursued in all deaths? Alternatively, should they only be considered when there is a family history of SIDS, or only when sleep practices are not clearly implicated?[152,153] Or might, for example, exposure to hypoxia, described below and arising from the sleep environment, place infants with mutations causing channelopathies at even greater risk for lethal dysrhythmias, according to the Triple Risk Model?

## The Use of Investigations of the Scene and Circumstances of Sudden Infant Death

One type of sudden unexpected death for which scene investigations have always been crucial is infanticide. The perceived importance of infanticide as a frequent cause of death has waxed and waned. Dramatic series of cases[88] remind us that infanticide, with or without antecedent Munchausen syndrome by proxy, cannot be ignored. Gross and, occasionally, microscopic autopsy findings are of obvious importance when diagnosing nonaccidental trauma as a cause of death; however, it is less clear by autopsy how to prove intentional but subtle suffocation (e.g., using a pillow).[154] Southall and coworkers used covert video surveillance in the hospital to document that 30 of 39 very high-risk infants were subjected to intentional suffocation.[155] Twelve had siblings who had died suddenly and unexpectedly. Although bloody froth from the nose and mouth is common among SIDS victims, 11 of 38 subjects in Southall's study had a history of an ALTE associated with frank bleeding from the nose and mouth, compared with none of 46 controls.

Two studies compared the presence of alveolar hemosiderin-laden macrophages (AHLM) as evidence for pulmonary hemorrhage in cases of SIDS, suffocation,[156] and sudden unexpected infant deaths when nonaccidental injuries were suspected. AHLM were more likely to be present in deaths associated with direct or circumstantial evidence for nonaccidental injuries.[157] Nevertheless, in this study, two-thirds of infants with significant numbers of AHLM had no historical or postmortem evidence to suggest nonaccidental injury.

It seems probable that the percentage of sudden unexpected infant deaths that will be proven to be intentional will increase as the overall number of sudden deaths declines.[158] Before the Back-to-Sleep campaign in the United States, based on serial cross-checks of data from social and law enforcement agencies, it was estimated that about 5% of SIDS deaths were likely to be due to maltreatment.[159] Certainly, both multiple deaths within families after genetic causes have been ruled out, and simultaneous deaths of twins should raise cautious suspicion. Nevertheless, the best evidence suggests that foul play is unlikely in the vast majority of second-infant deaths within a family.

The addition of scene data and the appreciation of the potential for thermal stress and lethal rebreathing have led to diagnostic shifting: very similar deaths that had been called unexplained (SIDS) before death scene data became available are increasingly diagnosed as accidental suffocation or positional asphyxia, or undetermined.[106,160,161] This evolution in designation of manner and cause of death reflects the increase in information available to forensics teams. The prevalence of risks created within the sleep environment, especially for prone infants, is also more broadly realized.

Thus, it seems likely though still controversial that, compared to the early 1990s, fewer deaths will be designated as unexplained and SIDS, not because of arbitrary decisions, but because “previously unsuspected sleeping accidents are now being detected.”[106]

## Physiology Related to the Sleep Environment That May Make Infants More Vulnerable to SIDS

Infants at increased risk for SIDS have been postulated and shown to have abnormal arousal, hypoxic drive, and airway protective reflexes, among other physiologic aberrations.[162,163] These abnormalities are reviewed below, and in light of the risk associated with prone sleep position.

### Arousal and Prone Positioning

Arousal during sleep is defined as full awakenings with eyes opened, or as a change to a different sleep stage by electroencephalogram (EEG) criteria, or by a constellation of EEG, electromyographic, and airflow changes. Arousal may be cortical as evidenced by obvious changes in EEG frequency, or imputed (subcortical arousal) from changes in autonomic measurements (e.g., changes in heart rate) or suppression of EEG sleep spindles.[164,165] Arousal has been assessed experimentally in response to airway obstruction[165–167] and central apnea,[166] breathing hypercarbic[168] or hypoxic gas mixtures,[169] laryngeal stimulation with fluid,[15,170] sound,[171] and jets of air hitting the face.[172] Changes in sleep state or awakening "may produce a fundamental change in the nature of the ventilatory response to a respiratory stimulus."[170] Arousal is often associated with the termination of obstructive apnea[167] and is the probable cause, at some level, of sleep fragmentation leading to daytime sleepiness with obstructive sleep apnea.

Although arousal may be essential to ending some threats to ventilation during sleep (see Fig. 80.5) in infants, the reliability of arousal from sleep in interrupting threats to sleep in risky environments is uncertain. For example, infants dying beneath bedclothes have often pulled them over their face, or moved beneath them.[173] Although these infants died while unobserved, it is conceivable that they suffocated while awake and not asleep, and that arousal played little role, except possibly to cause the awakening that got them into trouble in the first place. It has also been shown that the normal arousal sequence after having the nose and mouth covered—sigh, startle, arm thrashing, head lift, and turn—can actually worsen the infant's predicament within the sleep microenvironment, by pulling bedclothes farther over the head or by placing the infant face down into soft bedding.[100,174]

Arousal deficits also do not appear to explain gender differences in susceptibility to SIDS. Male infants are at greater risk for dying suddenly and unexpectedly, but their arousal thresholds to air jets are the same as females at 2–3 months of age, and actually lower at 2–4 weeks.[175] Thus, a consistent finding when infants die suddenly and unexpectedly, male preponderance, seems not to be explained by deficient arousal but may be explained by too brisk arousal. In this regard, it should be pointed out that arousal may foster excessive ventilatory compensation for transient underventilation. An "increased loop gain" in response to airway obstruction has been shown to increase respiratory pattern instability, and sustain rather than interrupt obstructive events.[59,176,177] Finally, as discussed above, infants may gain access to fresh air and end the threat to effective ventilation by subtle head (nose and mouth) repositioning without apparent awakening or EEG changes.[178]

In any event, whether or not an infant arouses to compromised ventilation, and how much ventilation is improved, or further compromised, as a result of movements or changes in breathing pattern during an arousal, may together define a developmental vulnerability for specific infants exposed to threats within their sleep environment.

## Soft Bedding and Learned Infant Behaviors as Effect Modifiers

Arousal and ventilatory responses to challenges may be less in prone than in supine sleeping infants. What gives rise to the "challenge" that must be responded to is suggested by studies of factors within the sleep environment that increase risk in the prone position. The epidemiologic findings and physiologic studies implicating rebreathing of exhaled air from near an infant's face have been spelled out in detail in the eighth edition of this text. It has been possible to show with mechanical and animal models and human infants that assuming the prone and face-down position on items of soft bedding can markedly increase $CO_2$ concentration and decrease $O_2$ concentration near the face of an infant so positioned.[103,109]

Waters and coworkers have also shown that this scenario occurs spontaneously.[100] In a study done using home recordings of $SpO_2$%, transcutaneous ($PCO_2$), respiratory effort, and videos, they showed that an infant sleeping prone, without adults present, assumed the face-down position on a mattress pad. Although the infant escaped this position, her $PtcCO_2$ rose from 50 to 87 mm Hg. The danger of such a scenario would be obvious for an otherwise healthy infant with blunted responses to hypoxemia or $CO_2$ concentration, or inefficient airway-protective behaviors.

It is also interesting to speculate about neurodevelopmental mechanisms for the very high risk of dying when infants who usually sleep supine are placed prone for the first time (see Fig. 80.5).[111] It is possible that infants who are usually placed prone learn to lift and turn their heads in order to gain access to fresh air. The cerebellum may have a role in learning this unconscious motor choreography. Some neurons in the cerebellum are known to respond to changes between real and anticipated sensory input and to modulate motor activity to respond to a changed environment with an unconscious change in motor activity.[116] Delayed cerebellar "motor learning" might be explained by brainstem findings implicating the medullary serotonergic system, which has multiple links to the cerebellum, including the inferior olivary nucleus.

In addition to preventing the ingress of fresh air, soft bedding, particularly comforters (duvets), provides much thermal insulation and has the potential to cause thermal stress.[179,180] What the mechanism or resultant cardiorespiratory abnormality due to thermal stress is, particularly beyond the first month of life, remains unknown. Infants do seem to be able to thermoregulate when exposed to environments that had been presumed to cause thermal stress,[120,121] and success with Back-to-Sleep occurred without reduction in thermal stress.[179,181,182] Furthermore, analysis of data from New Zealand, based on hypothetical models of SIDS infants' thermal environment, has shown that "Too little thermal insulation for the lower critical temperature was associated with an increased risk of SIDS…"[183]

## Bed Sharing and Racial Disparities

The epidemiologic evidence linking bed sharing to sudden unexpected infant death (SUID) is consistent and quite strong. Carpenter et al.[184] have outlined an argument for a causal association between bed sharing and SUID, using classic epidemiologic constructs.[185] The increased risk remains even when maternal smoking and alcohol use have been accounted for. Avoiding prone or side sleeping does not reduce SIDS risk when infants are bed sharing.[186,187] Higher rates of bed sharing and higher rates of SUID occur among both African Americans and Maori people from New Zealand. The most recent data from the United States National Infant Sleep Position Study, covering 1993–2000 and 2001–2010, show that the rates of bed sharing among white respondents increased during the earlier years but stayed the same for 2001–2010.[188] In contrast, rates of bed sharing among black and Hispanic respondents increased over both time periods. For whites, the rates rose from 4.9% in 1993 to 9.1% in 2010; for blacks, from 21.2% to 38.7%; and for Hispanics, from 12.5% to 20.5%. The impact of increased rates of bed sharing on the leveling off of the rates of all SUIDS is plausible but has not been quantified (see Fig. 80.7).

In a recent historical review based on over 60 years combined years of work on SIDS and SUID, Mitchell, from New Zealand, and Krous, from the United States, have concluded that the major risk factors for SUID are "maternal smoking and bed sharing and the major challenge is to implement effective strategies that will reduce the exposure to such risks as was done with prone sleeping position."[189]

In this regard, there are encouraging findings from New Zealand, where the decline in postneonatal mortality associated with nonprone sleeping had "plateaued" after 2000, as it had in the United States. A 2009 modification of their decades-old safe sleep program emphasized use among Maoris of a "wahakura, a bassinet-like portable infant Safe Sleeping Device, hand-woven from native flax that was designed to increase safety in the bed sharing environment," and, later, widespread use of a plastic infant sleeping surface (Pepi-Pod).[190] From 2009 through 2015, there was a 29% fall in postneonatal mortality in New Zealand that was most dramatic among the Maori people.

With respect to why babies die while bed sharing, in addition to increased risk for suffocation,[191] there is other evidence that might explain increased risk for sudden and unexpected death among infants sharing an adult bed. Careful studies of infants in their homes[120] comparing bed-sharing infants to those room sharing but in a separate crib ("cot") have shown that infants sharing a bed are exposed to an increased relative thermal stress, "requiring more vasodilatation to maintain core temperature." Baddock and colleagues also found that bed-sharing infants were more likely to sleep on their sides and less likely to be found supine, and much more likely to have their heads covered,[120,192] both factors that increase SIDS risk dramatically. Infants who bed shared also awoke more often. If they also had more spontaneous arousals, particularly with their heads covered, they might be more likely to experience the ventilatory instability discussed above, associated with desaturations and a dysfunctional arousal that did not gain access to fresh air.

## Summary

It was estimated in 1967, that in industrialized countries, 25,000 infants per year died suddenly and unexpectedly.[97] Most children who died suddenly and unexpectedly then and now did not have pathologic findings to explain their demise and, after 1967, their deaths were diagnosed as SIDS.[193] A triple-risk model can be used to explore explanations for sudden death: infant susceptibility, developmental vulnerability, and exogenous stressors of varying magnitude. Abnormalities in ventilatory control or reflexes and in behavioral or minute volume responses can usually be implicated. These abnormalities may be nonlethal when most infants sleep supine on their own sleep surface. Newer approaches to the pathology of cardiorespiratory control, lethal inherited dysrhythmias and energy metabolism, and continued emphasis on safe sleeping practices should lead to further reductions in the number of infants dying suddenly and unexpectedly each year.[194,195]

## Acknowledgments

The authors would like to acknowledge the substantial contribution to the science and understanding of sudden infant death syndrome provided by Dr. Bradley Thach, an author on previous versions of this chapter.

## Basic Mechanisms and Architecture of Normal Sleep

### Neural Circuitry of Sleep and Waking

Sleep is a global and dynamically regulated life-sustaining state, the control mechanisms of which are manifested at every level of biologic organization, from genes and intracellular mechanisms to networks of cell populations, and to all central neuronal systems at the organismal level, including those that control movement, arousal, autonomic functions, behavior, and cognition.[1–4] In mammals, sleep states can be readily differentiated into two major types, namely rapid eye movement (REM) and nonrapid eye movement (NREM) sleep. These two distinctive sleep states are defined in terms of their electroencephalographic (EEG) and electromyographic (EMG) characteristics. NREM sleep involves high-voltage, low-frequency "synchronized" wave activity with relatively preserved skeletal muscle tonic activity, whereas REM sleep is characterized by wakelike high-frequency, low-amplitude “desynchronized” activity in the EEG along with a typical attenuation of skeletal muscle tonic activity (i.e., REM atonia). Bursts of 12- to 14-Hz sleep spindles are characteristic of NREM sleep in adults and children, although such bursts may also occur during REM sleep; maximal development of phasic spindle activity emerges after approximately 16 weeks postnatally.

The neural sites underlying the onset, maintenance, and function of NREM and REM sleep continue to be the object of intensive research; however, sufficient insights are now available to link certain breathing patterns with the neural properties and activity patterns of state-related regulatory structures. Areas within the basal forebrain, including regions within the preoptic region, have long been implicated in initiating NREM sleep, with local stimulation eliciting the typical NREM sleep state and lesion studies resulting in pronounced loss of sleep. Single-cell studies assessing the discharge patterns of neurons within these neural regions conclusively demonstrate the existence of neurons that selectively fire with the onset of NREM sleep in this area. Certain features of NREM sleep, such as the large synchronous slow waves (delta waves) and bursts of 12- to 14-Hz sleep spindles, are critically dependent on the integrity of the thalamocortical circuitry, even if these characteristic neural activity patterns can be generated under certain pharmacologic conditions, such as subsequent to atropine administration during waking states. Furthermore, recent work has implicated adenosine and its cognate receptors as an important mechanism of NREM sleep regulation, such that this neurotransmitter is currently believed to regulate metabolic and recovery aspects of NREM sleep within the basal forebrain and thalamocortical regions.[5,6] It should also be stressed that thermoregulatory areas of the anterior hypothalamus closely interact with sleep-associated regions in the brain and dictate the generation of close relationships between warming, discharge of thermoregulatory neurons, and induction of sleep. Indeed, higher temperatures, whether externally applied or through localized warming of hypothalamic structures, will lead to increased sleepiness and NREM sleep duration.

Since the principal physiologic characteristics of REM sleep persist even after separation of the forebrain from the pons, it has been suggested that mechanisms underlying this unique sleep state lie caudal to the diencephalon within specific and spatially restricted brain stem regions such as the locus coeruleus and several pontine nuclei; notably, areas within the dorsal lateral pons have been particularly implicated in eliciting some of the characteristics of REM sleep state. For example, the atonia of REM sleep can be abolished by lesions in the dorsal pons, ventral to the locus coeruleus, and phasic somatic events can be terminated by lesions in the pedunculopontine tegmentum. Certain phasic elements, such as the variation of sympathetic and parasympathetic outflow during REM sleep, are dependent on the integrity of vestibular nuclei, while phasic eye movements, a hallmark of REM sleep, will persist even in the presence of lesions in the vestibular sites. A number of brain stem regions, namely the dorsal and caudal raphe, locus coeruleus, and ventral medullary surface, show declines in neural activity during REM sleep[7,8]; however, most of the brain will manifest substantial increases in neural cell activity and glucose consumption during REM sleep, sometimes exceeding levels seen during wakefulness. Brain regions that decrease their discharge patterns during REM sleep play important roles in blood pressure regulation; however, it is unclear whether the state-related cell patterns in these regions bear a relationship to blood pressure control (and indirectly to breathing patterns) during REM sleep.

## Developmental Aspects of Sleep

Sleep state organization undergoes rapid development during the first 6 months of life.[9,10] Neonates and young infants spend a disproportionate amount of time in REM sleep; indeed infants exhibit REM sleep at sleep onset, an event that is considered abnormal in the adult. NREM sleep (also termed quiet sleep) is poorly developed in newborns, since the slow oscillatory EEG patterns that define this state are not as readily apparent during early postnatal life and may manifest as intermittent slow and faster EEG patterns (e.g., tracé alternans). However, the relative amount of quiet sleep increases over the first 3 months of life, with K-complexes and sleep spindles becoming increasingly evident. Therefore scoring of sleep using adult criteria is not applicable before 3–6 months of age, and a more simplistic categorization of sleep states into awake, quiet sleep, active sleep (equivalent to REM sleep), and indeterminate sleep is usually used during the first year of life.[11–17] The total duration of sleep decreases relative to the 24-hour period, the relative proportion of NREM sleep increases, and that of REM sleep decreases with advancing age. At the age of 1 year, children will typically require 12–13 hours of sleep, primarily during the night, with one or two naps during the day.[18,19] At this age, well-defined NREM sleep alternates with REM sleep, the latter accounting for 30% of total sleep time in recurring 90-minute cycles very similar to those found in the adult. At approximately 2 years of age, the relative proportion of REM sleep will stabilize at approximately 20%–25% of total sleep time and will remain somewhat constant until old age, despite gradual reductions in total sleep duration with advancing age. NREM sleep acquires its maximal expression in duration and depth during the first decade of life. Indeed, the depth of sleep in childhood is quite remarkable considering how difficult it is to arouse a child during the first cycle of slow-wave sleep. During the second decade of life, slow-wave sleep gradually decreases by approximately 40%, continuing its gradual decline until old age. It is during slow-wave sleep that growth hormone is secreted in large amounts, and thus either sleep deprivation or disorders of sleep may interfere with the secretion and regulation of growth hormone, with potential and rather immediate clinical consequences.[20]

## Respiratory Control Mechanisms

Our understanding of respiratory control has undergone multiple evolutionary waves in the last century. Obviously, breathing is an important and vital function. Nevertheless, despite the critical functions of respiration, it is undeniable that the respiratory control system undergoes substantial maturation during the first few years of life. There is no doubt that the relative uncertainty about the anatomic and functional aspects pertaining to the neural respiratory pathways, the complexities of neuronal firing activities, the multitude of neurotransmitters within each brain stem nucleus, and the frequently nucleus-dependent opposing roles played by these neurotransmitters in respiratory function can be quite overwhelming and difficult to comprehend. Despite such problems, the field of respiratory control has evolved tremendously in recent years, and we are now witnessing the initial discovery of several of the genes that control the development and maturation of multiple neurally controlled respiratory functions.[21]

## The Respiratory Rhythm Generator

The putative neural center responsible for generation of respiratory rhythmic activity has now been identified,[22] and specific markers such as neurokinin and opioid receptors in these neurons have yielded estimates that this uniquely important neural center is a cluster of 150–200 neurons in the brain stem region designated as Pre-Botzinger complex.[23] This small number of rhythmically firing neurons appears both necessary and sufficient to generate most of the complex normal respiratory behaviors that we know such as eupnea, sigh, and gasping.[24–26] The development of several elegant models ranging from highly reductionistic (brain stem slice) to less reductionistic approaches (whole brain stem–heart-lung preparation) will undoubtedly permit extensive characterization of the network configuration responses, the functional neurotransmitters involved in generation of respiratory rhythm, and permit a thorough understanding of the electrophysiologic properties of these unique cells both during development as well as during disease. Several genes, such as PHOX2A, HOX paralogs, and HOX-regulating genes MAFB (formerly "Kreisler [mouse] maf-related leucine zipper homolog") and EGR2 (formerly Krox20), have been identified as important players in the embryonic generation of respiratory centers and their intrinsic connectivities.[27,28] These and other yet unknown genes that regulate the ontogeny of brain stem development may provide initial insights into the regulation of the initial phases involved in the normal and abnormal formation of the respiratory network.

## Sleep and Breathing During Development

The cyclic activity of respiratory rhythm generation is further modulated by suprapontine sites that include important efferent projections to areas mediating the sleep-wake cycle, thermoregulation, and circadian rhythm rhythmicity. Respiratory control areas also receive afferent inputs from central and peripheral chemoreceptors and from other receptors within the respiratory pump (upper airways, chest wall, and lungs). During fetal life, breathing is discontinuous and coincides with REM-like sleep. After birth, respiratory rhythm is established as a continuous activity to maintain cellular $O_2$ and $CO_2$ homeostasis. Respiratory pattern instability during sleep is typically present during early life such that short apneic episodes lasting less than 5 seconds are extremely common in preterm neonates, and their frequency is reduced in full-term newborns. These episodes occur predominantly during REM sleep as a result of the greater respiratory instability in this state. Several developmental differences between the neonate and the adult respiratory systems may further account for the emergence of sleep-associated disruption of normal gas exchange in early postnatal life, and include the following:

- Neonates have greater difficulty switching from the nasal to the oral route of breathing, and the majority of younger neonates can be considered as obligatory or near-obligatory nasal breathers.
- In neonates, reflexes originating in the upper airway (laryngeal chemoreflex) are potentiated and can induce profound apnea and bradycardia. This respiratory depressant component of the laryngeal chemoreflex decreases with maturation, such that prolonged apnea induced by stimulation of the laryngeal chemoreflex is more prominent in preterm than in full-term neonates.[29]
- The chest wall compliance is increased in neonates, thereby requiring dynamic, rather than passive, maintenance of the functional residual

capacity of the lungs. Furthermore, neonates have "barrel-shaped" rib cages, and the rib cage contribution to tidal breathing is smaller than in older children and adults. Thus, any condition whereby the ability to maintain functional residual capacity is compromised, as in REM sleep, will lead to increased susceptibility.

- Paradoxical breathing (i.e., asynchronous or out-of-phase motion of the chest and abdomen), especially during REM sleep, is common in newborns because of uncoordinated interactions between chest and abdominal respiratory musculature. The duration of paradoxical breathing during sleep decreases as postnatal age increases. Paradoxical breathing is rare or absent after 3 years of age.[30]
- The respiratory rate is high in the neonatal period and decreases during infancy and early childhood. Respiratory rate decreases exponentially with increasing body weight and parallels changes in overall metabolic rates. Notably, respiratory rate is higher during REM sleep than it is in NREM sleep.
- Apneas of short duration (less than 10 seconds) are extremely common during the early period of life. Apneic episodes are more frequent in REM sleep than during NREM sleep. Apneic episodes are mostly central and will decrease in number with advancing postnatal age. Obstructive and mixed apneic episodes are more frequently seen in

preterm than in full-term neonates, possibly reflecting developmental changes in pharyngeal, laryngeal, and central airway collapsibility.

- Periodic breathing, defined as three episodes of apnea lasting longer than 3 seconds and separated by continued respiration over a period of 20 seconds or less, is a common respiratory pattern in preterm neonates, and may also be highly prevalent in full-term newborns.[31,32] However, periodic breathing decreases in frequency during the first year of life and is usually not considered to be of any specific pathologic significance. Notwithstanding such considerations, environmental variables such as sleep state transitions, arousals, hypoxia, and hyperthermia can enhance the frequency and magnitude of periodic breathing in newborns, and ultimately lead to destabilization of cardiorespiratory homeostasis.
- Apneic episodes during sleep in neonates are associated with a fall in heart rate, particularly during NREM sleep. The presence of hypoxemia will enhance this reflex bradycardia during apnea.
- Arousal from sleep is thought to be a major determinant for termination of apnea, and therefore arousal deficits have been implicated in the pathophysiology of the sudden infant death syndrome (SIDS). However, fewer than 10% of apneic episodes will be terminated by a full-fledged EEG arousal in neonates. Autonomic

arousals are nevertheless quite frequent during the period surrounding the termination of an apneic event. Moreover, while hypercapnia is a potent stimulus of arousal, hypoxia, and particularly rapidly developing hypoxia, is much less effective in inducing arousal. Finally, prone position, sleep deprivation, and prenatal-postnatal exposure to cigarette smoking are all accompanied by decreased arousability in neonates.

- Healthy full-term newborns will usually maintain oxyhemoglobin saturation values of 92%–100% during sleep in the first 4 weeks of life. Arterial blood $O_2$ levels are lowest during the first week of life and increase over the next 1–3 months, such that all newborns will have values of 97%–100% after the age of 2 months. Basal values for arterial $CO_2$ tension during sleep are generally between 36 and 42 mm Hg in newborns and infants.

As delineated earlier, the implications of REM sleep on breathing are substantial, and as discussed later, the loss of muscle tone during REM sleep is particularly important to the upper airway muscles and airway patency. An important aspect of breathing control is the close interaction of breathing and blood pressure regulation. The respiratory system, using primarily somatic musculature, exerts substantial influence on moment-to-moment blood pressure; conversely, transient elevation of blood pressure can inhibit breathing efforts, while lowering of blood pressure can increase them. The interactions between the systems can be observed readily in breathing influences on heart rate (a classic example being respiratory sinus arrhythmia). Inspiratory efforts normally are associated with accelerated heart rate and expiratory efforts with deceleration, the result of reflex activity from pulmonary afferents and vagal outflow; the resulting coupling between breathing and heart rate is particularly prominent during NREM sleep, and measures of the interaction can provide a useful indication of state.[33] In addition, phasic activity during REM sleep induces substantial parasympathetic and sympathetic outflow, resulting in larger but typically slower variation in heart rate. Plots of cardiac beat-to-beat intervals demonstrate the substantial influences exerted normally during each state, with NREM sleep exerting a highly cyclic effect on heart-rate variation and REM sleep showing less modulation by breathing but larger slower sources of variation. Waking shows a large variation in heart-rate changes; typically very active periods are accompanied by high heart rates with little variation. The cyclic nature of cardiac rate variation has led to a variety of procedures to measure the sympathetic and parasympathetic influences. Particular syndromes exert unique patterns of respiration-related variation; for example, children with congenital central hypoventilation syndrome (CCHS) show a relative absence of variation of respiratory modulation of heart rate, and infants who later succumb to SIDS also show reduced variation to breathing.

## Central Chemoreceptors and Their Development

The chemoreflexes exert powerful influences over breathing as well as cardiac and vascular control. Chemoreflex physiology is complex, and the exact molecular mechanisms by which the chemoreflexes are activated remain unclear. The traditional and classic theory formulated during the late 1950s proposed that the central chemoreceptors were located in the ventrolateral medullary surface of the brain stem and responded to hypercapnia and pH changes, whereas the peripheral chemoreceptors were located in the carotid bodies and primarily responded to changes in blood $O_2$ tension. While this concept has now evolved (see later), it is worthwhile to mention that hypercapnia (particularly transient changes in $CO_2$ tension above the apneic threshold) can also activate the peripheral chemoreceptors, and may account for as much as one-third of peripheral chemoreceptor activity. Activation of either central or peripheral chemoreflexes exerts powerful effects on sympathetic activity in both health and disease and may be an important contributor to pathophysiology of obstructive sleep apnea (OSA)-induced morbidities.

## Multiplicity of Central Chemosensitive Centers

A critically important advance in the field of respiratory control involved discarding the classic concept of central chemosensitive sites as being located in restricted areas of the ventral medullary surface. Indeed, several lines of evidence have now clearly established that neurons showing intrinsic chemosensitive properties (i.e., the ability to sense changes in extracellular pH and contribute to the ventilatory response) are diffusely located in the central nervous system, and that regions such as the posterior hypothalamus, cerebellum, locus coeruleus, raphé, and multiple nuclei within the brain stem all contribute to the well-characterized hypercapnic ventilatory response.[34–36] Why is this important? One reason is that the phenotypic manifestations of conditions such as central alveolar hypoventilation, particularly when occurring secondary to other disorders (e.g., myelomeningocele, tumors, stroke) are not adequately explained by either the location or the magnitude of the brain lesions in these patients. Second, it is very possible that the normal developmental processes of the ventilatory response to elevations of $CO_2$ are not only important to long-term stability of the homeostatic system but may be even more important to the preservation of respiratory stability during respiratory transients, particularly during sleep. Conditions such as apparent life-threatening events or even SIDS may originate from dysfunctional development of either the respiratory rhythm controllers or, alternatively, that of the neural networks underlying hypoxic and hypercapnic chemosensitivities as well as those mediating arousal from sleep.[37,38]

The neurotransmitters involved in the intrinsic sensory pathways associated with central chemoreception are currently incompletely defined, although serotoninergic pathways are clearly involved.[39–42] The presence of cholinergic muscarinic receptors in those brain stem areas traditionally associated with $CO_2$ chemosensitivity appears to play a major role in the neuronal excitation associated with the enhanced ventilatory response to hypercapnia, although additional neurotransmitters are also clearly involved. It must be emphasized that the central $CO_2$ chemosensory mechanisms may not be fully functional or mature at birth. Indeed, animal models in various species show that hypercapnic ventilatory responses will increase with advancing age. Hypercapnia elicits a relatively sustained ventilatory increase in term infants that is almost entirely due to an increase in tidal volume without consistent change in respiratory frequency. In contrast, the ventilatory response to hypercapnia in premature infants is attenuated and can even become inhibitory at higher concentrations of inhaled $CO_2$, with $CO_2$ overall respiratory responses increasing with postconceptional age. In preterm neonates, the ventilatory increase to hypercapnia is accompanied by a progressive increase in expiratory duration and a consequent reduction in frequency over time, both of which appear to be associated with diaphragmatic recruitment during expiration (respiratory braking or grunting). This unique mechanism appears to preserve a high-end expiratory lung volume such as to optimize gas exchange and promote respiratory stability. Little is known about the development of central chemoreceptor function beyond infancy. In awake prepubertal children there appears to be an enhanced ventilatory response to hypercapnia compared with adults, and these differences may underlie differences in metabolic rate.[43] Similarly, significant developmental differences in $CO_2$ responses emerge when the $CO_2$ stimulus is presented in either a step (sudden increase) or ramp (slow progressive increase) fashion.[44] These findings in older children suggest that at some time during transition from infancy to childhood and on to adulthood, major changes occur in the relative contributions and integration of peripheral and central chemoreceptor activity. The cascades of genes, receptors, and neurotransmitters that mediate these developmental changes are unknown at the present time. Similarly, the elements involved in the integrated coordination of the developmental changes at the level of the carotid body, neural transmission, or central nervous system remain unclear.

## Peripheral Chemoreflexes

The ventilatory responses related to changes in blood $O_2$ levels are a complex interaction of a variety of peripheral and central responses. Nevertheless, the rapidity of the peripheral chemoreceptor responses to blood oxygenation changes allows for assessment of the initial stimulatory effect elicited by activation of these peripherally located chemosensory cells, of which the most important are glomus cells within the carotid bodies.[45] Peripheral chemoreceptor activity is typically assessed by monitoring the fast transient increase in minute ventilation after inhalation of gases containing low concentrations of $O_2$. Isocapnic hypoxic responses (over a period of 2–3 minutes) or five tidal breaths of pure $N_2$ are among the strategies that have been used.[46–48] Alternatively, the ventilatory decline subsequent to inhalation of 100% $O_2$ is also considered as a reliable indicator of peripheral chemoreceptor gain (Dejours test). However, it is important to indicate that the ventilatory decrease to acute hyperoxia is ultimately followed by an increase in ventilation that is centrally mediated.[49] More sophisticated paradigms using random alternations of $N_2$ and $O_2$ in a computerized setting have recently permitted the development of reproducible and consistent findings in infants and children suspected to be at risk for chemoreceptor dysfunction.[50–53] Independent of the test selected, substantial attention to sleep state is required when assessing respiratory chemoreceptor drive in infants and in the interpretation of such tests, so these tests are best reserved for specialized laboratories, in which specific normative values have been developed, and therefore allow for more reliable clinical assessment of individual patients presenting with symptoms suggestive of chemosensory dysfunction.

A typical phenomenon associated with more sustained exposure to hypoxic gas mixtures is the emergence of a relative ventilatory decline after 5–6 minutes of hypoxic exposure. This hypoxic ventilatory decline has also been termed hypoxic ventilatory roll-off. The phenomenon is particularly prominent during infancy, such that with sustained hypoxia in neonates there is a well-characterized increase in breathing followed by a reduction in ventilation that will usually reach levels below normoxic breathing.

In more mature children and in adults, the reduction in ventilation will usually reach levels that are below peak but still higher than the ventilation measured during baseline, room-air breathing. A study of premature neonates showed that this biphasic response will persist into the second month of postnatal life, but this only represented a postconceptional age of about 35 weeks.[54] Even term neonates may retain the biphasic response for at least 2 months when tested with normal bedding at room temperature of 24°C during NREM sleep. In addition, very small preterm neonates may show only a decrease in ventilation with hypoxia. The apparent differences between preterm and term neonates may be partially accounted for by developmental status in relation to postnatal age; indeed, premature but not term lambs or piglets also exhibit an attenuated hypercapnic response. Thus, prematurity and factors delaying normal maturation emerge as important contributors to the attenuated hypercapnic and hypoxic responses in newborns.

Studies suggest that a relatively high ventilatory drive exists during wakefulness in children, and that this drive decreases during adolescence and stabilizes during adulthood; the reason for this transition is currently unknown. Marcus and colleagues[43] studied hypercapnic and hypoxic ventilatory responses in a group of subjects aged 4–49 years and found significant correlations between both the awake hypercapnic and hypoxic ventilatory responses when corrected for age and body size.

# The Upper Airway

## Upper Airway Control

Since both snoring and OSA are opposite ends of a spectrum of increased upper airway resistance, it is important to review the anatomic and physiologic mechanisms that underlie the maintenance of upper airway patency during sleep.[55] The upper airway comprises the nose, pharynx, larynx, and extrathoracic trachea, and is designed for vocalization, ingestion, airway protection, and respiration. Maintenance of a rigid and patent upper airway is mandatory for achieving adequate respiration and is the result of a balance between forces that promote airway closure and dilatation. Thus, the inherent collapsibility of the pharynx predisposes to impaired respiration when the regulation of the pharyngeal muscles is impaired, such as may occur during sleep.

Anatomically, it is clear that a smaller cross-sectional area of the upper airway is associated with decreased ability to maintain upper-airway patency, and in adults the upper airway behaves as predicted by the Starling resistor model, a model that has been well-characterized in biologic systems. This model describes the major determinants of airflow in terms of the mechanical properties of collapsible tubes and predicts that, under conditions of flow limitation, maximal inspiratory flow will be determined by the pressure changes upstream (nasal) to a collapsible site of the upper airway, and flow will be independent of downstream (tracheal) pressure generated by the diaphragm. Collapse occurs when the pressure surrounding the collapsible segment of the upper airway becomes greater than the pressure within the collapsible segment of the airway. Pressures at which collapse of the airway occurs have been termed critical closing pressure ($P_{crit}$).[56,57] In normal subjects with low upstream resistance, pressures downstream never approach $P_{crit}$ and airflow is not limited. This model explains why snoring and obstructive apnea worsen during a common cold (increased nasal upstream resistance). Marcus and colleagues[58] further demonstrated the validity of this model in children and found that the upper airway collapsibility in children is reduced compared with the adult. Notably, and as predicted by the Starling model, the collapsible segment of the upper airway in children displayed less negative (higher and thus more collapsible) pressures in children with OSA. It follows that components that affect the upstream segment pressures or increase $P_{crit}$ will be of major consequence to the ability to maintain airway patency. Generally speaking, the smaller the cross-sectional area of the upper airway, the higher the upper airway collapsibility will be, because the upper airway behaves as a collapsible tube, such that increased inspiratory efforts may induce enhanced collapse of the airway rather than generate the desired increases in inspiratory flow.[58] Accordingly, it is not surprising that both snoring and obstructive apnea may worsen during a common cold (i.e., increased nasal upstream resistance), which provokes more inspiratory effort. In addition, tube law dictates that the longer the airway is, the more collapsible it is.[59,60] The contribution of the various anatomic nasopharyngeal structures to $P_{crit}$ and the interactions between these structures that will lead to upper airway patency or obstruction during sleep are thus of clear importance in increasing our understanding of the pathophysiology of childhood OSA.

Although the overall ventilatory drive appears to be normal in children with OSA, it is possible that central augmentation of upper airway neuromotor function is abnormal. During sleep, upper airway tone is diminished even though the same structural factors are present during wake and sleep, and OSA occurs only during sleep. It is unknown whether children with OSA become obstructed because of a relatively larger decrease in airway tone during sleep in comparison to controls, or whether the decrease in tone is similar but subjects with OSA have an increased structural load. The upper airway muscles are accessory muscles of respiration and, as such, are activated by stimuli such as hypoxemia, hypercapnia, and upper airway subatmospheric pressure. Previous studies have shown that, when upper airway muscle function is decreased or absent, as in postmortem preparations, the airway is prone to collapse.[61] Conversely, stimulation of the upper airway muscles with hypercapnia[62,63] or electrical stimulation[64] results in decreased collapsibility. These studies confirm that the tendency of the upper airway to collapse is inversely related to the level of activity of the upper airway dilator muscles. Therefore increased upper airway neuromotor tone may be one way that patients can compensate for a narrow upper airway. Indeed, this has been shown in adults. Mezzanotte and colleagues demonstrated that adult patients with OSA compensated for their narrow upper airway during wakefulness by increasing their upper airway muscle tone.[65] This compensatory mechanism was lost during sleep.[66] Recent studies in children have shown that children with OSA have greater genioglossal EMG activity during the awake state than control children and a greater decline in EMG activity during sleep onset.[66] Furthermore, upper airway dynamic responses are decreased in children with OSA but appear to recover after treatment.[67,68] Thus, pharyngeal airway neuromotor responses are present in normal children and serve as a compensatory response for a relatively narrow upper airway compared with adults. However, this compensatory neuromotor response is reduced or even lacking in children with OSA, probably as a result of habituation to chronic respiratory abnormalities during sleep, mechanical damage to the upper airway, or genetically determined differences in these upper airway protective reflexes.[69–72]

Ventilatory control in patients with OSA is the subject of intense study. In adults with OSA, it is suggested that there is a high-gain ventilatory control system that results in ventilatory instability and apnea.[73] However, studies in children have shown overall normal ventilatory responses to hypoxia and hypercapnia during wakefulness and during sleep when using standard tests.[43,44,74] Indeed, ventilatory responses to rebreathing hyperoxic hypercapnia were measured in 20 children and adolescents with OSA, and the mean slopes of the hypercapnic response were similar to those measured in age- and sex-matched controls.[75] Furthermore, no differences were found in the slopes calculated from plotting minute ventilation against $O_2$ saturation during isocapnic hypoxia. Nevertheless, other investigators have found some degree of blunting in central chemosensitivity of children with OSA undergoing surgery.[76,77] Despite such findings, central chemosensitivity during sleep was similar in children with OSA and matched controls. However, arousal to acutely induced hypercapnia was blunted during sleep in children with OSA, suggesting that subtle alterations in the central chemosensitive-arousal network have occurred in these patients. These subtle changes have been further substantiated by examination of the ventilatory responses to repetitive hypercapnic challenges during wakefulness, whereby reciprocal changes in respiratory frequency and tidal volume do occur.[78] In the study by Gozal and colleagues,[79] repeated $CO_2$ challenges were given in the early morning to children with OSA who were hypercapnic (as a result of obstructive alveolar hypoventilation) during sleep. These children showed a respiratory response to the $CO_2$ challenge but did not show the same adaptive changes in respiratory pattern that would be anticipated over the course of several $CO_2$ challenges as elicited from children without OSA. However, when children with OSA were studied later in the day (i.e., a few hours after awakening and resolution of sleep-associated alveolar hypoventilation) or after treatment of OSA, a similar respiratory pattern to that seen in controls emerged, suggesting that such deficits may be related to habituation to nocturnal episodic hypercapnia. Additional evidence in support of this comes from Marcus and colleagues,[43] who found an inverse correlation between the duration of hypercapnia during the night and the awake hypercapnic ventilatory responses. In addition, children with OSA demonstrate impaired arousal responses to inspiratory loads during REM and non-REM sleep compared with control children.[61] This arousal threshold was particularly high during REM sleep, a time when most obstructive apneic events occur, and suggests that neuromotor influences play a key role. The absence or delayed arousal in children during an obstructive respiratory event and the presumed lack of ventilatory compensation to upper airway loading may contribute to the development of the prolonged periods of obstructive alveolar hypoventilation that uniquely characterize OSA in children. Furthermore, diminished laryngeal reflexes to mechanoreceptor and chemoreceptor stimulation with reduced afferent inputs into central neural regions underlying inspiratory inputs could be present. For example, chemoreceptor stimuli such as increased $\mathrm{Pa}\mathrm{CO}_2$ or decreased $\mathrm{Pa}\mathrm{O}_2$ stimulate the airway dilating muscles in a preferential mode; that is, upper airway musculature is more stimulated than the diaphragm.[80,81] This preferential recruitment tends to correct an imbalance of forces acting on the airway and therefore maintain airway patency. Similarly, stimuli resulting from suction pressures in the nose, pharynx, or larynx rapidly stimulate the activity of upper airway dilators, and this effect is also preferential to the upper airway, causing some degree of diaphragmatic inhibition and thus compensating for increase in upstream resistance. The function of these upper airway receptors in children with adenotonsillar hypertrophy with and without OSA is currently unknown.

While dynamic factors such as those just discussed have been implicated in the pathophysiology of upper airway obstruction during sleep in children, we should not omit the contribution of either anatomic elements or genetic factors to this complex equation. In otherwise normal children, Arens and colleagues have shown that the mandibular dimensions of children with OSA are similar to those of controls.[82] However, regional analysis of the upper airway using magnetic resonance imaging techniques further suggested that the upper airway in children with OSA is most restricted where adenoids and tonsils overlap. Furthermore, the upper airway is narrowed throughout the initial two-thirds of its length in pediatric patients with OSA, and this narrowing is not in a discrete region adjacent to either the adenoids or tonsils, but rather emerges in a continuous fashion along both lymphadenoid structures.[83,84] It should be emphasized that, contrary to the previous conceptual framework whereby the higher prevalence of OSA in children during the age period from 2 to 8 years was attributed to the increased growth rate of lymphadenoid tissue within the upper airway compared with other upper airway structures,[85,86] recent evidence refutes this concept. It shows that all tissues within the upper airway including adenoids and tonsils grow proportionally and thus that stimuli leading to enhanced proliferation of lymphadenoid tissues within the airway are probably implicated in the pathophysiology of OSA.[87,88] In fact, recent evidence has further indicated that the extent of lymphadenoid proliferation is not confined to the adenoids and tonsils, and in fact encompasses the full length of the upper airway including the nose and sinuses, suggesting that OSA is a diffuse disease of the upper airway.[89] Recent exploration of upper airway characteristics in obese children provided further confirmation on the integrated roles of the upper airway structures and their estimated contributions to the upper airway flow characteristics, thereby enabling prediction of risk for OSA when applying computational fluid dynamic approaches to MRI or CT images of the airways.[90–94]

## Upper Airway Dysfunction

In infancy, abnormalities that reduce the patency of the upper airway are frequently associated with OSA. The upper airway has decreased muscle tone, there is high nasal resistance, and the chest wall is highly compliant. The exact prevalence of OSA in infants is not well documented, since most epidemiologic studies have thus far concentrated on older children. However, OSA has been shown to occur in as many as 10% of infants, is more frequent in preterm infants, and is associated with hypoxemia. OSA may occur more frequently in male infants than in females, and this may be attributable to sex-related differences in the anatomy of the upper airway than to a protective role of female hormones.[95] The main risk factors for OSA in this age group include: (1) craniofacial abnormalities (e.g., micrognathia, cleft palate, Pierre Robin syndrome, Treacher Collins syndrome, choanal atresia, mucopolysaccharidoses, Down syndrome); (2) soft tissue infiltration, which may result from infection, inflammation, laryngomalacia, subglottic stenosis, and adenotonsillar hypertrophy. Indeed, adenotonsillar hyperplasia or hypertrophy has been found to contribute significantly to the generation of OSA in infants younger than 1 year old[96,97]; (3) neurologic disorders that induce pharyngeal hypotonia, such as Arnold-Chiari malformation, cerebral palsy, and poliomyelitis, are also associated with an increased risk for obstructed breathing. Although the anatomic site of obstruction in infants is widely believed to be the retroglossal region,[98] evidence using magnetic resonance imaging and airway manometry suggests that upper airway obstruction with clinically significant OSA occurs in the retropalatal region 80% of the time and only 20% of the time in the retroglossal region.[99] Other influences may alter breathing characteristics and predispose infants to OSA, including upper airway reflexes such as the laryngeal chemoreflex. This unique defense reflex that aims to prevent aspiration of food is enhanced by upper airway infection, and indeed, respiratory syncytial virus infection, which potentiates the laryngeal chemoreflex, has also been shown to facilitate the occurrence of both central and obstructive apneic episodes.[100] Similarly, prenatal exposure to maternal smoking, which potentiates the laryngeal chemoreflex, also increases the frequency of OSA in infants.[101,102]

To determine the region of maximal airway narrowing in children with OSA, the static pressure/area relationships of the passive pharynx were endoscopically measured in 14 children with

OSA and 13 normal children under general anesthesia with complete paralysis.[103,104] The minimum cross-sectional area was found to be at the level of the adenoid and the soft palate. Thus, children with OSA closed their airways at the level of enlarged tonsils and adenoids at low positive pressures, whereas normal children required subatmospheric pressures to induce upper airway closure. The cross-sectional area of the narrowest segment was significantly smaller in children with OSA, and particularly involved the retropalatal and retroglossal segments, such that it becomes clear that anatomic factors, both congenital and acquired, play a significant role in the pathogenesis of pediatric OSA.[105,106] For these reasons, use of endoscopic approaches is increasingly being adopted in the clinical evaluation of OSA or residual OSA after treatment.[107–110] Furthermore, as mentioned earlier, airway narrowing in children with OSA occurs along the upper two-thirds of the airway and is maximal where the adenoids and tonsils overlap.[83,111]

In summary, several potential mechanisms have been identified in the maintenance of upper airway patency during sleep and wakefulness. Each of these mechanisms or a combination thereof probably plays a role in the causation of respiratory compromise in the normal child during sleep and in children with clinical problems that predispose to OSA. A systematic approach to identification and modification of these mechanisms should lead to improved therapeutic approaches and reduction of unnecessary morbidities in these patients.

# Apnea

## Central Apnea or Hypoventilation Syndromes

Unrelated to upper airway obstruction, insufficient central respiratory drive can also be a cause of hypoventilation. The presence of a hypoventilation syndrome is suggested by the medical history as well as examination of the patient during wakefulness and sleep. All disorders that could explain the hypoventilation must be excluded, and to confirm the diagnosis, a polysomnographic evaluation, including measurements of tidal volume, should be conducted. The measurement of spontaneous resting tidal volumes and noninvasive blood gas values across all sleep states should be sufficient to establish the presence and severity of alveolar hypoventilation. The most important objective finding is the inability to increase respiratory frequency, tidal volume, or both, regardless of the severity of the progressive asphyxia that occurs.

## Congenital Central Hypoventilation Syndrome

Central hypoventilation syndromes can be primary (congenital CHS [CCHS] and late-onset CHS) or secondary (Box 81.1). Primary CCHS is a relatively rare genetic disorder, yet it is being increasingly recognized around the world. It was originally described in 1970 by Mellins and colleagues[112] and is traditionally defined as the idiopathic failure of automatic control of breathing.[113,114] The classic presentation of CCHS is a life-threatening disorder primarily manifesting as sleep-associated respiratory insufficiency and markedly impaired ventilatory responses to hypercapnia and hypoxemia very shortly after birth.[115] Ventilation is most severely affected during quiet sleep, a state during which automatic neural control is predominant. Abnormal respiratory patterns also occur during active sleep and even during wakefulness, though to a milder degree. The spectrum of disease in CCHS cases is wide, ranging from relatively mild hypoventilation during quiet sleep with fairly good alveolar ventilation during wakefulness to complete apnea during sleep with severe hypoventilation when awake. Progress in the recognition and clinical management of CCHS patients has revealed the presence of broader structural and functional impairments of the autonomic nervous system.[116–118] In particular, Hirschsprung disease[116] and tumors of autonomic neural crest derivatives such as neuroblastoma, ganglioneuroblastoma, and ganglioneuroma[118,119] are noted in 20% and in 5%–10% of CCHS patients, respectively. Several major clinically relevant advances have undoubtedly advanced our understanding of the pathophysiology and treatment of CCHS: (1) the identification of the putative gene underlying CCHS; (2) the functional assessment of neural structures in patients with CCHS to provide insights into the respiratory and autonomic disturbances that characterize the syndrome[120]; (3) the successful transition of many patients to noninvasive ventilatory support; and (4) the publication of a consensus statement on the diagnosis and management of this condition.[121]

**Box 81.1**

## Causes of Central Hypoventilation in Children

### Primary

- Congenital (CCHS/Ondine's curse)
- Late-onset CHS
- Idiopathic hypothalamic dysfunction
- Arnold-Chiari malformation

### Secondary

- Trauma
- Infection
- Tumor
- Central nervous system infarct
- Asphyxia
- Increased intracranial pressure
- Metabolic

*CCHS*, Congenital central hypoventilation syndrome.

A genetic origin was originally hypothesized for CCHS because of (1) its manifestation in the newborn period; (2) published reports of familial recurrence of CCHS, including cases of monozygotic female twins, female siblings, and male-female half-siblings[122,123]; and (3) its association with Hirschsprung disease, an autosomal-recessive disorder of neural crest origin.[124] Furthermore, a genetic segregation analysis among families of 50 probands with CCHS also indicated that CCHS was consistent with familial transmission.[125] Importantly, vertical transmission of CCHS was also reported, and among infants born to women with CCHS without Hirschsprung disease.[126,127] The association of CCHS and Hirschsprung disease suggested that both disorders may be related to abnormal development or migration of the neural crest cells; indeed, mutations of genes (e.g., the RET proto-oncogene) that are involved in neural crest development and migration have been found in patients with Hirschsprung disease.[127–129] The putative gene, pairedlike homeobox 2B (PHOX2B), underlying CCHS was ultimately discovered in 2003 by Amiel and colleagues in France.[130] The PHOX2B gene mutation, consisting primarily of increased polyalanine expansions, manifests an autosomal-dominant mode of inheritance and *de novo* mutations at the first generation. This gene is critical for embryologic development of the autonomic nervous system, and Phox2b$^{-/-}$ mice die *in utero* with absent autonomic nervous system circuits, since neurons either fail to form or degenerate.[131–134] Furthermore, selective stimulation of Phox2b neurons in specific regions of the brainstem elicits the anticipated respiratory and cardiovascular responses,[135–137] and targeted disruption of Phox2b in brainstem neurons leads to alterations in Task2 potassium channels, which are believed to be the main effectors in central chemoception.[138] Accordingly, heterozygous mutations of PHOX2B may account for several combined or isolated disorders of autonomic nervous system development, namely late-onset CHS,[139] Hirschsprung disease,[140] and tumors of the sympathetic nervous system such as neuroblastoma.[141] The identification of PHOX2B mutations in most patients with CCHS is an important landmark in the pursuit of the pathophysiologic mechanisms of this condition. Furthermore, the finding of *de novo* PHOX2B polyalanine expansions in the majority of patients with CCHS along with improved delineation of other mutations allows for accurate genetic counseling in a disease with an unexpected autosomal-dominant mode of inheritance.[142] The prevalence of SIDS is high in CCHS families, suggesting that these two disorders may share developmental breathing control abnormalities in a subset of

SIDS cases.[143]

Taken together, the genetic data strongly suggest a diffuse alteration in autonomic nervous system function in patients with CCHS. This concept includes major disruption of multiple brain regions underlying autonomic functions, in particular those sites mediating respiratory, cardiovascular, and thermal regulation,[144] as evidenced from recent studies using functional magnetic resonance imaging.[145–151] Decreased heart rate beat-to-beat variability is consistently found in Holter recordings, and the circadian patterning of such variability further suggests an imbalance in sympathetic/parasympathetic regulation in patients with CCHS.[152–155] As additional testament to such an assumption, alterations in blood pressure regulation during simple daily maneuvers or during sleep further support the presence of predominantly vagal dysfunction with signs of vagal withdrawal and baroreflex failure, and relative preservation of the cardiac and vascular sympathetic function.[156–158] In addition, the frequent neuro-ocular findings in children with CCHS[159] and the marked reduction in the size of arterial chemoreceptors, carotid bodies, and neuroepithelial bodies with decreased staining for tyrosine hydroxylase and serotonin[160] can all be construed as evidence for a more diffuse autonomic nervous system involvement. Putative models aiming to dissect the specific contributions of the various components of cardiorespiratory control have been recently proposed and provide a comprehensive and structured approach to the evaluation of patients with CCHS.[161]

## Diagnosis and Clinical Management

The clinical presentation of CCHS varies greatly depending on the severity of the disorder. Some infants will not breathe at birth and will require assisted ventilation in the newborn nursery. Such infants may mature to a pattern of adequate breathing during wakefulness over time. However, apnea or hypoventilation will persist during sleep. The apparent improvement over the first few months of life most likely results from normal maturation of the respiratory system and does not represent a true change in the severity of the disorder.[162] Other infants may present at a later age with cyanosis, edema, and signs of right-sided heart failure and may be mistaken for patients with cyanotic congenital heart disease (Box 81.2). However, cardiac catheterization reveals only pulmonary hypertension. Infants with even less severe CCHS may present with tachycardia, diaphoresis, and/or cyanosis during sleep, and others may present with unexplained apnea or an apparent life-threatening event. Thus, the wide spectrum of severity in clinical manifestations determines the age at which recognition of CCHS takes place. Increased awareness of this unusual clinical entity and a comprehensive evaluation of every patient are critical for early diagnosis and appropriate intervention.

**Box 81.2**

### Conditions Associated With Apnea in Infants

- Prematurity
- Infection
- Impaired oxygenation
- Central nervous system problems (intracranial hemorrhage, asphyxic episode, malformation of the brain)
- Gastroesophageal reflux
- Metabolic disorders (hypoglycemia, electrolyte imbalance, fatty acid disorders, metabolic acidosis)
- Temperature instability (hyperthermia, hypothermia)
- Drugs (e.g., narcotics, anticonvulsants)

Although other symptoms indicative of brain stem or autonomic nervous system dysfunction may be present, the criteria for diagnosis of CCHS usually include: (1) persistent evidence of sleep hypoventilation ($PaCO_2$ >60 mm Hg), particularly during quiet sleep (best achieved by overnight polysomnography); (2) presentation of symptoms during the first year of life; and (3) absence of cardiac, pulmonary, or neuromuscular dysfunction that could explain the hypoventilation.[121] Hypercapnic ventilatory challenges are an important component for the diagnosis of CCHS. Steady-state or rebreathing incremental $CO_2$ challenges are similarly valid and will usually reveal an absent or near-absent response.[163] Confounding issues, including asphyxia, infection, trauma, tumor, and infarction, must be distinguished from CCHS by appropriate assessments. Specific guidelines regarding the use of genetic testing for CCHS and other diagnostic considerations have now become available, and should be implemented.[121] Identification of mutations in genes such as RET, HASH, BDNF, GDNF, and the endothelin gene family may be helpful when the phenotype is atypical, but assessment of PHOX2B gene mutations in the context of clinical manifestations supporting central alveolar hypoventilation should be carried out to support the diagnosis of CCHS.[121,164,165]

Congenital CHS is a lifelong condition and, depending on the severity of clinical manifestations, patients may require ventilatory support while asleep or as much as 24 hours a day. As such, a multidisciplinary approach to provide for comprehensive care and support of the child is needed. The treatment of CCHS should aim to ensure adequate ventilation when the patient is unable to achieve adequate gas exchange while breathing spontaneously. Since CCHS does not resolve spontaneously, chronic ventilatory support is required, such as positive pressure ventilation, bilevel positive airway pressure, or negative pressure ventilation. The majority of children with CCHS use positive pressure ventilation through a permanent tracheotomy, although successful transition to noninvasive ventilation has now been extensively reported,[113] with a trend toward earlier intervention (sometimes even during infancy) and more widespread transition to noninvasive ventilation (typically mask ventilation).[166–172] Several families have opted to use negative pressure ventilation. Daytime diaphragm pacing in children with CCHS who exhibit 24-hour mechanical ventilation dependency provides greater mobility compared with mechanical ventilation. Thus, potential candidates for diaphragm pacing will be ambulatory patients who require ventilatory support 24 hours per day by means of tracheotomy and do not exhibit significant ventilator-related lung damage. Diaphragm pacer settings must provide adequate alveolar ventilation and oxygenation during rest as well as during daily activities such as exercise. Major disadvantages of diaphragm pacing include cost, discomfort associated with surgical implantation, and potential need for repeated surgical revisions due to pacer malfunction.[173,174] Despite such potential limitations, parental reports of their experience are favorable in the vast majority. Recent development of a quadripolar electrode offers several advantages, which primarily include greater durations of pacer support at diminished risk of phrenic nerve damage and diaphragmatic fatigue, and optimization of pacing requirements during exercise.[175,176] Neurocognitive deficits are a disappointing outcome that may be detected in early preschool ages, and were initially attributed to unrecognized hypoxic events during infancy.[177] However, the possibility is now being invoked that such cognitive deficits may reflect dysmaturation of neural pathways in cortical regions.

## Secondary Central Hypoventilation Syndromes

Patients with myelomeningocele or Arnold-Chiari type I or type II malformation frequently exhibit sleep-disordered breathing, and such respiratory control disturbances are frequently suspected as causative mechanisms in the sudden unexpected deaths that occur in this population. Moderate or severe breathing disturbances occur in approximately 20% of cases.[178–183] The largest proportion of patients exhibit central apnea, while others show obstructed breathing; patients with obstruction are seldom helped by surgical intervention for tonsillectomy, suggesting that the primary dysfunction is of neural origin. The possible damage to vermis cerebelli structures from foramen magnum herniation in Chiari type II malformation has the potential to interfere with both blood pressure and breathing regulation, particularly under extreme challenges of hypotension or prolonged apnea. Compression of ventral neural surfaces is also a concern. The presence of thoracic or thoracolumbar myelomeningocele or the addition of severe brain stem malformations has been shown to enhance the potential for sleep-disordered breathing. Support for affected patients with either Chiari I or II must consider the need for recovery from pronounced hypotension during sleep, the overall respiratory disturbances that are present, and the surgical interventions required for decompression of neural structures. As such, a multidisciplinary approach is necessary to yield optimal outcomes.[184]

Patients with Prader-Willi syndrome (PWS) present a unique combination of sleep- and breathing-related manifestations. Excessive daytime sleepiness and increased frequency of REM sleep periods is pervasively present in PWS patients, while others show disturbances in circadian rhythmicity with a tendency for multiple microsleep periods. In addition, the combination of obesity and hypotonia favors the occurrence of OSA. Patients with PWS also display significant alterations in central and peripheral elements of respiratory control that, though not immediately related to the obesity, can be severely affected by the mechanical consequences of increased adiposity and that ultimately lead to ventilatory failure. A unique and almost universal feature of these patients is the absence of ventilatory responses to peripheral chemoreceptor stimulation; this deficiency leads to abnormal arousal patterns during sleep.[185–187] When untreated, obesity progressively reduces central chemosensitivity as well, with the latter being ameliorated by growth hormone therapy and increased muscle mass.[188,189] However, it is important to emphasize that sudden death cases have been reported worldwide in children with PWS receiving growth hormone therapy, and that the mechanisms of such adverse outcomes remain unclear.[190–192] Accordingly, overnight sleep studies have been advocated as part of the evaluation routine before initiation of growth hormone therapy and additional monitoring after implementation of growth hormone is also recommended, usually within a few weeks and subsequently on a yearly basis.[193–200]

A condition termed late-onset central hypoventilation has been observed in some children. Although an underlying congenital brain stem abnormality is probable, significant hypoventilation becomes evident only as a consequence of an intercurrent illness such as pneumonia, with the development of severe obesity, or as a consequence of cor pulmonale.[201–205] In addition, a recognizable entity consisting of hypothalamic dysfunction and late onset of central hypoventilation is now well established, has been termed Rapid-onset Obesity with Hypothalamic dysfunction, Hypoventilation, and Autonomic Dysregulation (ROHHAD) and does not appear to be associated with Phox2B mutations.[206–208] Alveolar hypoventilation can also develop in a child with previously normal control of breathing subsequent to an event resulting in brain stem injury, such as severe asphyxia, encephalitis, and infectious encephalopathies.

## Obstructive Sleep Apnea

The spectrum of sleep-disordered breathing, which includes OSA and upper airway resistance syndrome, occurs in children of all ages, from neonates to adolescents. OSA is characterized by repeated events of partial or complete upper airway obstruction during sleep, resulting in disruption of normal gas exchange and sleep patterns (Figs. 81.1–81.5).[209] Nighttime symptoms and signs include snoring, paradoxical chest and abdomen motion, retractions, witnessed apnea, snorting episodes, difficulty breathing, cyanosis, sweating, and disturbed sleep. Daytime symptoms can include mouth breathing, difficulty in waking, moodiness, nasal obstruction, daytime sleepiness, hyperactivity, and cognitive problems, with severe cases of OSA associated with cor pulmonale, failure-to-thrive, developmental delay, or even death. This complex and relatively frequent disorder is only now being recognized as a major public health problem, despite being initially described more than a century ago[210] and rediscovered in children in 1976 by Guilleminault and colleagues.[211] It is clear that the classic clinical syndrome of OSA in children is a distinct disorder from the condition that occurs in adults, in particular with respect to gender distribution, clinical manifestations, polysomnographic findings, and treatment approaches.[212,213] As discussed before, childhood OSA is frequently diagnosed in association with adenotonsillar hypertrophy, and is also common in children with obesity, craniofacial abnormalities, and neurologic disorders affecting upper airway patency.

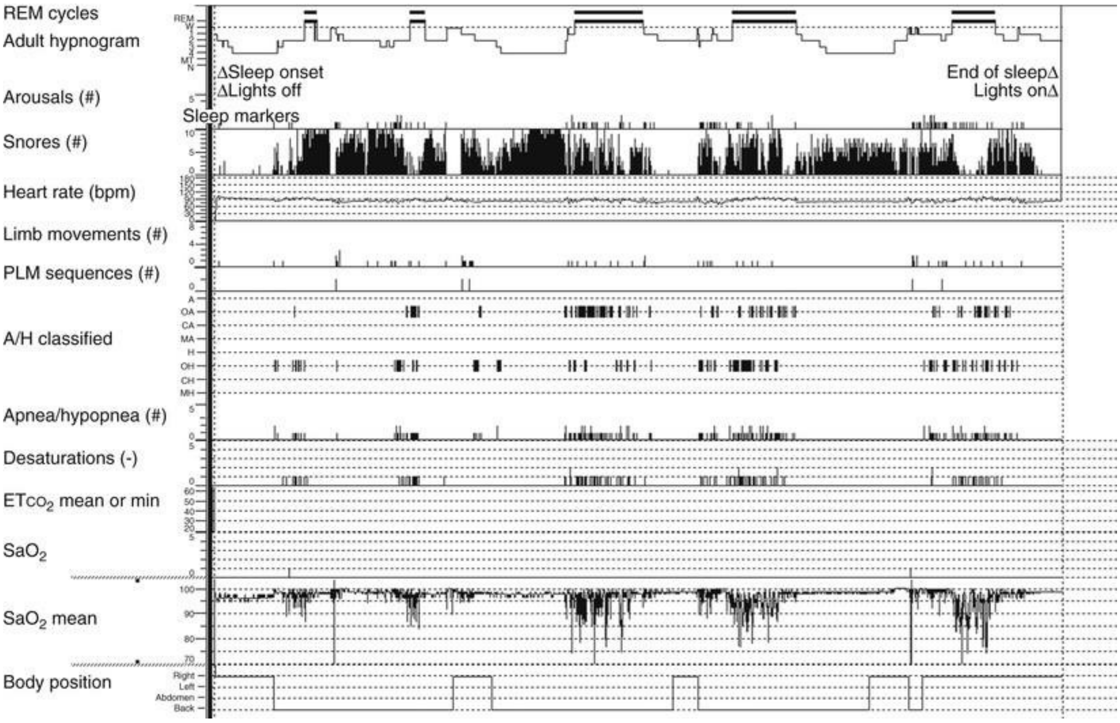

**FIG. 81.1** Overnight trends in several polysomnographic measures in a 7-year-old child with moderately severe OSA. Note REM sleep clustering of respiratory events. *A,* Apnea; *ET,* end-tidal; *H,* hypopnea; *OSA,* obstructive sleep apnea; *PLM,* periodic leg movement; *REM,* rapid eye movement.

## Epidemiology

Obstructive sleep apnea occurs in all pediatric age groups including infancy. Accurate prevalence information is only now emerging in infants, and suggests that habitual snoring and mild sleep-disordered breathing are frequent even during infancy, and that the risk for OSA is exacerbated by tobacco smoke exposure and reduced by breastfeeding.[214–216] OSA is particularly common in young children (preschool and early school years), with a peak prevalence around 2–8 years, and it subsequently declines in frequency,[217] possibly related to reductions in viral loads associated with adenotonsillar lymphoid tissue proliferation.[218–221] Habitual snoring during sleep, the hallmark indicator of increased upper airway resistance, is an extremely frequent occurrence and affects as many as 27% of children.[222–229] While the exact clinical polysomnographically defined thresholds associated with morbidity in snoring children are still being defined, the diagnosis of OSA based on consensus criteria[230] is currently estimated to affect approximately 2%–4% of young children.[231] Thus, the ratio of habitual snoring to OSA is between 4 : 1 and 6 : 1, and accurate identification of habitually snoring children who have OSA is particularly challenging, considering that clinical history and physical examination are poor predictors of the presence or absence of disease.[232] Although simple questionnaire-based,[233–236] overnight oxymetry,[237–240] multichannel recordings,[241] or biologically based[242–244] screening tools are being developed, they are either unreliable,[233] have not been extensively validated,[240] or are not yet available for widespread use.[241,244] Thus, despite the objections to its widespread implementation and current prominent underuse,[245–248] the overnight polysomnographic recording remains the only currently accepted approach to unequivocally establishing whether a snoring child has OSA or not.[249–251]

## Pathophysiology

The pathophysiology of childhood OSA remains relatively poorly understood. As discussed earlier, OSA occurs when the upper airway collapses during inspiration. Such collapse is a dynamic process that involves interaction between sleep state, pressure-flow airway mechanics, and respiratory drive. When resistance to inspiratory flow increases or when activation of the pharyngeal dilator muscles decreases, negative inspiratory pressure may collapse the airway.[61] Both functional and anatomic variables may tilt the balance toward airway collapse. Indeed, it has been determined that the site of upper airway closure in children with OSA is at the level of the tonsils and adenoids, whereas in normal children it is at the level of the soft palate.[103] The size of the tonsils and adenoids increases from birth to approximately 12 years of age, with the greatest increase being in the first few years of life, albeit proportionately to the growth of other upper airway structures.[55] However, lymphadenoid tissue will grow especially large in children exposed to cigarette smoking,[252,253] children with allergic rhinitis,[254,255] children with asthma,[256–259] and obviously children exposed to a variety of upper airway respiratory infections, particularly viruses.[219,220]

Although childhood OSA is associated with adenotonsillar hypertrophy, it is not caused by large tonsils and adenoids alone. Several lines of evidence suggest that OSA is the combined result of structural and neuromuscular variables within the upper airway. Indeed, patients with OSA do not obstruct their upper airway during wakefulness, and thus structural factors alone cannot be fully responsible for this condition. In addition, several studies have failed to show a definitive and robust correlation between upper airway adenotonsillar size and OSA, even if it accounts for a great proportion of the variance in the prediction of upper airway dysfunction during sleep. Furthermore, a small percentage of nonobese children with adenotonsillar hypertrophy but no other known risk factors for OSA are not cured by surgical removal of tonsils and adenoids. Finally, Guilleminault and colleagues reported a cohort of children whose OSA temporarily resolved after surgery but in whom OSA recurred during adolescence.[260,261] Thus, it appears that childhood OSA is a dynamic process resulting from a combination of structural and neuromotor abnormalities rather than from structural abnormalities alone. These predisposing factors occur as part of a spectrum: In some children (e.g., those with craniofacial anomalies), structural abnormalities predominate, whereas in others (e.g., those with cerebral palsy), neuromuscular factors predominate. In otherwise healthy children with adenotonsillar hypertrophy, neuromuscular abnormalities are probably subtle.

## Conditions Associated With OSA

Obstructive sleep apnea also occurs in children with upper airway narrowing due to craniofacial anomalies, or those with neuromuscular abnormalities such as hypotonia (e.g., muscular dystrophy) or muscular lack of coordination (e.g., cerebral palsy). In addition to craniofacial anomalies and abnormalities of the central nervous system, altered soft tissue size may result from infection of the airways, allergy, supraglottic edema, adenotonsillar hypertrophy, mucopolysaccharide storage disease, laryngomalacia, subglottic stenosis, neck tumor, or hypothyroidism. In recent years, the epidemic increase in obesity seems to be leading to substantial changes in the cross-sectional demographic and anthropometric characteristics of the children being referred for evaluation of OSA. Indeed, while fewer than 15% of all children were obese (i.e., >95th percentile for body mass index adjusted for age and gender) in the early 1990s, more than 50% met the criteria for obesity in the last 2 years in our Sleep Center.[262] Genetic factors also play a role in the pathophysiology of OSA, as demonstrated by studies of family cohorts.[263,264] It is unclear whether the influence stems from modulating effects of genetic factors on ventilatory drive, anatomic features, or both. Ethnicity is also important, with OSA occurring more commonly in African Americans. Finally, asthmatic children appear to be at higher risk for OSA, and in fact treatment of OSA appears to benefit the persistence or severity of the underlying asthmatic condition.[265–268] Box 81.3 lists the major conditions associated with OSA in children.

**Box 81.3**

## Conditions Associated With Obstructive Sleep Apnea in Children

- Adenotonsillar hypertrophy
- Obesity
- African American race
- Allergic rhinitis
- Asthma
- Micrognathia
- Down syndrome
- Craniofacial syndromes (e.g., Treacher Collins syndrome,

midfacial hypoplasia, Crouzon syndrome, Apert syndrome, Pierre Robin sequence)

- Achondroplasia
- Mucopolysaccharidoses
- Macroglossia
- Sickle cell disease
- Myelomeningocele
- Cerebral palsy
- Neuromuscular disorders (Duchenne muscular dystrophy, spinal muscular atrophy)
- Cleft palate repair and velopharyngeal flap
- Foreign body

## Clinical Evaluation and Diagnosis of Obstructive Sleep Apnea

It is clear that several potential mechanisms, including those genetically determined, are involved in the maintenance of upper airway patency during sleep and wakefulness. Each of these mechanisms or a combination thereof can therefore be implicated in the causation of respiratory compromise during sleep in the otherwise normal child with enlarged tonsils or adenoids, as well as in those children with clinical problems that predispose to OSA. The clinical presentation of a child with OSA syndrome is usually very nonspecific, requiring increased awareness on the part of the primary care professional, since the current number of children being referred for evaluation of sleep-disordered breathing may in fact represent only the tip of the iceberg. A thorough history should include detailed information pertaining to the sleep environment (Box 81.4). In the otherwise normal child, the principal parental complaint will be snoring during sleep. Nevertheless, even when the diagnostic interview is conducted by a sleep specialist, the accuracy of OSA prediction based on history alone is poor, such that an overnight polysomnographic evaluation is required as the more definitive diagnostic tool. The routine clinical evaluation of a snoring child is usually not likely to demonstrate significant and obvious findings. Attention should be directed to the size of the tonsils,[269,270] with careful documentation of their position and relative intrusion into the retropalatal space. In addition, nasopharyngoscopic evaluation or imaging approaches may be helpful in guiding the clinical decision.[271–273] In addition, the presence of allergic rhinitis, nasal polyps, nasal septum deviation, or any other condition likely to increase nasal airflow resistance should be evaluated. The relative size (i.e., micrognathia) and positioning of the mandible (e.g., retrognathia) should also be documented. Body habitus, particularly the presence of obesity, and associated signs of complications such as acanthosis nigricans should be noted. Finally, attention should be paid to blood pressure values and to the presence of auscultatory findings suggestive of increased pulmonary artery pressures.

**Box 81.4**

## Pertinent Clinical Findings in Pediatric Obstructive Sleep Apnea

### During Sleep

- Habitual snoring
- Difficulty breathing during sleep with snorting episodes
- Restless sleep and frequent awakenings
- Excessive sweating
- Night terrors
- Enuresis
- Breathing pauses reported by parents

### During Daytime

- Mouth breathing and limited nasal airflow
- Chronic rhinorrhea
- Adenoidal facies
- Recurrent ear infections

- Difficulty swallowing
- Pectus excavatum
- Retrognathia
- Enlarged neck circumference
- Truncal obesity
- Frequent visits to primary care physician for respiratory-related symptoms

### Sequelae

- Neurobehavioral deficits (poor school performance, learning deficits, aggressive behavior, moodiness, shyness, and social withdrawal)
- ADHD-like behaviors
- Depression and low self-esteem
- Excessive daytime sleepiness
- Systemic hypertension
- Left ventricular hypertrophy
- Pulmonary hypertension and *cor pulmonale*
- Failure to thrive
- Reduced quality of life

*ADHD,* Attention deficit–hyperactivity disorder.

## Polysomnography

An overnight polysomnographic evaluation is, at least presently, the only definitive diagnostic approach for OSA.[249,274,275] The American Academy of Pediatrics has published a consensus statement outlining the requirements for pediatric polysomnography.[249] Box 81.5 shows the currently recommended channels usually used in the laboratory evaluation of snoring children. Available reference values in children are clearly lower than the thresholds defined for adults.[276–284] While the reasons are not completely understood, the relative resistance of the upper airway of children to collapse may underscore that complete obstructive events are less likely and that prolonged periods of heightened upper airway resistance associated with alveolar hypoventilation (also termed obstructive hypoventilation) are more readily apparent in children.[285] It should also be mentioned that, unlike adults, children with OSA often will not develop obvious EEG arousals following obstructive apneas,[286,287] and as a result, sleep architecture is relatively preserved in many children with OSA.[288] This reduced propensity to manifest arousals (based on the 3-second EEG criteria developed for adults) has led to the assumption that excessive daytime sleepiness, the cardinal symptom of OSA syndrome in adults, is an uncommon feature in children with OSA. Indeed, in initial parental surveys only 7% of parents indicated that excessive sleepiness was a problem.[232] Furthermore, more objective measurement of excessive daytime sleepiness using the multiple sleep latency test in snoring children revealed that, although linear relationships existed between the severity of OSA (as measured by the obstructive apnea-hypopnea index) and the mean sleep latency measured during the multiple sleep latency test, manifest excessive daytime sleepiness occurred in only 13% of children.[289] However, excessive daytime sleepiness is very likely to occur in obese children with OSA,[290] and has prompted the delineation of 2 distinct phenotypes in pediatric OSA.[291] More elaborate examination of the patterns of arousal among snoring children further showed that as respiratory-related arousals increase in frequency with increasing OSA disease severity, the opposite phenomenon (i.e., decreases in spontaneous arousal index) occurs,[292] suggesting a very powerful attempt by these children to preserve sleep homeostasis. On the basis of the mutual interdependencies of these two types of arousal, a model was developed that allows for sensitive assessment of the resulting sleep pressure derived from disrupted sleep using polysomnographic data.[293] This approach has thus far permitted assessment of the independent contribution of sleep fragmentation to neurobehavioral morbidity in snoring children.[294] Thus, more subtle manifestations of arousal may be present in children, even if apnea-related EEG arousals are less common than in adults. For example, subcortical arousals, as demonstrated by movement, or autonomic changes, occur frequently in children.[295] It is also possible that subtle disturbances in sleep architecture are present that go undetected by routine polysomnography but are detectable through spectral analysis of EEG frequency domains,[296] and may contribute to neurobehavioral and autonomic complications of OSA (see later). Treatment of OSA has resulted in improved reports of sleepiness by parents.[297]

**Box 81.5**

## Usual Polysomnographic Montage in Children Evaluated for Suspected Sleep-Disordered Breathing[a]

- Electroencephalogram: minimum two channels (central and occipital leads); usually four to eight channels
- Chin EMG
- Anterior tibial EMG, left and right
- Electro-oculogram, left and right
- Electrocardiogram
- Pulse oximeter and pulse waveform
- Oronasal airflow thermistor
- Nasal pressure catheter[b]
- End-tidal capnography and waveform
- Chest and abdominal respiratory inductance plethysmography
- Body position sensor
- Tracheal sound sensor or microphone
- Time-synchronized video

*EMG,* Electromyogram.

---

[a] In younger children, consider transcutaneous $CO_2$ tension measurements.

[b] Esophageal catheters are used in some laboratories instead of nasal pressure catheters to assess respiratory effort.

As mentioned earlier, the role of ambulatory sleep studies, whether abbreviated (home video, sound recordings, or nocturnal oximetry) is now being intensively explored, along with exploration of biomarkers.[237–244,298–303]

## Short-Term and Long-Term Morbidity of Obstructive Sleep Apnea

One of the major drives to treat any medical condition is the prevention of morbidity and mortality. Indeed, the consequences of untreated OSA in young children can be serious. Early reports of children with severe OSA were often associated with failure to thrive, although currently only a minority of children with OSA will present with this problem, most probably because of earlier recognition and referral for evaluation and treatment. The mechanisms mediating reductions in growth velocity most likely represent a combination of increased energy expenditure during sleep,[304,305] and disruption of the growth hormone and insulin-like growth factor and binding proteins.[306,307] Tonsillectomy and adenoidectomy (T&A) and complete resolution of OSA in children with failure to thrive will result in catch-up growth and will also increase the height and weight velocities even in children with normal growth and OSA. Interestingly, even obese children with OSA will demonstrate weight gain following surgery.[308]

Frequent $O_2$ desaturations during sleep are common in children with OSA. Elevation of pulmonary artery pressure due to hypoxia-induced pulmonary vasoconstriction is a serious consequence of OSA in children, and can lead to cor pulmonale. While pulmonary hypertension is probably more frequent than predicted from clinical assessment, the exact prevalence of this complication is unknown.[309–312] In addition, while treatment of OSA will result in normalization of pulmonary artery pressures,[313] it remains unclear whether untreated OSA will result in persistent vascular remodeling of the pulmonary circulation. Indeed, evidence from animal models exposed to hypoxia for a short period of time during early postnatal life reveals that pulmonary hypertension is increased when exposed to hypoxia later in infancy, suggesting that some remodeling may have occurred.[314] Furthermore, intermittent hypoxia may also affect left ventricular function through both direct and indirect effects on myocardial contractility.[315] In the context of OSA, systemic hypertension has emerged as a major cardiovascular consequence in adult patients. Although the pathophysiologic mechanisms of such elevation in arterial tension are still under intense investigation, it appears that intermittent hypoxemia is the major contributor to this serious consequence of OSA, with lesser roles being played by sleep fragmentation and episodic hypercapnia. It is now thought that intermittent hypoxia during the night will lead to increased sympathetic neural activity, and that the latter will be sustained and induce changes in baroreceptor function leading to hypertension.[316] While the data pertaining to pediatric patients are still scant, increased surges in sympathetic activity have been reported in children with OSA,[317,318] and elevation of arterial blood pressure will occur.[319–321] It is also probable that episodic nocturnal hypoxia will induce changes in the physical properties of resistance vessels and contribute to the overall elevation of blood pressure.[322,323] Furthermore, preliminary evidence suggests that OSA-induced disruption of baroreceptor function may not resolve after treatment and in fact may be lifelong.[324–326] Thus, early childhood perturbations may lead to lifelong consequences, or in other words, certain types of adult cardiovascular disease may represent, at least in part, sequelae from *a priori* “unrelated events” during childhood. Therefore early identification of children with alterations of baroreceptor and autonomic nervous system function in the context of pediatric OSA may lead to detection of a population potentially at risk for ultimate development of hypertension and its cardiovascular-associated morbidity. More recent studies have further uncovered that pediatric OSA is associated with a systemic inflammatory response; leads to excessive catecholaminergic release, indicative of increased sympathetic activity; and promotes the occurrence of endothelial dysfunction, the latter being palliated by the intrinsic recruitment of endothelial progenitor cells.[327–340] However, accurate assessment of the long-term implications of the cardiovascular morbidity found in pediatric OSA has yet to be systematically pursued.

It is likely that similar mechanisms induced by OSA, particularly in the presence of concurrent obesity, will promote the development of dyslipidemia and insulin resistance, and also potentiate hepatic injury.[341–344]

Another potentially very serious consequence of intermittent hypoxia may involve its long-term deleterious effects on neuronal and intellectual functions. Reports of decreased intellectual function in children with tonsillar and adenoidal hypertrophy date back to 1889, when Hill reported on "some causes of backwardness and stupidity in children."[345] Schooling problems have been repeatedly reported in case series of children with OSA, and in fact may underlie more extensive behavioral disturbances such as restlessness, aggressive behavior, excessive daytime sleepiness, and poor test performances.[346–359] Moreover, habitual snoring in the absence of OSA has also been demonstrated to be associated with neurocognitive deficits, and therefore even mild disturbances in breathing patterns during sleep may change regional brain responses during attention tasks.[360,361]

There is increasing evidence to support an association between OSA and attention-deficit/hyperactivity disorder (ADHD) in children, particularly with the hyperactive-impulsive subtype.[362] Several subjective studies have documented that children with habitual snoring and with OSA often have problems with attention and behavior similar to those observed in children with ADHD. In addition, several survey studies encompassing almost 8000 children have documented daytime sleepiness, hyperactivity, and aggressive behavior in children who snored. In a recent study from our laboratory, both subjective and objective sleep measures were obtained, and showed that objectively measured sleep and respiratory disturbances are relatively frequent among children with ADHD, albeit not as frequent as anticipated from parental reports. In this study, the prevalence of OSA in a cohort of children with ADHD, verified by neuropsychologic testing, did not seem to differ from the prevalence found in the general population. However, an unusually high frequency of OSA was found among children with mild-to-moderate increases in hyperactivity, as opposed to those children with true ADHD. This suggests that while OSA can induce significant behavioral effects manifesting as increased hyperactivity and inattention, it will not overlap with true clinical ADHD when the latter is assessed by more objective tools than just parental perception.[224] Therefore in a child presenting with parental complaints of hyperactivity and who does not meet the diagnostic criteria of ADHD after undergoing a thorough evaluation, a careful sleep history should be taken and if snoring is present, an overnight polysomnographic evaluation should be performed.

The mechanism(s) by which OSA may contribute to hyperactivity remain unknown. It is possible that both the sleep fragmentation and episodic hypoxia that characterize OSA will lead to alterations within the neurochemical substrate of the prefrontal cortex, with resultant executive dysfunction.[362,363] Notwithstanding these considerations, sleep disturbances are frequently reported by parents of ADHD children, even when snoring is excluded. According to the available literature, the comorbidity of OSA and ADHD could be shared by a substantial number of hyperactive children, and in fact, it has been suggested that as many as 25% of children with a diagnosis of ADHD may actually have OSA.[361] However, such rather extensive overlap may be less prominent than previously estimated if medication status and psychiatric comorbidity are accounted for in the analysis.

Inverse relationships between memory, learning, and OSA have also been documented. In addition, improvements in learning and behavior have been reported subsequent to treatment for OSA in children,[364–366] suggesting that the neurocognitive deficits are at least partially reversible. In a large cohort of first graders whose academic performance was in the lowest (10th) percentile of their class, a six- to nine-fold increase in the expected incidence of OSA was found. More importantly, however, a significant improvement in school grades following T&A and resolution of OSA occurred in these children.[347] Since the optimal learning potential for these children is unknown, it is possible that long-term residual deficits may occur even after treatment. Indeed, children who snored frequently and loudly during their early childhood were at greater risk for poor academic performance in later years, well after snoring had resolved.[367] These findings suggest therefore that even if a component of the OSA-induced learning deficits is reversible, there may be a long-lasting residual deficit in learning capability, and that the latter may represent a “learning debt”; in other words, the decreased learning capacity during OSA may have led to such a delay in learned skills that recuperation is only possible with additional teaching assistance. Alternatively, the processes underlying the learning deficit during OSA may have irreversibly altered the performance characteristics of the neuronal circuitry responsible for learning particular skills. Another important observation is that at any level of severity, not all children suffering from OSA manifest evidence of cognitive or behavioral pathology, even if a dose-dependent relationship is detectable.[368,369] Of note, such severity-dependent relationship is applicable only to cognition and not to behavioral functioning, whereby the more severe behavioral perturbations appear at the milder levels of sleep-disordered breathing.[370] This conundrum has been further exacerbated by the inability to detect major improvements in cognitive function in children randomized to be treated with either T&A or watchful waiting,[371] even if a posthoc secondary analysis revealed some degree of improvements in a subset of the neurocognitive tests.[372]

As mentioned before, overt excessive daytime sleepiness is not immediately apparent in children with OSA, yet morbidity that could be construed as related to sleepiness is indeed detectable. Recent studies clearly support a role for sleepiness (measured as sleep pressure) in the cognitive and behavioral disturbances occurring in children with OSA.[373]

In animal models, we found that intermittent hypoxia during sleep is associated with significant increases in neuronal cell loss and adverse effects on spatial memory tasks in the absence of significant sleep fragmentation or deprivation. Furthermore, when this model was applied to developing rodents, a unique period of neuronal susceptibility to episodic hypoxia during sleep emerged and corresponded to ages at which OSA prevalence peaks in children.[374–376] Since this age coincides with that of a critical period for brain development, it is possible that, during a critical time for brain development, delayed diagnosis and treatment of OSA will impose a greater burden on vulnerable brain structures and ultimately hamper the overall neurocognitive potential of children with OSA. Adverse effects of sleep-disordered breathing on quality of life,[377–379] mood,[379] enuresis,[380–382] and health-related costs[383,384] further buttress the extensive and multifactorial impact of this condition.

In summary, it is becoming increasingly clear that OSA in children can have adverse effects on somatic growth, induce cardiovascular and metabolic alterations such as pulmonary hypertension, systemic hypertension, endothelial dysfunction and atherosclerosis,[385,386] insulin resistance,[387–389] and hyperlipidemia, and lead to substantial neurobehavioral deficits, some of which may not be reversible if treatment is delayed. Based on our current understanding of the morbidity affecting pediatric OSA, it is imperative to direct future efforts toward an improved definition of the spectrum of OSA-induced syndrome, so as to provide more accurate guidelines for treatment.

## Treatment of Obstructive Sleep Apnea

Tonsillectomy and adenoidectomy is usually the first line of treatment for pediatric OSA, and a meta-analysis on the efficacy of T&A suggested a relatively high immediate curative rate of surgery for OSA in children.[390] Since OSA is the conglomerate result of the relative size and structure of the upper airway components, rather than the absolute size of the adenotonsillar tissue, both tonsils and adenoids should be removed, even when one or the other seems to be the primary culprit. Although the majority of children will have improvement in the severity of OSA, cure may actually occur in a smaller proportion than previously estimated, particularly in children with more severe OSA, in those who are obese, and in those with a positive family history of OSA or asthma.[371,391–395]

Children with OSA are at risk for respiratory compromise postoperatively, as a result of upper airway edema, increased secretions, respiratory depression secondary to analgesic and anesthetic agents, and postobstructive pulmonary edema. A high risk for such complications is particularly encountered among children younger than 3 years of age, those with severe OSA, and those with additional medical conditions such as craniofacial syndromes; these patients should not undergo outpatient surgery, and cardiorespiratory monitoring should be performed for at least 24 hours postoperatively to ensure their stability.[396–400]
Postoperative polysomnographic evaluation 10–12 weeks after surgery is probably needed in most patients.[395] However, it should

definitely be recommended for those patients with additional risk factors, and thus ensure that additional interventions are not required.[395]

Additional treatment options are available for the management of OSA in children either before T&A, for those children who do not respond to T&A, or for the small minority in whom T&A is contraindicated. Nasal CPAP has been reported to be both effective and well tolerated in hundreds of infants and older children, with only minor side effects (similar to those seen in adults), such as nasal symptoms and skin breakdown.[401–409] However, adherence is routinely low, and the implementation of behavioral modification programs and family supportive services aimed at improving adherence results in relatively high health care costs that are unlikely to be assumed by third-party payers.[410] Younger children may develop central apneas or alveolar hypoventilation at higher pressure levels, presumably due to activation of the Hering-Breuer reflex by stimulating pulmonary stretch receptors. However, this can be remedied by the use of bilevel positive airway pressure ventilation with a backup rate. Supplemental $O_2$ results in improved arterial $O_2$ saturation in children with OSA without worsening the degree of obstruction. However, since $O_2$ does not address many of the pathophysiologic features associated with the symptoms of OSA, it should be reserved as a temporary palliative measure preceding T&A, and it clearly should not be used as a first-line treatment. Furthermore, supplemental $O_2$ should never be used without monitoring the potential resultant changes in $P\text{CO}_2$, since some patients with OSA can develop unpredictable and potentially life-threatening hypercapnia when breathing supplemental $O_2$.[411,412]

Uvulopharyngopalatoplasty has not been systematically evaluated in children. It has been found to be useful in patients with upper airway hypotonia; in other words, those with Down syndrome or cerebral palsy. Craniofacial reconstructive procedures are reserved for some children with craniofacial anomalies. Other procedures such as tongue wedge resection, epiglottoplasty, mandibular advancement, and lingual tonsillectomy occasionally may be indicated. Additionally, the role of intraoral appliances and myofunctional therapy remains unclear, even if favorable outcomes have been reported in recent clinical series.[413–415] With the advent of CPAP, tracheostomy is now rarely required. Although pharmacologic agents are not usually useful in frank OSA, recent work has demonstrated that intranasal steroids and oral leukotriene receptor modifiers may have a role in the clinical management of symptomatic children with either primary or secondary (after T&A) upper-airway-resistance syndrome.[416–426]

Finally, the use of high-flow oxygen via a nasal cannula has recently been proposed as an alternative to CPAP in selected cases. Further studies, however, will be necessary to validate this approach and appraise its limitations.[427,428]

**A**

A disintegrin and metalloproteinase domain 33 (ADAM33), in asthma, 653*t*

AAD, Assisted autogenic drainage

AAQOL, Adolescent Asthma Quality of Life Questionnaire

ABCA3 deficiency, indication of, 58

Abdominal binders, 285

Abdominal wall, movement of, 5

Aberdeen cohort, 253

Aberdeen SEATON study, in asthma, 654

Aberrant right subclavian artery, in Down syndrome, 1002*f*

About My Asthma (AMA), 234–235, 236*t*–237*t*

ABPA, Allergic bronchopulmonary aspergillosis

Abscess, lung, 154, 155*f*

Absent-in-melanoma-like receptors, 125

Acapella, 275*f*, 281*f*

Accidental deaths, in drowning, 634

Accuhaler, 265*f*, 266

ACD, Alveolar capillary dysplasia

ACDMPV, Alveolar capillary dysplasia with misalignment of pulmonary veins

Acetaminophen

- antenatal effects of, 249–250
- during pregnancy, asthma and, 653–654

Acid-base balance, 94–97, 96*t*

- buffering and transport, 94–96, 95*f*

Acidemia, 96

Acidosis, metabolic, asthma and, 688

Acinar area, in postnatal lung growth, 72–73

Acinar dysplasia, 314

Acinus, 63

- as portion of lung parenchyma, 66–67

Acquired atelectasis, 1027

Acquired bilateral vocal cord paralysis, 1121–1122

Acquired digital clubbing, 19

Acquired immune deficiency syndrome (AIDS), nontuberculous mycobacterial disease with, 499

Acquired immunity, in pulmonary host defense systems, 37–38

Acquired immunodeficiency, in children, 923

Acquired immunodeficiency states, pulmonary pathogens associated with, 924*t*

Acquired thrombophilia, 888

Acrocyanosis, 17

ACT, Airway clearance technique

Activator protein-1 (AP-1), as proinflammatory transcription factors, 109–110

Active cycle of breathing techniques, 275*f*
  modification, 284
  teaching, 279–281
Active immunization, for pertussis, 533
Active smoking, 252
  severe asthma and, 729
Acute alveolitis, in hydrocarbon aspiration, 626
Acute asthma
  episode of, management of, 717–719
  management of, in medical facility, algorithm for, 718*f*
Acute bronchitis, etiologic agents with, 397*t*
Acute cerebral insult, 590
Acute chest syndrome, 904–905

- exploratory behaviors, 244–245
- exposure pathways in, 50*t*
- health issues, addressing, 244–245
- health-risk behaviors, 244–245
- independence/autonomy, increase, 241
- lung apices, parenchymal opacifications (chest radiograph) in, 865*f*
- nasal passageways of, inspection of, 16
- obesity, 215–216
- pulmonary embolism in, 888, 888*t*
- self-management, promotion, 244
- study of CPET in, 216
- tasks of, 242*b*

Adrenal suppression, corticosteroids and, 706

Adrenaline, 410–411

Adult dermatomyositis, 857

Adult disease, pediatric origins, 212

Adult onset DM (morbidity/mortality), ILD (impact) of, 858

Adult type tuberculosis, 481, 482*f*

Adulthood, pediatric respiratory disorders, 242*b*

Adults

- allergic rhinitis, 737

- bronchiolitis obliterans organizing pneumonia (BOOP) developed in, 880
- care models, differences, 242
- chronic respiratory disorder, transition, 241
- exposure pathways in, 50*t*
- hamartomas, 1072
- health care needs/patterns, 242
- lungs in
  - children and, contrast between, 609
  - microvascular bed in, perfusion of, 583–584
- self-management, promotion, 244
- services
  - preparation, 245
  - trust/respect, absence, 246
- shrinking lung syndrome in, 856

Advanced Trauma Life Support (ATLS), guidelines, 1062

Adventitious respiratory sounds, indication of, 11

Adventitious sounds, in categories of respiratory sounds, 14*f*

AECs, Alveolar epithelial cells

Aerobic metabolism, 97

Aerobic training, 218

Aerodigestive model
- health care value for complex patients through coordinate care, 1094–1096
- historical perspective of, 1094
- interdisciplinary team in, 1095, 1095*f*
- patient evaluation in, 1094–1095
- patient selection in, 1094

Aerodigestive program referral, typical complaints leading to, 1095*t*

Aerodigestive tract
- anatomic abnormalities, 1100
- evaluation of, 1104–1105

Aerodynamic filtering, 120

Aerosol devices, 120, 264–270

Aerosol drug-delivery device design, 270
Aerosol generation, 261–263
Aerosol therapy, 257
  advantages of, 257
  advice and training for parents, 271
  aerosol generation, 261–263
  assessment techniques, 261–264
  brownian motion/diffusion, 260
  delivery, 263
    and deposition, 258–260
  delivery system, progress, 271
  disadvantages of, 257
  dosage considerations, 270–271
    calculation of, 270
    patient considerations, 270
  electrostatic attraction, 260
  gravitational sedimentation, 259–260
  inertial impact, 259, 262, 262*f*
  laser diffraction, 262–263
  particle size, 258–259, 258*t*
    distribution, 261–263
  patient-related variables, 260–261
    age, 260
    regimen and device compliance, 260–261
  systemic dose, from inhaled drugs, 270–271
  total drug output, 263
  in vivo deposition, 263–264, 264*f*
Afferent fibers, stimulation of, 120–121
African American boy, skin lesions (history/biopsy) of, 864*f*
Agar gel immunodiffusion, 949*f*
Age, in immunopathogenesis of pediatric asthma, 665
b$_2$-agonist, for hydrocarbon aspiration, 627–628
AHLM, Alveolar hemosiderin-laden macrophages

AHR, Airway hyperresponsiveness

Air bronchograms, presence of, 858*f*

Air embolism, 312

Air leak syndromes, as complication of mechanical ventilation, 601, 601*f*

Air quality, 221

- in asthma, 661–664
  - indoor, 662–663

Air-liquid interfaces, collapsing forces in, 26

Airspace fluid, clearance rate of (augmentation), 593

Airspaces, of lungs, distention of, 71

Airway clearance

- methods, 454
- respiratory physiotherapy, 274–282
- treatment options, 274

Airway clearance technique (ACT), 275*f*–278*f*

- review, 282
- variety, 274

Airway compression

- due to vascular rings and slings, 615–619, 616*f*–618*f*
  - clinical presentation of, 619
  - diagnosis of, 619
  - treatment of, 619, 619*f*–620*f*
- dynamic, 80

Airway endoscopy abnormalities, in Down syndrome, 994*f*

Airway eosinophilia, in pediatric allergic asthma, 667

Airway hyperreactivity

- asthma and, 686, 689
- cystic fibrosis and, 781
- in human immunodeficiency virus–infected children and adolescents, 979
- reduced symptoms of, 715
- to substances, 695

Airway hyperresponsiveness (AHR), 102–103, 118
  in asthma development, 665

Airway inflammation, 101–119, 221
  direct measurement of, 114–115, 114*f*–115*f*
  due to asthma, 1027
  indirect inflammatory markers, 118
  neural control, two-way interaction, 112*f*
  noninvasive assessment of, 115–118
  in pediatric respiratory disease, 118
  therapeutic implications for, 118

Airway obstruction, 589
  asthma and, 688
  bronchiolitis, 421
  diagnostic bronchoscopy for, 138
  in infants, 180–181
  pulmonary edema and, 587

Airway pressure release ventilation, in acute respiratory distress syndrome, 611

Airway protection
  instrumental assessment of, 1109–1112
  pharyngeal phase, 1107–1108
  problems, 1108–1109
    neurologic conditions, 1109

Airway remodeling, 689–690
  in asthma development, 665, 669*f*

Airway resistance
  factors that affect, 80
  increase in, 585–586
  plethysmographic measurement of, 198–199
  sites of, 79–80

Airway smooth muscle, in pulmonary immunity and asthma pathogenesis, 671

Airway surface liquid (ASL), 121–122, 762
  - depletion, 122

Airways, 63–66
  - anastomosis, dehiscence of, 985
  - branching, model of, 65*f*
  - cartilage, congenital deficiency of, 65–66
  - cellularity, dominant, 458*t*
  - compression, diagnosis, 1123
  - compromise, risk of, 1067
  - conditions, impact, 1109
  - defense functions, 121
  - dehydration, impact, 762–763
  - diameter, 72*f*
    - increased, 83–84
  - dilation, 444–445
  - dryness of, 872
  - epithelium, 110
  - examination of, bronchoscopy for, 134
  - flaccidity, 450
  - function of, prostaglandins (PG) in, 110
  - functional compartments of, 63
  - gas flow within, 78–79
  - guy wire effect on, 80
  - inflammation
    - and neural control, 112*f*
    - pathogenic processes (impact), 446–447
  - inflammatory response of, neural mechanism in, 111–112
  - models of, sound generation in, 10
  - mucosal abnormality, 450*f*
  - mucus production/secretion (reduction), antisecretagogues, 453–454
  - muscles, bronchoconstriction of, 66
  - narrowing, maximum, 1149
  - nerves, release neurotransmitter from, 112
  - oxygen and carbon dioxide in, partial pressures of, 85*f*

  - patency, maintaining, 65–66
  - pathology, management of, 1121–1124
  - radiologic evaluation of, 1122
  - reflexes, 120–121
  - resin cast of, 64*f*
  - smooth muscle content of, 66
  - submucosa in, 65–66
  - tortuosity, 444–445
  - vascular compression, 1123
  - wall structure of, 65*f*
- AKITA JET Inhalation system, 269, 270*f*
- Alae nasi, flaring of, 5
- Albendazole, for echinococcosis, 542
- Albuterol (Salbutamol), 219
  - for asthma, 702–703
    - acute episodes of, 717
    - nebulized, in emergency department, 717
- Alemtuzumab (Campath), 883
- Alkalemia, 96
- Alkaline phosphatase (ALP), elevation of, 792
- Alkylating agents, 878–879
- Allergen immunotherapy, 747–750
  - administration, 747–748
  - allergic sensitivity development, prevention of, 749
  - asthma, prevention of, 749
  - asthma control, impact on, 748–749
  - clinical application, 750
  - indication of, 747
  - mechanism of action, 748, 748*f*
  - patient selection, 747
  - persistent clinical effects, after discontinuation, 749
  - safety, 749–750

Allergens
- asthma and, 692
- avoidance, 741
  - strategies, 741*b*
- exposure to, severe asthma and, 728–729
- immunotherapy, 742
- provocation studies, 738
- removal of, 715

Allergic angiitis, 962

Allergic bronchopulmonary aspergillosis (ABPA), 781, 952–958
- central bronchiectasis in, 956*f*
- clinical features of, 955–957
- clinical staging of, 955–956, 956*t*
- cystic fibrosis with, lung biopsy of, 953*f*
- development of, genetic risk factors in, 954*b*
- diagnostic criteria for, 952*b*
- differential diagnosis of, 957
- eosinophils, biology of, 953–955
- epidemiology of, 952
- etiology of, 952
- IL-4, increased sensitivity to, 954
- immunotherapy for, 958
- laboratory findings in, 956–957
- management and treatment of, 957–958
- pathogenesis of, 952–955
- pathology of, 952–955
- physical findings in, 955
- prednisone in, dose of, 957
- prognosis of, 958
- radiographic findings in, 956
- serum IgE in, elevated, 955
- symptoms of, 955
- as Th2 hypersensitivity lung disease, 952

Allergic fungal sinusitis, 744

Allergic inflammation, 101

- cells predominate in, 103
- characterization of, 101
- in environmental exposures, 51–53, 53*f*
- infiltration with eosinophils, 101

Allergic inflammatory cytokines, in asthma, 665

Allergic rhinitis, 737–742, 1054–1055

- asthma and, 693
  - association, 737–738
  - epidemiologic relationship, 737–738
  - pathophysiologic connections, 739–740
- burden, addition, 738
- diagnosis, 741
- diagnostic/therapeutic implications, 741–742
- histologic studies, 738
- immunopathology, 738
- pharmacotherapy, 741–742, 746*b*
- therapeutic implications, 741–742

Allergic salutes, transverse crease from, 6

Allergic sensitivity development, prevention of, 749–750

Allergic sensitization

- in asthma development, 665, 666*f*
- in environmental exposures, 51–53, 53*f*

Allergic shiners, 6

Allergy

- to food, asthma and, 725
- testing, for asthma, 698

All-*trans* retinoic acid (ATRA), 881

Alpha-1 antitrypsin (ATT) deficiency, 823–824

- clinical features of, 824
- diagnosis of, 824

    - epidemiology of, 823–824
    - etiology of, 824
    - management of, 824
    - pathobiology of, 824
    - predispositional testing of, 824
    - treatment of, 824
- ALRI, Acute lower respiratory infection
- ALTE, Apparent life-threatening event
- Altered responsiveness, BRUE definition and factors for inclusion and exclusion, 1126*t*
- *Alternaria* spp., 526
- Altitude, exercise, 226
- Alveolar capillary dysplasia (ACD), 298, 999
- Alveolar capillary dysplasia with misalignment of pulmonary veins (ACDMPV), 825–826, 827*f*
    - clinical features of, 826
    - diagnosis of, 826
    - differential diagnosis of, 826
    - epidemiology of, 825
    - etiology of, 825–826
    - *FOX F1* gene and, 825
    - histologic findings in, 826
    - management of, 826
    - pathogenesis of, 825–826
    - presentation of, 826
    - prognosis of, 826
    - radiologic findings in, 826
    - treatment of, 826
- Alveolar capillary membrane
    - integrity, 344
    - permeability, increased, 584
- Alveolar development, 252

Alveolar edema, in smoke inhalation, 630

Alveolar epithelial cells (AECs), 26

- type II, 67*f*

Alveolar filling disorders, therapeutic bronchoscopy for, 145

Alveolar gases, humidification of, 26

Alveolar hemorrhage, incidence of, 879

Alveolar hemosiderin-laden macrophages (AHLM), presence of, 1140

Alveolar hypoventilation, 17–18

- treatment of, 390–391

Alveolar macrophages (AM), 66–67, 70, 104, 105*f*

- prevention of, from catabolizing surfactant, granulocyte-macrophage colony-stimulating factor deficiency and, 58

Alveolar period, 28*f*, 30–31

Alveolar proteinosis

- clinical syndrome of, 58
- gene mutations and, 38–39

Alveolar region, 66–68

Alveolar septum, membranes in, fusion of, 581*f*

Alveolar spaces

- protein clearance from, 584
- protein presence in, 584

Alveolar stability, 58–59

Alveolar type II epithelial cell (AEC2), storage of, 836

Alveolar ventilation, 86

- alveolar gases and, 86–88
- effect of changing, 87*f*

Alveolarization, 72–73

Alveoli

- epithelial cells in, 67

  - portrayal of, 580

Alveologenesis, 35–36

AM, Alveolar macrophages

AMA, About My Asthma

American College of Rheumatology, SLE classification criteria of, 855*b*

Amikacin, for nontuberculous mycobacterial infections, 504*t*

Aminophylline, effects of, 21

4-aminopteroylglutamic acid, 879–880

Amiodarone, 883–884

Amphotericin B
  - for candidiasis, 519–520
  - for coccidioidomycosis, 513
  - for fungal infections, 975
  - for invasive aspergillosis, 517–518
  - for pulmonary mycoses, 507
  - for sporotrichosis, 524

Amphotericin B deoxycholate, for candidiasis, 520

Ampicillin, for early onset septicemia, 346

AMS, Acute mountain sickness

Anaerobic metabolism, 97–98

Anaerobic threshold, 215

Anastomotic narrowing, development of, 985

ANCA, Antineutrophil cytoplasmic antibody

Aneuploidy, 292

Angiogenesis, increased number of blood vessel, 102–103, 103*f*

Angiography, 168, 334, 336*f*

Annexin, 102

Anomalous innominate artery, 309

Ansa-cervicalis reinnervation, 1121

Antenatal lung development, 248

Antenatal steroids, exposure, absence, 343–344

Anterior axillary fold, chest wall and, 148

Anterior diaphragmatic hernias, 331–332, 332*f*

Anterior diverticulum, 248

Anterior left upper lobe, in spectra of respiratory sounds, 11*f*

Anterior malignant teratoma, posteroanterior/lateral radiographs of, 1078*f*

Anterior mediastinum, widening of, thymus and, 147

Anterior right upper lobe, fluid-filled cysts in, 541*f*

Anterior superior mediastinum, benign thymoma (location), 1076*f*

Anterolateral right upper lobe, bilateral circumscribed densities in, 540*f*

Anteroposterior (AP) chest diameters, mean values of, 8*f*

Antiarrhythmic therapy, in pulmonary arterial hypertension, 578

Antibiotics

- for asthma during pregnancy, 653–654
- bacterial resistance and, 432
- for pneumonia, in human immunodeficiency virus–infected children and adolescents, 970*t*
- for pregnant, 250
- for preschool asthma, 685

Antibody-dependent cellular cytotoxicity (ADCC), eosinophil degranulation, 953

Anticholinergic agents, for asthma, 703

Anticoagulation, in pulmonary arterial hypertension, 572–573

Antigen detection assays, 402

Antigen presenting cells, 102*f*

Antigenic drift, in influenza virus, 460

Antigenic shift, in influenza virus, 460

Antiglomerular basement membrane (anti-GBM) disease, 897–898, 899*f*

Antihistamines, 739

Antiinflammatory mechanisms, 113–114

Antimetabolites, 879–880

Antimicrobial peptides, 125–126

Antimicrobial regimen, for pediatric lung transplantation, 984

Antimicrobial susceptibility testing methods, 403–404

Antimicrobial-resistant bacteria, in human immunodeficiency virus–infected children and adolescents, 969

Antineutrophil cytoplasmic antibody (ANCA), 867–869

- ANCA-associated vasculitis, 867–869

Antinuclear antibodies (ANA), presence of, 850–852

Antioxidant defense, in environmental exposures, 51, 52*f*

Antiphospholipid antibodies (APLA)

- presence of, 856, 895

Antiphospholipid syndrome, 572–573

Anti-PIV-specific immunoglobulin E (IgE), role of, 407–408

Antiretroviral therapy (ART), in human immunodeficiency virus–infected children and adolescents, 968

Antisecretagogues, 453–454

- impact, 453–454

Antistreptolysin O titer (ASOT), 1018

Antiviral immunization, 379

Antiviral treatment, for influenza, 463

AOP, Apnea of prematurity

Aorta, preductal coarctation, 18

Aortic arch, and derivatives, 616*f*

Aortic bodies, peripheral chemoreceptors, location of, 342

Aortopexy, 310

APAH-CHD, Associated pulmonary arterial hypertension with congenital heart disease

Aplasia, 320–322

- pulmonary, 321–322

Apnea, 1149–1159

- bronchiolitis and, 422
- caffeine treatment, 343
- central apnea, 1149–1152
- differential diagnosis, 1130
- home monitors, 1129–1130
- laryngeal chemoreflex apnea, 1126
- newborn infants, 343
- short duration, 1145

Apnea of prematurity (AOP), 1125

- first-line treatment of, 1133
- management and treatment of, 1133–1134
- methylxanthines for, 1133
- natural history of, 1132
- pathogenesis of, 1130–1131, 1132*f*
- prognosis of, 1132–1133
- treatment, high-flow therapy, efficacy of, 1133–1134

Apoptosis, 132–133

- in pulmonary arterial hypertension, 568

Apoptosome, 132–133

Apparent life-threatening event (ALTE), 1125

- clinical approach to, 1129, 1129*f*
- clinical features of, 1128
- differential diagnosis of, 1126*b*
- GER, impact, 1126

  - laboratory findings, 1129
  - management and treatment of, 1128–1129
  - physical findings, 1128
- Appendicitis, 796
- Architectural distortion, 168
- ARDS, Acute respiratory distress syndrome
- Area of reactance (AX), asthma and, 695
- Arnold-Chiari malformation, 306, 1148–1149
- Arousal, sudden infant death syndrome and, 1140
- ARQOLS, Asthma-Related Quality of Life Scale
- Arterial blood, reduced hemoglobin in, 17
- Arterial hemoglobin desaturation, mechanisms of, 17–18
- Arthritis-like signs, 448
- Arthrogryposis multiplex congenita, 1005*t*–1006*t*
- Aryepiglottic folds, 303
- *Ascaris lumbricoides*, 962
- ASL, Airway surface liquid
- ASOT, Antistreptolysin O titer
- Aspergillosis
  - in cystic fibrosis, 955
  - invasive, 515–518
    - clinical features of, 516
    - diagnosis of, 516–517
    - differential diagnosis of, 517
    - epidemiology of, 515
    - etiology of, 516
    - imaging of, 516
    - laboratory findings on, 516
    - management and treatment of, 517–518
    - pathology/pathogenesis of, 516
    - prevention of, 518
    - prognosis of, 518
    - pulmonary function testing for, 516

*Aspergillus flavus*, 516

*Aspergillus fumigatus*, 319, 516, 781

*Aspergillus nidulans*, 516

*Aspergillus* pneumonia, 928, 928*f*

*Aspergillus* species, 516

  in human immunodeficiency virus–infected children and adolescents, 975

  pulmonary infection and, 928–929

*Aspergillus terreus*, 516

Asphyxiating thoracic dystrophy, 384, 1005*t*–1006*t*, 1049, 1052–1054, 1054*f*, 1060–1061

Aspiration, 1094, 1097–1105

  evaluation, radiographic and endoscopic tests, role of, 1100–1101

  of gastroesophageal reflux, 1101–1103

  hydrocarbon, lung injury from, 626–633

    clinical findings of, 627, 627*f*

    diagnosis and differential diagnosis of, 627

    epidemiology of, 626

    etiology of, 626

    management and treatment of, 627–628

    pathology of, 626

    pathophysiology of, 626–627

    prevention of, 628

    prognosis of, 628

  of oral secretions, 1103

  protection against, 1097–1098

  swallowing dysfunction, caused by, 1097–1100

  upper airway infection, relationship, 443

Aspiration pneumonia, 354, 354*f*

Aspiration pneumonitis, in human immunodeficiency virus–infected children and adolescents, 978

Aspirin, 884

  asthma and, 693–694

Assist/Control (A/C) mode, 388

Assisted autogenic drainage (AAD), 279

Associated hypereosinophilic syndrome, 966*b*

Associated pulmonary arterial hypertension with congenital heart disease (APAH-CHD), 561–572

- survival in, 564

Asthma, 221, 286, 686–721

- acute episode of, management of, 717–719
  - in medical facility, algorithm for, 718*f*
- adherence to treatment regimen for, 717
- allergens and, 692
- allergic bronchopulmonary aspergillosis in, 952*b*
- allergic rhinitis
  - association, 737–742
  - epidemiologic relationship, 737–738
  - pathophysiologic connections, 739–740
  - and sinusitis, 693
- allergy testing for, 698
- altitude, 226–227
- anticholinergic agents for, 703
- antiinflammatory mechanisms in, 113
- atopic, 650–651
- beclomethasone for, 704–705
- biologic therapy for, 710
- biomarkers for, 701
- breast-feeding diet and, 655–656
- bronchial challenge and, 695–696, 695*t*
- budesonide for, 704
- chronic, management of, 711, 712*f*
  - sample treatment plan for, 716*f*
- chronic sinusitis, 745
  - epidemiologic relationship, 745
  - pathophysiologic links, 745
- ciclesonide for, 705
- classification of, 699–701
- complete blood cell count for, 696

control of
  determination of, 700–701, 700*t*
  impairment domain of, 698–699
  measures for, 701
  risk domain of, 698–699, 711
controller medications for, 703–705
corticosteroids for
  inhaled, 703–704, 704*t*
  systemic, 706–709
cough-variant, 690–691
cytokines in, 109–110
cytologic examination of sputum and, 696
deaths, 647
defined, 686
diagnosis of, 641, 690–693
diagnostic testing, 741
difficult, 726–730
early childhood and, 655–657
economic impact of, 648
education for, 729
emotional factors and, 693
endocrine factors of, 694
environmental contributions to, 55, 55*t*–56*t*
environmental influences on, 653–664
epidemiologic studies, defining, 641–642
epidemiology of, 640–664
epigenetics of, 652–653
etiology of, 688–689
exacerbations, immunology of, 674
exercise and, 217–223, 692–693
  role of, 217–218
exercise challenge test for, 696
exhaled nitric oxide and, 696–697, 697*t*
fluticasone propionate for, 704
food allergy and, 725
gastroesophageal reflux and, 693, 725

gene environment interactions in, 652, 653*t*
general treatment of, 719–721
genetics of, 651–652
high risk of death from, 723*b*
holding chambers and spacer devices for, 714, 714*t*
hospital management of, 719
hospitalization in, 646–647
HRQoL measures, 236*t*–237*t*
in human immunodeficiency virus–infected children and adolescents, 979
immunopathogenesis of, 665–676
    altered pulmonary immunity in, 665, 666*f*
    cells, molecules, and cytokines involved in, 665–669
    multiple interactions and factors leading to, 666*f*
    preschool wheeze, 671–674
    school age allergic asthma, 669–670
    specific clinical scenarios for considerations in, 674–675
    structural airway cells in, 670–671
immunopathology, 738
infections and, 657–659, 658*f*, 692–693
inflammation in, 104*f*
inflammatory subtypes of, 650
intermittent, 711–712
irritants and, 692
labile, 690
laboratory diagnosis of, 695
leukotriene antagonists for, 709–710
long-acting b-agonists for, 706–709
long-acting muscarinic antagonists for, 710
lung attacks, 734
lung function tests for, 695
maternal stress in, 250–251, 250*b*
measures, 234–235
    recommendation, 235
mild, 689
    persistent, 712–713
moderate, 689

    - persistent, 713
- modern molecular therapies, for application in managing childhood, 747–755
- mometasone for, 705
- mortality of, 646–647, 690
- natural history and prognosis of, 689–690
- nocturnal, 694
- nonallergic hypersensitivity to drugs and chemicals and, 693–694
- nonatopic, 650–651
- nonpharmacologic measures for, 715–717
- obesity and, 656–657, 725
- overview of, 640
- pathology of, 686–687, 687*f*–688*f*
- pathophysiology of, 687–688
    - inflammatory cell biology and, 688–689
- peak expiratory flow rate monitoring for, 714–715
- pharmacologic management of, 701
- phenotypic variation in, 648–651
- physical examination for, 691–692, 692*f*
- plus extrapulmonary comorbidities, 724–726
- pregnancy and childbirth and, 653–655
    - fetal growth and birth size, 654–655
    - maternal factors, 653–654
    - maternal lifestyle and environment, 654
    - mode of delivery, 655
- in preschool age child, 677–685
    - clinical patterns of wheeze in, 679
    - diagnosis of, 677–678, 678*t*
    - environmental factors of, 679
    - epidemiology of, 677, 678*f*
    - natural history of, 679
    - pathology of, 679
    - treatment of, 680–685, 684*f*
- prevalence of, 642–646
    - childhood, outcomes of, 646
    - in gender and ethnicity, 645–646
    - spatial variation in, 644–645
    - temporal variation in, 642–644, 643*f*–644*f*
- prevention of, 749

quality of life in, 648
radiographs for, 698, 699*f*
reliever medications for, 701–703
rhinitis therapy, effects, 738–739
rhinosinusitis and, 725–726
safe sleeping zone, 715
serum tests for, 697–698
severe, 647, 650, 722–736
    adherence and, 727–728
    airway inflammation assessment, 731–732
    airways disease deconstructed, 723, 731*b*
    definitions of, 722–723
    differential diagnoses of, 725*t*
    environmental factors of, 728–729
    exacerbating phenotype, treatment of, 734–735
    hospital admission for, 729–730, 730*b*
    investigation of, modified diagnostic protocol for, 724, 724*f*
    overarching principles of, 722
    persistent, 713–714
    persistent airflow limitation in, assessment of, 732–733
    problematic, 723*b*
    psychosocial morbidity and, 729
    steroid responsiveness assessment, 732, 732*t*
    therapy-resistant, 730–732
    types of, 723
severity of, 223*f*, 646–647, 698, 700–701
    measures for, 701
short-acting b agonists for, 701–703
sinus therapy
    effects, 738–739
    medical treatment, 744–745, 746*b*
    surgical treatment, 744
sleep disordered breathing and, 726
study of, epidemiologic approaches to, 640–641
sweat test and, 698
symptoms
    improvement, 739
    reporting, 729
syndromes of vocal cord dysfunction and, 726

  - systemic corticosteroid treatment of, tapering of, 962
  - temporal progression of symptoms of, 648–650, 649*f*
  - theophylline for, 710
  - therapeutic considerations for, 698–699
  - therapy, 454
  - transcription factors and, 112, 113*f*
  - treatment considerations, 221–223
  - triggers of, 692
    - avoidance of, 715
  - uncontrolled, 218, 722
  - weather changes and, 692
- Asthma-Related Quality of Life Scale (ARQOLS), 236*t*–237*t*
- Asthmatics
  - radiologic sinusitis
    - features, 743–744
    - prevalence, 743*t*
  - responses, 692
- Astra, 280*f*
- Asymmetrical lung volume, 148–149, 149*f*
- Asymptomatic pulmonary function abnormalities, 859
- Ataxia telangiectasia (AT), 821, 921
- Atelectasis, 1027–1033
  - during anesthesia, 1027
  - causes of, 1028*b*
  - chest physiotherapy of, 1031
  - clinical manifestations of, 1028–1029, 1029*f*
  - congenital, 1027
  - cystic fibrosis and, 780
  - definition of, 1027
  - diagnosis of, 1029–1031, 1030*f*, 1030*t*
    - bronchography, 1031, 1032*f*
    - chest radiography, 1029–1030
    - CT usage, 1030, 1030*f*–1031*f*
    - fluoroscopy, 1029–1030, 1029*f*

- magnetic resonance imaging, 1030–1031, 1031*f*
- ultrasound, 1031, 1031*f*
- etiology of, 1027
- as mechanical ventilation complication, 599–600
- pathogenesis of, 1027
- pathogenic mechanisms of, 1027–1028
- presence of, 1028
- prevention of, 1032–1033
- secondary, 1027
- in smoke inhalation, 630
- sound transmission and, 8–9
- total obstruction, lesion persistence, 1088*f*
- treatment of, 1031–1032
- ultrasonography, usage, 1031

Atopic asthma, 650–651

Atopic status, independent, 103

Atopic wheezers, 679

Atopy, 725

ATRA, All-*trans* retinoic acid

Atresia
- bronchial, 321*f*
- congenital bronchial stenosis, 311
- esophageal, 322–324, 1003
- laryngeal, 304–306
- pulmonary, 622–624
- tracheal, 298, 299*f*, 299*t*
- upper respiratory tract, 298, 299*f*

Atrial premature contractions, 21

Atrial septostomy, in pulmonary arterial hypertension, 578

Attention deficit hyperactivity disorder (ADHD)
- OSA and, 1158
- periodic leg movements, 1155*f*

Attentional capacity, changes, 232–233

Auerbach's plexuses, presence, 1085

*Aureobasidium pullulans*, contamination with, 946–947

Auscultation, 10–14

- technique of, 12–14, 13*f*–14*f*, 13*t*–14*t*
- thoracic acoustics, 10–12, 10*f*–11*f*

Auscultatory signs, basis of, 14

Autocrine-paracrine interactions, in lung injury and repair, 37

Autogenic drainage, 278*f*, 280*f*

Autoimmune pulmonary alveolar proteinosis

- term, usage of, 839
- whole lung lavage for, 847–849

Autonomic nervous system

- development of, 384–385
- dysfunction, 1150–1151

Autophagy, 132

Autosomal dominant disorders, 41

Autosomal recessive *CSF2RA* mutations, 839–840

Autosomal recessive *CSF2RB* mutations, 840

Autosomal recessive neurodegenerative disorders, 1047

Autosomal-recessive CGD, 909

Avian antigens, in hypersensitivity pneumonitis, 944

Azathioprine, 883

Azithromycin

- for cystic fibrosis, 785
- for nontuberculous mycobacterial infections, 504*t*
- for pertussis, 533

**B**

Bacillus Calmette-Guérin (BCG) vaccination, 6–7
  - for tuberculosis, 496

Back-to-Sleep campaign, 1140

Bacterial antigens, detection, 430

Bacterial colonization, 1119–1120, 1120*t*

Bacterial pneumonia, in human immunodeficiency virus–infected children and adolescents, 969–970
  - antibiotic treatment of, 970*t*

Bacterial tracheitis
  - clinical features of, 415
  - epidemiology of, 414
  - etiology of, 414
  - management of, 415
  - pathology of, 414

Bactericidal assays, 913

Bacteriologic complications, of bronchoscopy, 146

Bag mask valve, 284*f*

BALF, Bronchoalveolar lavage fluid

Barium swallow, 156, 334, 336*f*
  - for vascular rings, 619

Barrel-shaped chest, 6

Basal cells (BCs), 66*f*

Basement membrane, thickening of, asthma and, 686–687, 687*f*

Basophils, 108

B-cell immunodeficiencies, 920

BCG vaccine, in HIV-infected children, 972

Beckett, Katie, 382

Beclomethasone, for asthma, 704–705

Bed sharing, sudden infant death syndrome and, 1141

Bedaquiline, for drug-resistant tuberculosis, 494

Benign cystic teratoma, 1075–1077
- mediastinal dermoid cyst, 1075–1076

Benign neurofibromas, pediatric rarity, 1080

Benign solid teratoid tumors, 1077

Benign thymoma, 1075
- anterior superior mediastinum location, 1076*f*

Benralizumab, 754

Berkson fallacy, 724–725

Bernoulli principle, 406

Beta sympathomimetics, effects of, 21

Beta-adrenergic agonists, for acute respiratory distress syndrome, 613

BHR, Bronchial hyperresponsiveness

Bilateral congenital small lungs, causes of, 322*t*

Bilateral diaphragmatic paralysis, 384

Bilateral paralysis, 1121

Bile flow (improvement), ursodeoxycholic acid (usage) and, 793

Biogenesis, 759

Biologic therapy, for asthma, 710

Biological agents, for severe therapy-resistant asthma, 734

Biologics, 754

Biomarkers, for asthma, 701

Biopsy, 143
- liver, for non-CF-related liver disease, 792
- lung, in hypersensitivity pneumonitis, 950–951, 951*f*

Biot breathing, 5

*Bipolaris* spp., 526

Bird fancier's lung, 944

Birth

- changes in the circulation at, 354–355
- depression, 339
- functional residual capacity, 338
- respiration, initiation, 338

Birth cohort study, in asthma, 640–641

Birth size, on asthma, 654–655

*Blastomyces dermatitidis*, 514

Blastomycosis, 514–515, 514*f*

- pulmonary infection and, 929–930

Bleomycin

- lung injury caused by, 876–878
- withdrawal, 878–879

Blood, gas analysis, 609

Blood clots, therapeutic bronchoscopy for, 144

Blood flow, distribution of, 82–83, 83*f*

Blood oxygenation, assessment of, 91–92, 92*f*

Blood specimens, 401

Blood vessels, increased number of (angiogenesis), 102–103, 103*f*

Blood volume, increase in, 589

Blue light lasers, for pediatric airways, 144

B-lymphocytes, 107–108

- in IgE production, 107–108
- lung defense and, 130–131

BMPR2 mutations, in pulmonary arterial hypertension, 560

Body, interior of, visualization of, 134

Body mass index (BMI), percentile, 239

Body plan, formation of, 26

Body plethysmography, 176–177

Body ventilators, 387–388

BOOP, Bronchiolitis obliterans organizing pneumonia

*Bordetella*, 528

*Bordetella bronchiseptica*, 528

*Bordetella holmesii*, 528

*Bordetella parapertussis*, 528

*Bordetella pertussis*, 528

- pneumonia associated with, 969

*Bordetella petrii*, 528

*Bordetella* resistance to killing factor (brkA), in *Bordetella* pertussis, 530*t*

*Bordetella trematum*, 528

Botulinum toxin injection, 1103

Boyle's law, 74, 177

Boys

- chest diameters of, mean values of, 8*f*
- neuroblastoma in, 1081*f*
- thymic cyst in, 1077*f*

Bradycardia, presence of, 346–347

Bradypnea, 4

Brain, after drowning, magnetic resonance imaging of, 637*f*

Brain stem, dysfunction, 1150–1151

Branching morphogenesis, 26–27, 35–36

- lung proliferation during, control of, 36

Breast-feeding diet, on asthma, 655–657

Breast milk, as exposure pathway, 49

Breath condensate, exhaled, 117–118

Breath print, 697

Breathing, 190

- absent, decreased, or irregular, BRUE definition and factors for inclusion and exclusion, 1126*t*
- exercises, 287
- noisy, 16, 17*b*
- pattern
  - disorders, 286
  - inspection of, 4
- rhythm of, changes in, 4–5
- sleep disordered, asthma and, 726
- technique, active cycle, 280*f*
- ventilation and mechanics of, 73
- work of, 80–81
  - support, 3

Breathlessness, exercise-induced, 726

- differential diagnosis of, 726*b*

BRICHOS, 838

Bronchi (bronchus), lumens, lesions of, 1088*f*

Bronchial abnormalities

- branching, 311–312, 311*f*
- congenital, 311–313
- laterality, 312

Bronchial adenomas, 1072–1073

- histologic types, definition of, 1072–1073
- symptoms/signs of, 1073

Bronchial arteries, 68

Bronchial brushing, 143

Bronchial buds, 1008*f*

Bronchial challenge, 950

- asthma and, 695–696, 695*t*

Bronchial change, 167–168, 168*f*

Bronchial circulation, 893
    role of, 580
Bronchial disease, in tuberculosis, 479–480, 480*f*–481*f*
Bronchial diverticula, 311–312
Bronchial epithelial function, altered, in asthma, 665
Bronchial hyperreactivity, 872–873
Bronchial hyperresponsiveness (BHR), 641–642
Bronchial lumen occlusion, 1027
Bronchial reactivity, exercise, 220
Bronchial rupture, management of, 1066
Bronchial stenosis, 144
    therapeutic bronchoscopy for, 144
Bronchial tree, as proximal conducting zone, 63
Bronchiectasis, 14–15, 439–459, 440*f*, 1041
    airway clearance methods, 454
    antiinflammatory agents, 453
    antimicrobials, 453
    antioxidant agents, 453
    antisecretagogues, 453–454
    asthma therapy, 454
    Bhalla score, 450–451
    bronchial structural changes, vascular changes, 445
    bronchoscopic findings, 449–450
    causes, 442*t*
    chest HRCT scans
        diagnosis, 449*b*
        features, 448*b*
    c-HRCT evidence, 439
    clinical features, 447–448
    comorbid conditions, 447–448
    CSLD, contrast, 439
    CT scan findings, 445*f*

definition of, 439–440
development, 446*f*
  radiologic risk factors, 447
diagnosis of
  delay, 447
  median age, 447
diagnostic criteria, 448
diagnostic evaluations, 448–452
disease progression, assessment, 451
economic cost, 441
environmental modification, 454
epidemiology of, 440–444
etiologic evaluation, 449
etiologic risk factors, 441
etiologies of
  evaluation, 449*t*
  studies, 443*t*
exacerbations, assessment/importance, 452
genetics, 444
health care, 455
in human immunodeficiency virus–infected children and adolescents, 978
infection, assessment, 451–452
initial trigger, 445
lobectomy, indications/contraindications, 455*b*
macro malnutrition/micro malnutrition, impact, 443–444
malnutrition, predisposition, 443–444
management
  issues, review, 452*b*
  principles, 452–455
mucoactive agents, 453–454
mucociliary clearance, 445
negative predictive value, 451
nonsteroidal antiinflammatory agents, 453
pathology/pathophysiology, 444–447
positive predictive value level, 451
predisposing factor, 444

  - presenting clinical features, 447
  - prevalence, 440–444
  - prevention, 454
  - prognosis, 455–456
  - public health issues, 443–444
  - in pulmonary tuberculosis, 480–481, 481*f*
  - radiographic finding, 448
  - radiographic scoring systems, 450–451
  - severity, 447
    - assessment, 450–451
  - signet ring appearance, high-resolution finding, 448*f*
  - social determinants, 455
  - surgical considerations, 454–455
  - technology dependence, 385
  - upper airway infection/aspiration, 443
  - vaccines, impact, 454
  - varicose/cystic changes, 444*f*
  - worsening, 454
- Bronchiolar lining layer, 65
- Bronchiole, light micrograph of, 66*f*
- Bronchiolitis, 287, 420–426
  - associated with all respiratory viruses
    - high-risk population for, 420
    - population risk for, 420
  - clinical features of, 421–422
    - clinical scores, 422, 423*t*
    - disease severity, 422
    - imaging, 422
    - laboratory findings, 422
    - physical findings, 422
    - symptoms, 421–422
  - diagnosis of, 404, 422–425
  - differential diagnosis of, 422–425
  - epidemiology of, 420–421
  - etiologic agents with, 397*t*

- etiology of, 421
- guidelines for, 424, 424*t*
- management of, 425
- mechanical ventilation in, 553
- pathology/pathogenesis of, 421
- physical therapy, impact, 287
- in preschool asthma, 677
- prevention of, 425–426
- prognosis of, 426
- respiratory syncytial virus
  - high-risk population for, 421, 421*f*
  - population risk for, 420
- treatment of, 425

Bronchiolitis obliterans (BO)
- clubbing in, 19
- in human immunodeficiency virus–infected children and adolescents, 978, 978*f*
- in pediatric lung transplantation, 988

Bronchiolitis obliterans organizing pneumonia (BOOP), 850

Bronchiolitis obliterans syndrome, 938–939, 938*f*
- in pediatric lung transplantation, 988

Bronchitis, protracted bacterial bronchitis, 456–459

Bronchoalveolar lavage (BAL), 139–142, 941
- across studies
  - limitation, 1104–1105
  - lipid-laden macrophage index *versus*, 1102*f*
- assays, 142*b*
- bacterial presence, 443
- cell profiles, usage of, 866
- as diagnostic tool, 815
- excessive volumes of topical anesthetic, 140
- findings, interpretation of, 141–142
- human defensins in, 126
- in hypersensitivity pneumonitis, 950–951
- increasingly utilized, 876

- indications for, 139–140, 139*b*
- performing, 141
- processing of, 141
- research application of, 142
- samples of, 134
- sampling, allowance of, 1088–1090
- severe asthma and, 729
- techniques for, 140–141

Bronchoalveolar lavage fluid (BALF), 61
- from CF, 778–779
- culturing, 772
- in hypersensitivity pneumonitis, 948
- surface tension lowering properties, reduction of, 842

Bronchobiliary fistula, occurrence of, 539

Bronchoconstriction, 221–223
- as airway reflexes, 120–121
- inadequate, 66

Bronchodilation, 69

Bronchodilators
- for preschool asthma, 683
- response, assessment of, 189, 190*f*
- use of, 379

Bronchogenic carcinoma, 1073

Bronchogenic cysts (foregut cysts), 1081–1083, 1083*f*
- asymptomatic characteristic, 1082
- classification of, 1081

Bronchography, of atelectasis, 1031, 1032*f*

Bronchomalacia, 450*f*

Bronchoprovocation challenge testing
- direct, 695
- indirect, 695–696

Bronchopulmonary anatomy, nomenclature of, 64*f*

Bronchopulmonary dysplasia (BPD), 367–381

- altitude, 227
- antiviral immunization, 379
- bronchodilators, 379
- cardiovascular abnormalities, 374–375
- chest radiographs of, 368*f*
- clinical findings of, 375
- corticosteroid therapy, 377
- definition of, 367–369, 369*f*
- diagnostic criteria for, 369*t*
- diuretics, usage, 379
- drug therapies, 379
- epidemiologic studies of, 370–371
- epidemiology of, 369–370
- etiology of, 370–372
- genetic susceptibility, 371
- histologic features of, 368*f*
- HRQoL measure, 240
- imaging of, 375
- incidence of, 370, 370*f*
- in infants, chest radiograph of, 373*f*
- inflammation, 372–373
- laboratory findings of, 375
- late pulmonary hypertension, mortality with, 374*f*
- long-term outcome, 376
- lung pathophysiology, 374*f*
- oxygen toxicity, 372
- pathogenesis, of, 372–373, 372*f*
- pathologic features of, 369*t*
- pathophysiology of, 373–375
- physical findings of, 375
- postnatal factors of, 371–372
- prenatal factors of, 371

  - prevention of, 376–378
  - prognosis of, 380
  - pulmonary circulation, 373–375
  - pulmonary function tests, 375
  - pulmonary hypertension and, 357–358, 379–380, 560–561
  - respiratory disease with risk for, 370*f*
  - respiratory function, 373
  - steroids, use of, 379
  - systemic administration, adverse effects, 377
  - technology dependence, 385
  - treatment of, 378–380
  - ventilator-induced lung injury, 372
- Bronchopulmonary secretion, removal of, physical therapy and, 273
- Bronchopulmonary sequestration, 296
- Bronchoscope
  - care and maintenance of, 135
  - flexible, 134–135
  - manipulation of, 136
  - nomenclature, 134
  - rigid, 134
- Bronchoscopic intubation, 145
- Bronchoscopy, 134–146, 334–335
  - anesthesia for, 136–137, 138*f*
  - complications of, 145–146
  - contraindications to, 139
  - economic aspects of, 146
  - for examination of airway, 134
  - facilities for, 135
  - flexible, 136, 136*t*
  - instrumentation for, 134–135
  - rigid, 135–136
  - specimens, 400
  - techniques for, 135–136

  therapeutic, 143–145

  for vascular rings, 619

Bronchospasm, asthma and, 688

Bronchus, bronchoscope, wedged into, 140

Brownian motion/diffusion, 260

BRUE, 1125

  definition and factors for inclusion and exclusion, 1126*t*

Bruxism, 1154*f*

bteA, in *Bordetella* pertussis, 530*t*

B-type natriuretic peptide (BNP), usage of, 587

Budesonide, for asthma, 704

Bulbar musculature, weakness of, 384

*Burkholderia cepacia* complex (BCC) organisms, 982

Busulfan (Myleran), 879

BVG intermediate-phase, in *Bordetella* pertussis, 530*t*

**C**

CAD, Congenital alveolar dysplasia

Caesarean section delivery, 251

Calcineurin inhibitor (CNI), 984

Calcitonin-gene-related peptide (CGRP), 112, 120–121

Calcium channel blockade, 573–575

  epoprostenol treatment for, 564–565

Calcium channel blockers, use of, 380

Calcium-dependent chloride channels (ClCa), 777

Calor, inflammation and, 101

Calreticulin/CD91, actions of, 60

Camellote sign, 539

CA-MRSA, Community-associated MRSA

Canalicular period, 28*f*, 30

Canalicular phase, 248

Canalicular stage, 70

Cancer therapy, cytotoxic drugs used in, 876–881, 877*t*

*Candida* species, 518

- pulmonary infection due to, 929

Candidate gene approach, in asthma, 651–652

Candidiasis, pulmonary, 518–520

- clinical features of, 519
- diagnosis of, 519
- differential diagnosis of, 519
- epidemiology of, 518
- etiology of, 518
- imaging of, 519
- laboratory findings on, 519
- management and treatment of, 519–520
- pathology/pathogenesis of, 518–519
- prevention of, 520
- prognosis of, 520
- pulmonary function testing for, 519

CAP, Community-acquired pneumonia

Capillaries

- absolute concentration of reduced hemoglobin in, 17
- endothelial membrane of, 580

Capillary leak syndrome, 936

Capillary malformations, 329

Capnometry, 390–391

CAQ, Childhood Asthma Questionnaire

Carbamazepine, 882

Carbohydrate recognition domain (CRD), 57

Carbon dioxide

- addition of, to blood, 97
- in blood, 96*t*
- dissociation curve, 95*f*
- level of, elevated, 18
- in sensory feedback system, 99
- transport, 94–97

Carbon monoxide

- in diffusing capacity, 88
- poisoning, 629, 629*f*
- transfer, 254

Cardiac arrhythmia, 634

- detection of, 21
- sudden infant death syndrome and, 1139

Cardiac catheterization

- in pediatric pulmonary arterial hypertension, 571–572
- studies of, 373

Cardiac disorders, congenital, 332

Cardiac effusions, in Down syndrome, 999

Cardiac failure, pulmonary edema and, 589

Cardiac glycosides, in pulmonary arterial hypertension, 578

Cardiac output, decreased, 18

Cardiac surgery, pulmonary complications of, 625, 1002*t*

Cardiac trauma, 1067–1068, 1068*f*

Cardiac wounds, suspicion, 1067

Cardiomyopathy, in human immunodeficiency virus infected children, 979–980

Cardiopulmonary bypass, pulmonary complications related to, 625

Cardiopulmonary exercise testing (CPET), 213–214, 213*f*, 572

- challenge, 215–216
- modern, 214
- normal values, 216
- protocol, 214–215
- variables, 215*f*

Cardiorespiratory compromise, 1109

Cardiorespiratory monitoring, use of, 390–391

Cardiorespiratory sounds, 12

Cardiothoracic ratio, 147

Cardiovascular abnormalities, 374–375

Cardiovascular signs, 19–21

Cardiovascular system, assessment of, 21

Care, pediatric/adult models (differences), 242

Carinal bronchogenic cyst, posteroanterior chest radiograph (overexposure), 1082*f*

Carmustine (BCNU), 879

Carotid bodies, peripheral chemoreceptors, location, 342

Carpal tunnel syndrome, 860–861

Cartilaginous congenital subglottic stenosis, 308

Cascades, 38

Caseating consolidation, in pulmonary tuberculosis, 480, 481*f*

Case-control study, in asthma, 640–641

CASI, Composite Asthma Severity Index

Casoni skin test, 540–541, 541*f*

Caspofungin, for mucormycosis, 523

b-catenin, in gene expression, 26

Cathelicidin, 126

CBAVD, Congenital bilateral absence of the vas deferens

CCAM, Congenital cystic adenomatoid malformation

CCHS, Congenital central hypoventilation syndrome

CCSP, Club cell secretory protein

CD4/CD8 ratio, depressed, 880

CDH, Congenital diaphragmatic hernia

Cefoxitin, for nontuberculous mycobacterial infections, 504*t*

Cell adhesion, role of, 36–37

Cell proliferation, in pulmonary arterial hypertension, 568

Cell shape, role of, 36–37

Cells
  function of, 63
  junctions (zonulae occludentes), 67
  in pediatric allergic asthma, 665–669

Cell-to-cell contact, promotion of, 372–373

Cellular debris, 844

Cellular defenses, 126–129

Cellular distribution/function, 759

Centers for Disease Control and Prevention (CDC), in quality of life, in asthma, 648

Central apnea, 1149–1152

Central chemoreceptors
  development of, 1145–1146
  impact of, 342

Central chemosensitive centers, multiplicity of, 1146

Central hypoventilation syndrome (CHS), 1149–1150, 1149*b*

Central intracellular R domain, presence, 758–759

Central nervous system (CNS), programmed cell death, 1137–1138

Central nervous system disease, in extrathoracic tuberculosis, 483–484

Centrilobular nodules, in hypersensitivity pneumonitis, 949–950

Centrioles, cilia derivation, 63–65

Cephalosporin, 414

Cerebral hydrogen 1 magnetic resonance spectroscopy, 638*f*

Cerebrocostomandibular syndrome, 1005*t*–1006*t*

Cervical injury, impact of, 384

Cervical lymphadenopathy, 418

Cervicomediastinal lymphangioma, diagnosis of, 1079

Cetuximab, 880–881

CF, Cystic fibrosis

CF transmembrane conductance regulator (CFTR), 777

C-fiber receptors, 69

CFRD, Cystic fibrosis-related diabetes mellitus

CFTR, CF transmembrane conductance regulator

CFTR-related metabolic syndrome (CRMS), 773–774

CGD, Chronic granulomatous disease

CGRP, Calcitonin-gene-related peptide

Challenge materials, studies, 740

Challenge to personalizing therapy, for preschool asthma, 680

CHAOS, Congenital high airway obstruction syndrome

Charcot-Leyden crystal protein, 953

CHARGE association, 1099–1100

Charles' law, 74

Chemicals, nonallergic hypersensitivity to, asthma and, 693–694

Chemokines, 105, 110–111, 111*f*, 121

Chemoprophylaxis, for influenza, 464

Chest

- action, diagram of, 1063*f*
- auscultation, 10–14
  - performing, 12
- cardiovascular signs in, 19–21
- circumference
  - distribution of, 7*f*
  - mamillary level of, 6
- configuration, objective documentation of, 6
- deformities, 6*f*
- expansion, symmetry of, 8–9
- fluid-filled cysts in, CT confirmation of, 541*f*
- high-resolution computed tomography scan of, in hypersensitivity pneumonitis, 949*f*
- inspection, palpation and, 8
- movement of, 5
- percussion of, 9–10
  - performing, 9*f*
- radiographic examination of, 1087–1088
- surface of
  - pulmonary lobes on, projections of, 13*f*
  - symmetric sites of, 9
- tube insertion, 1065
- tumors of, 1072–1092
  - epidemiology of, 1072
  - etiology of, 1072
- vertical reference lines of, 9*f*

Chest disease, in children, signs and symptoms of, 14–23
- cardiovascular signs, 19–21
- chest pain, 22–23, 23*b*
- cough and sputum, 14–16, 16*t*
- cyanosis, 17–18, 18*f*
- digital clubbing, 18–19, 19*b*, 20*f*
- exercise limitation and dyspnea, 21, 22*f*
- noisy breathing, 16, 17*b*
- wheezing, 16–17, 17*b*, 18*f*

Chest high-resolution computerized tomography (c-HRCT)

- irreversible dilatation, 439–440
- radiological features, 439
- scans, timing, 440

Chest pain, 22–23
- causes of, 23*b*
- treatment of, oral/sublingual nitrates in, 578

Chest physiotherapy, 287, 1031

Chest radiography, 333, 333*f*
- for atelectasis, 1029–1030
- for bronchiolitis, 422
- features of, 147–148
- lateral view of, 150*f*
- for pulmonary edema, 586–587
- systematic review of, 148–156
- for vascular rings, 619

Chest wall
- anterior axillary fold and, 148
- augment inspection of, 6
- compliance, increase of, 1148–1149
- elastic properties of, 76, 77*f*
- function, assessment, 1046*b*
- injury, tracheostomy in, 1064
- movements, 1046
- in newborn, 1044, 1045*f*
- respiratory muscle disorders and, 1044–1061
  - considerations in, 1044–1045
- tumors, 1073–1074

Chest wall deformities
- prevention of, 284
- visual perception of, 6
  - optical markers in, 6*f*

Chest wall disorders, 287
- clinical features of, 1049–1053

- congenital, 329–332
- diagnosis of, 1053–1054
- etiologies of, 1046–1047
- involving bony structure of
  - clinical features of, 1051–1053
  - diagnosis of, 1054
  - management of, 1058–1061
  - pathogenesis of, 1048–1049
- management of, 1054–1061
- pathogenesis of, 1047–1049

Chest wall dysfunction
- causes of, 1047*t*
- general management of children with, 1054–1055
- respiratory function, assessment, 1046–1047

Cheyne-Stokes breathing, occurrence of, 5

Chiari malformation, 384–385

ChILD, Childhood interstitial lung disease

Child Health and Illness Profile, 232

Childbirth, pregnancy and, asthma on, 653–655
- fetal growth and birth size, 654–655
- maternal factors, 653–654
- maternal lifestyle and environment, 654
- mode of delivery, 655

Childhood, Children
- asthma
  - diet and, 656
  - management of, 110
  - outcomes of, 646
- chronic granulomatous disease, 909
- genetic variation, lung disease and
  - interpretation of, 43
  - research study designs to, 44–46, 45*t*
  - technologies to identify, 41–43
  - type of, 40–41, 41*f*, 43*t*
- lung disease and, 40–48, 41*f*, 42*t*

        - clinical genetic testing, 44, 44*f*
    - OSA, adenotonsillar hypertrophy, 1154
    - pulmonary arterial hypertension, 556–579
    - sternum, fractures of, 1063
    - systemic inflammatory disease of, pulmonary involvement in, 850–875
        - approach to, 874*b*
        - diagnosis/management of, 873–874
        - serologic test for, 851*t*
        - significant, 872–873
    - systemic scleroderma in, rarity of, 860
    - taste and smell, examination of, 14
- Childhood Asthma Management Program (CAMP) research group, 646
- Childhood Asthma Questionnaire (CAQ), 234, 236*t*–237*t*

    - radiographic testing for, 940, 940*t*
    - viral pathogens in, 924–927
- indications and special considerations for, 175–176
- intrathoracic lipoma rarity in, 1079
- laryngeal anatomy of, 406
- lung sounds of, objective acoustic measurements of, 11
- lungs in, adults and, contrast between, 609
- malnutrition in, 3
- mechanical ventilation in, studies on, 610
- medical history of, 3
- methacholine bronchial provocation in, 18*f*

nasal interfaces for, 389
nasal passageways of, inspection of, 16
neck, adenoid tissue enlargement/OSA, lateral roentgenogram, 1153*f*
neurological injury in, 637
obesity, 215–216
  asthmatic, 219
obstructive sleep apnea
  conditions, 1154–1156, 1156*b*
  polysomnographic measures, 1152*f*
with oligoarticular disease, ANA presence in, 850–852
palpation in, 8–9
physical activity
  biological importance, 212
  levels, reduction, 212
physical development of, 3
physical inactivity, effects, 212
pneumonia in, 427–438
posteroanterior film, 147
prior tests and immunizations in, detailed report, 4
psychosocial concerns for, 983
REM-associated obstructive apneic events, polygraphic tracing, 1153*f*
respiratory symptoms, presentation of, 3
respiratory tract, diseases in, 3
secondary pneumothorax of, 1010*t*
sleep-disordered breathing, polysomnographic montage, 1157*b*
sleep-related breathing disorders, HRQoL measures, 239*t*
study of CPET in, 216
with suspected tumors of chest, general approach to evaluation of, 1087–1090
systemic inflammatory disease in, pulmonary manifestations of, 851*t*
systemic lupus erythematosus (SLE) in
  pulmonary hemorrhage, rarity of, 855
  pulmonary hypertension, rarity of, 855–856
technical and staff requirements for, 175–176, 176*f*
traumatic thoracic injury in, 1062
tuberculosis in, 478, 478*t*, 479*f*
with Turner syndrome, 839–840

- upper airways of, partial obstruction of, 16
- upper respiratory tract infection, posteroanterior chest radiograph, 1084*f*
- vulnerability of, to adverse environmental exposures, 49–54

Children's interstitial lung disease (chILD)
- bronchoalveolar lavage (BAL) in, usage of, 815
- bronchoscopy in, usage of, 815
- classification of, 813–814
- diagnostic approach of, 814–816
- diffuse pediatric lung disease classification, proposal, 814*t*
- families and physicians, resources for, 816
- genetic testing in, 815
- lung biopsy for, 816
- new concepts in, 813–816
- noninvasive testing, completion of, 814
- retrospective studies in, 814
- terminology in, 813–814

Children's Interstitial Lung Disease Research Network (ChILDRN)
- in lung biopsy identification, 825
- study, 829–830

ChILDRN, Children's Interstitial Lung Disease Research Network

Chlamydia organism, 106

*Chlamydia pneumoniae*, infections, occurrence, 427

Chloral hydrate, for infant sedation, 175

Chloramphenicol, intravenous, 414

Chlorine gas, inhalation of, 591

Cholesterol needles, 844

Chondromas, 1074

“Chord” compliance (Cchord), 193–194

c-HRCT, Chest high-resolution computerized tomography

Chromatin state, 34

Chromatin topology/3D structure, 34

Chromosomal microarray (CMA), 41, 45*t*

Chronic anticoagulation, consideration of, 572–573

Chronic aspiration
- causes of, 1098*f*
- histopathology of, 1098*f*
- lung injury, 1104*f*
- multidisciplinary approach, 1104–1105
- rigid bronchoscopy, consideration, 1104

Chronic asthma
- clubbing in, 19
- management of, 711, 712*f*
  - sample treatment plan for, 716*f*

Chronic cough
- causes of, 16*t*
- long-term risk for, 878

Chronic disease, self-management, 244

Chronic eosinophilic leukemia, not otherwise specified, criteria for, 965*b*

Chronic eosinophilic pneumonia, 960–961

Chronic eosinophilic pneumonitis, characteristics of, 959*t*

Chronic granulomatous disease (CGD), 909–917
- chest roentgenogram for, 911*f*
- clinical features of, 909–910
- clinical findings in, 910*t*
- defect in phagocyte function and, 909
- diagnosis of, 911–913
- encapsulated pneumonia in, 912*f*
- fluorescence-based screening assays on, 913
- gene therapy for, 916–917
- hematopoietic cell transplantation for, 916–917
- “honeycombing” in, 911
- inheritance, 914–915

  - laboratory findings on, 911–913
  - management of, 915–916
  - molecular defects in, 914–915, 914*t*
  - nitroblue tetrazolium (NBT) test for, 913
  - positive screening test for, 913
  - pulmonary complications of, 910–911
  - pulmonary disease, expression of, 911
  - pulmonary infections, range of microbial agents causing, 910–911, 911*t*
  - purulent rhinitis, clinical features, 909
  - registry, patient enrollment for, 909, 910*t*
  - screening tests for, 911, 913
- Chronic hypersensitivity pneumonitis, 949
- Chronic illness, 2
- Chronic infection, in human immunodeficiency virus–infected children and adolescents, 977

- radiologic findings of, 429–430
- serologic tests for, 430
- sputum examination for, 430
- treatment of, antibiotic dosages, 434*b*
- tuberculosis, consideration, 431

Community-associated MRSA (CA-MRSA), 433, 435

Comorbidities, extrapulmonary, asthma and, 724–726

Comparative auscultation, 12

Complement proteins, in lung defense, 125

Complement-derived chemoattractants, 778–779

Complete blood cell count, for asthma, 696

Complete tracheal rings, 1124

Compliance, 189–190
- of lungs, 75–76
- measurement of, 189–205
  - forced oscillation technique in, 199–205, 200*f*–201*f*, 203*f*–204*f*
  - general considerations for, 194, 194*f*–195*f*
  - interpretation of, 191–194, 191*f*–193*f*
  - measurement of interrupter resistance in, 196–198, 197*f*
  - physiological principles and assumptions in, 190–191
  - plethysmographic measurement of airway resistance and, 198–199, 199*f*
  - single-breath occlusion technique, 194–196, 195*f*

Composite Asthma Severity Index (CASI), 701

Compression phase, 121

Computed tomography (CT), 149–150, 157, 157*f*, 334, 335*f*

- for cystic fibrosis, 792, 792*f*
- for pulmonary edema, 587, 588*f*
- for vascular rings, 619

Computed tomography (CT) angiography, for pulmonary embolism, 889

Confidentiality, establishment, 243

Congenital abnormalities of the trachea, 309–310

Congenital alveolar capillary dysplasia, 327

Congenital alveolar dysplasia (CAD), 999

Congenital alveolar proteinosis, term, 840

Congenital atelectasis, 1027

Congenital bilateral absence of the vas deferens (CBAVD), 767–768

Congenital central hypoventilation syndrome (CCHS), 384–385, 1149–1150

- clinical management of, 1150–1151
- clinical manifestations of, 1150
- clinical presentation of, 1150
- diagnosis of, 1150–1151, 1151*b*
- genetic origin, 1150

Congenital cystic adenomatoid malformation (CCAM), 289, 425

Congenital diaphragmatic hernia (CDH), 58, 291–292, 329–331, 330*f*

- outcomes of, 293*t*
- specific diagnoses of, 292–298, 293*f*

Congenital gastrointestinal defects, in Down syndrome, 1003

Congenital heart disease

- associated pulmonary arterial hypertension with, 561–572
- in Down syndrome, 1000–1001

  - mechanical ventilation in, 553
  - pediatric patients with, special pulmonary considerations in, 604
  - pulmonary disease associated with, 615–625
    - with Fontan repair of single ventricle physiology, 624–625
    - pulmonary hypertension and postoperative pulmonary hypertensive crisis, 619–621
    - pulmonary vein stenosis, 621–622, 622*f*–623*f*
    - related to cardiac surgery and cardiopulmonary bypass, 624–625
    - reperfusion pulmonary edema, 622–624
    - vascular rings and slings, 615–619, 616*f*–618*f*
  - pulmonary hypertension and postoperative pulmonary hypertensive crisis
    - background of, 619–620
    - evaluation and monitoring of, 621
    - pathophysiology of, 621
    - risk factors of, 620–621
    - treatment of, 621
  - vascular rings and slings
    - clinical presentation of, 619
    - diagnosis of, 619
    - treatment of, 619, 619*f*–620*f*

Congenital high airway obstruction syndrome (CHAOS), 291–292, 304–305

Congenital large hyperlucent lobe (CLHL), 290

Congenital lesions, bronchiolitis and, 425

Congenital lobar emphysema, 65–66, 320–321, 320*f*–321*f*

Congenital lung disease
  - age-related presentations of, 290–291, 291*t*
  - antenatal presentation of, 290–292, 291*t*
  - in childhood and adult, presentations of, 312–313
  - clinical approach of, 289–290
  - clinical/pathologic descriptions of, 290
  - epidemiology of, 290
  - systematic approach in, use of, 290

Congenital lung malformations, clinical appearances, 290*t*

Congenital myasthenic syndromes, 1047, 1050, 1053, 1056

Congenital pulmonary airway, 1027

Congenital pulmonary airway malformation (CPAM), 314–316
  antenatal diagnosis and prognosis of, 294–295, 295*f*
  antenatal treatment options of, 295–296
  rare, 316
  type 0, 314
  type 1, 314–315, 315*f*
  type 2, 315–316
  type 3, 316
  type 4, 316, 316*f*
Congenital pulmonary lymphangiectasis, histopathology in, 999, 1000*f*
Congenital scoliosis, 1048, 1052, 1055*f*, 1059
Congenital small lung (CSL), 290
Congenital thoracic malformation (CTM), 314
  antenatal diagnosis of, 292*b*
  diagnosis
    bronchopulmonary sequestration, 296
    CPAM, 294–296
  long-term follow-up cystic, 320
  malignant transformation, prevention of, 318
  management of, 297–298
  optimizing lung growth, 318
  postnatal treatment decisions in, 316–317, 317*f*
  presentation of, in postnatal period, 296–298, 297*f*
  prevention of complications of, 317–318
  requirements for fetal surgery for, 296*b*
Congenital tracheal stenosis, 310, 310*f*–311*f*
Congenital tracheobronchomegaly, 312
Congenital vocal cord paralysis, 1121
Congestive heart failure (CHF) identification, BNP usage in, 587
Congestive vasculopathy, 899, 900*f*
Connective tissue disease, mixed, 862–863

Constipation, 795

Continuation phase, of multidrug therapy, for pulmonary tuberculosis, 493

Continuous positive airway pressure (CPAP), 274*f*, 310, 367
- application of, 339, 346
- patient transfer, 284
- usage, 273, 388

Continuous spontaneous ventilation, 550

Controlled mechanical ventilation, 1064

Controlled ventilation technique, 165

Conventional ventilation
- mechanical, in acute respiratory distress syndrome, 609–610
- oscillatory *versus*, in pediatric intensive care, 596–598, 598*f*

Coordinate care
- aerodigestive model health care value for complex patients through, 1094–1096
- value in, 1096

Copenhagen Study on Asthma in Childhood (COPSAC), in asthma, 659

Cor pulmonale, 19–21, 781

Cord blood studies, 254

Correctors, 804

Corticosteroids, 377, 879
- for acute respiratory distress syndrome, 612
- DMD usage, 1058
- inhaled
  - adverse effects of, 706
  - asthma and, 703–704, 704*t*
  - mechanism of action and clinical use of, 705–706
- systemic, for asthma, 706–709
- use of, 410

Costimulatory molecules, aid of, 105

Costophrenic angles, blunting, 148

Cotrimoxazole prophylaxis, in human immunodeficiency virus infected children, 970, 975*t*

Cotton-Meyer grading system, 308

Cough

- anterolateral right upper lobe and, bilateral circumscribed densities in, 540*f*
- cardinal manifestation of, 14–15
- cause of, 15
- in chest disease in children, 14–16
- dependent clearance, 122
- detailed history of, 15
- expulsion of, 121
- in hydrocarbon aspiration, 627
- irritant and, 121
- manually assisted, 284*f*
- mechanics of, 121
- production, 14
- reflex, abnormalities in, 121
- spikes, superimposition, 283*f*
- strength (measurement), peak cough flow (usage), 283

Cough-assist, 599

- devices, 121, 285*f*

Cough-variant asthma, 690–691

Coughing

- act, components, 283
- components, impairment, 283
- compression phase of, 121
- expulsive phase of, 121
- glottic closure, 121
- inspiratory phase of, 121
- irritation phase of, 121
- phases of, 15, 121
- relaxation phase for, 121

  - timing of, importance of, 15

Count median diameter (CMD), 261

Counterimmunoelectrophoresis (CIE), 949

CPAM, Congenital pulmonary airway malformation

CPAP, Continuous positive airway pressure

CPET, Cardiopulmonary exercise testing

Crack cocaine users, in Loeffler's-like syndrome, 958

Crackles, 11, 13–14

CRD, Carbohydrate recognition domain

C-reactive protein, 60–61

Crescent sign, 539

Cribriform membrane, 1007–1008

Cricopharyngeal achalasia, aspiration opportunities, 1099–1100

Cricotracheal resection (CTR), 308

Critical closing pressure ($P_{crit}$), 1147

Critical exercise-asthma, 218

CRMS, CFTR-related metabolic syndrome

Cross-sectional study, in asthma, 640–641

Croup, 406
  - diagnosis of, 404, 409
  - humidification, 410
  - pharyngitis associated with, 397*t*
  - recurrent or spasmodic, 409
  - supportive care for, 410

Cryptococcosis, 520–522
  - clinical features of, 521
  - diagnosis of, 521–522
  - differential diagnosis of, 522
  - epidemiology of, 520

  - etiology of, 520–521
  - imaging of, 521
  - laboratory findings on, 521
  - management and treatment of, 522
  - pathology/pathogenesis of, 521
  - prognosis of, 522
  - pulmonary function testing for, 521

*Cryptococcus*, 520–521

*Cryptococcus gattii*, 520–521

*Cryptococcus neoformans*, 520–521
  - pulmonary infection and, 930

Cryptogenic organizing pneumonia, 939

*Cryptosporidium parvum*, 930

C-shaped rings, 65–66

CSL, Congenital small lung

CSLD, Chronic suppurative lung disease

CTM, Congenital thoracic malformation

CTR, Cricotracheal resection

C-type lectin receptors, 124

Culture, 401–402

Cumbo sign, 539

Cumulative dose ($PD_{20}$), 695

*Curvularia* spp., 526

Cutaneous lesions, in Churg-Strauss syndrome, 962–963

Cutaneous or mucocutaneous stimulation, 98

Cutis laxa, 312

CXC chemokines, 111

CXCL1 and CXCL8, 108

Cyanosis, 17–18

- BRUE definition and factors for inclusion and exclusion, 1126*t*
- clinical impression of, 18
- in physical findings, 6–7
- reduced hemoglobin, requirement, 18*f*

Cyclic adenosine monophosphate (cAMP), 777
- response element, 757

Cyclic GMP
- augmentation, 380
- breakdown, prevention of, 577

Cyclophosphamide, 878–879

Cyclosporine, 984

Cysteine leukotrienes, in asthma, 667

Cysteinyl leukotrienes (cysLTs), 709
- bronchiolitis and, 421

Cystic adenomatoid malformation, 289

Cystic fibrosis (CF), 256, 439
- airway
  - clearance, 782–783
  - inflammation, 766
- allergic bronchopulmonary aspergillosis in, 952*b*
- altitude, 227

  - protein with, 801, 802*f*
- mutations, 771*b*
  - analysis, 771–772
  - clinical consequences, 761–762, 772*t*
  - molecular consequences, 760–761
  - severity, 775
- protein, 758–759
  - characteristics, 758–759
- in small bowel, 794–795

Cystic fibrosis transmembrane conductance regulator-related disorders, 775, 775*b*

Cystic fibrosis transmembrane conductance regulator-related metabolic syndrome, 775–776

Cystic fibrosis-related diabetes mellitus (CFRD), 798–799

Cystic hydatidosis, of lung, occurrence of, 539–540

Cystic hygroma, 301, 301*f*

- confinement of, 1079

Cystic lung lesions, 292*t*
- outcomes and postnatal management in, 298*t*

Cystic masses, impact, 1076–1077

Cystic teratomas, commonness, 1076

Cytochrome $b_{558}$, 913

Cytochrome oxidase, decrease in, 590

Cytochrome P-450-dependent detoxification, 65

Cytokines, 109–110, 109*f*, 111*f*, 121
- antiinflammatory actions of, 113
- in pediatric allergic asthma, 665–669
- release of, 106–107

Cytomegalovirus (CMV), 924–926
- clinical manifestations of, 987
- incidence of, 987
- pneumonia, 925, 973
  - antibiotic treatment of, 970*t*
- reduced, significance of, 984

Cytosine arabinoside, 880

Cytosolic oxidase components, 914

Cytotoxic drugs, 880–881
- usage, 876–881, 877*t*

**D**

DAH, Diffuse alveolar hemorrhage

Daily preventive monotherapy, for preschool asthma, 680–681

Daily therapy dose, for preschool asthma, 683

Daily *versus* preemptive asthma controller, for preschool asthma, 683

Dalton's law, 74

Data processing, 158–161

Daytime sleepiness, excessive, 1151–1152

DC, Dyskeratosis congenita

*DCTN4* (dynactin subunit 4), 45

*De novo* SFTPC mutations, impact of, 845–846

De novo synthesized lipid mediators, 953

Dead space, 86–88

Death

- in asthma, 647
- in pediatric lung transplantation, 990, 991*f*

Death inducing signaling complex, 132–133

Decannulation, achievement, 1121

Deep inspiration, 283

- in coughing, 15

Deformities, stereographic measurements, 6

Delamanid, for drug-resistant tuberculosis, 494

Deletions, 41

Delivery room resuscitation, 339–341

Dendritic cells (DCs), 105, 126–127

- in asthma, 665

Dennie lines, 6

Deoxyribonuclease (RhDNase), mucoactive agents, 282

Deoxyribonucleic acid (DNA), polymerized actin and, 122

Dermonecrotic toxin, in *Bordetella* pertussis, 530*t*

Dexamethasone, use of, 410

Diagnostic bronchoscopy, indications for, 137–139, 138*t*, 139*f*

Diaphragm

- chest pieces, placement of, 12

- dysfunction of, 1044–1045
- flattening of, 148
- in muscles of respiration, 83
- paralysis of, 384
- penetration of, 1085
- relaxation of, in coughing, 15
- traumatic blunt rupture of, 1070, 1070*f*
- tumors of, 1087

Diaphragm paralysis
- clinical features of, 1049
- diagnosis of, 1053
- management of, 1055
- pathogenesis of, 1047
- treatment of, 1055

Diaphragmatic dome, 63
- flattening of, 148

Diaphragmatic dysfunction, ventilator induced, 554

Diaphragmatic eventration, 332

Diaphragmatic hernia, 292–298

Diaphragmatic muscle, in muscles of respiration, 84

Diaphragmatic paralysis, in cardiac surgery, 1002*t*

Diaphragmatic weakness, 1051

Diastolic murmurs, appearance of, 19–21

Dichotomous branching, 63

Diet, maternal, on asthma, 654

Differential auscultation, 12

Difficult asthma, 726–730
- misdiagnosis, 440

Diffuse alveolar hemorrhage (DAH), 867, 937
- in children, 893–902, 894*f*
  - anti-GBM disease, 897–898, 899*f*

    - approach to, 899–901
    - causes of, 894*b*
    - clinical manifestations of, 901*t*
    - COPA syndrome, 899
    - diagnosis of, 899–901
    - etiology of, 893–899
    - immune-mediated, 893–897, 898*f*
    - isolated pulmonary capillaritis, 898
    - nonimmune-mediated, 899
    - pathophysiology of, 893–895
    - treatment of, 901–902
- Diffuse interstitial lung disease, 154, 155*f*, 813–816
  - classification of, 813–814
  - diagnostic approach of, 814–816
  - diffuse pediatric lung disease classification, proposal, 814*t*
  - families and physicians, resources for, 816
  - new concepts in, 813–816
  - new genetic mutations associated with, 815*t*
  - noninvasive testing, completion of, 814
  - pattern (determination) of, imaging (usage), 814
  - pediatric-specific classification for, designation of, 813–814
  - terminology in, 813–814
- Diffuse lung disease, of surfactant deficiency, 845
- Diffuse Pediatric Lung Disease Classification, 814*t*
- Diffuse small airway obstruction, 589
- Diffusing capacity (DLCO), 88
  - increase in, 586
  - measurement of, 181–182
- Diffusion, 88–89
  - capacity for carbon monoxide, decreased, 948
  - impairment of, 17–18
  - measurement of, 88–89
  - principles of, 88
- Diffusion-weighted magnetic resonance imaging, 637

Digital clubbing, 18–19, 781
  asthma and, 691
  cystic fibrosis and, 781
DIHS, Drug-induced hypersensitivity syndrome
DIOS, Distal intestinal obstruction syndrome
Dipalmitoyl phosphatidylcholine (DPPC), 836
Diphenylhydantoin, 882
Diphtheria, 415–416
  clinical features of, 415–416, 416*f*
  epidemiology of, 415
  etiology of, 415
  management of, 416
  pathology of, 415
Direct hemodynamic monitoring, in pulmonary hypertension, 621
Direct lung injury, occurrence of, 584
DISABKIDS
  Asthma Module, 234, 236*t*–237*t*
  Cystic Fibrosis Module, 238*t*
Disaturated phosphatidylcholine (DSPC), 836
  levels/content, reduction of, 842
Disease
  diagnosis of, 2
  onset of, 2
  physical inactivity and, 213*f*
Disease-specific HRQoL instruments, 232
  design, 232
Disease-specific respiratory health-related quality of life measures, 234–240
  review of, 234–240
    asthma measures, 234–235
Distal intestinal obstruction syndrome (DIOS), 796

- abdominal pain and, 796
- Gastrografin enemas for, 796
- management of, 796

Distal phalangeal diameter, to interphalangeal diameter ratio, 19, 20*f*

Distal respiratory zone, 63

Diuretics
- detection of, 21
- in pulmonary arterial hypertension, 578

Diverticulum bifurcates, 248

DMD, Duchenne muscular dystrophy

DNA methylation, 34, 46–47, 47*f*
- in asthma, 652–653
- in respiratory disease, 50–51

Docetaxel, 880

Docosohexanoic acid prostaglandin D (PD)1-derived mediator, 114

Dolor, inflammation and, 101, 112

“Domino” transplant, 981

Doppler ultrasound, 296
- for cystic fibrosis liver disease, 792

Double aortic arch, 309, 615, 616*f*–617*f*, 619*f*

Down syndrome
- aberrant right subclavian artery in, 1002*f*
- airway endoscopy abnormalities in, 994*f*
- cardiorespiratory interactions in, 1000–1003
- congenital heart disease in, 1000–1001
- disease complicating respiratory illness in, 993*t*
- effusions in, 999
- endoscopic findings in, 994*t*
- endotracheal tube diameter in, size of, 1004*t*
- gastrointestinal disorders in, treatment of, 1005

- gastrointestinal-respiratory interactions in, 1003
- genetic anomalies in, 1005–1006, 1005*t*–1006*t*
- hemosiderosis in, 999*f*
- imaging abnormalities in, 1001*f*
- immune function in, 998*t*
- laryngomalacia in, 993–994
- lower respiratory tract in, 996–999
    - imaging of, 999–1000
    - infection of, 996–998, 1004–1005
- magnetic resonance imaging of, 995*f*
- obesity in, 1003–1005
- pneumonia in, 1003*f*
- pulmonary edema in, cardiac disease leading to, 1001*t*
- pulmonary vasculature in, 1000–1003
- radial count in, 996, 997*f*
- respiratory complications of, 992–1006
    - treatment of, 1004
- respiratory disease in, 1001–1003
    - patterns of, 993*t*
- respiratory disturbance index in, 995, 996*f*
- sleep-related breathing disorders in, 995–996
- subglottic stenosis in, 995
- subpleural cysts in, 997*f*
- survival in, 993*f*
- trachea, 992–995
- tracheal bronchus in, 1002*f*
- tracheal stenosis in, 995
- tracheomalacia in, 993–994
- upper airway in
    - anatomy of, 992–993
    - disease of, 992–995, 993*t*
- upper respiratory tract disease in
    - clinical presentation of, 995
    - treating, considerations when, 1004
- wheeze in, 998–999

DPIs, Dry powder inhalers

DPPC, Dipalmitoyl phosphatidylcholine

DRESS, Drug rash with eosinophilia and systemic symptoms

Drowning, 634–638

- accidental deaths in, 634
- animal data in, 635
- broad-spectrum antibiotics for, 636
- chest radiograph of, victim of, 635*f*
  - initial, 635*f*
- definitions of, 634
- electrolyte imbalances in, 635–636
- epidemiology of, 634
- in hypertonic fluid, 635
- hypothermia in, 635
- hypoxic-ischemic damage in, 636
- neuroprotection following, in induced hypothermia, 636
- nonpulmonary sequelae in, 635–636
- postulated, 635
- prevention, 637–638
- as primary event, 634
- sequence, 634
- trauma in, 636
- victims, in hypothermia, 635

"Drug holidays", 261

Drug rash with eosinophilia and systemic symptoms (DRESS), 876

Drug susceptibility testing (DST), for *Mycobacterium tuberculosis*, 477

Drug-induced eosinophilia, 958–959, 958*t*

Drug-induced hypersensitivity syndrome (DIHS), 876

Drugs

- administration, by inhalation, in children, 257–272
- nonallergic hypersensitivity to, asthma and, 693–694

Dry powder inhalers (DPIs), 257, 266–267

DSPC, Disaturated phosphatidylcholine

Duchenne muscular dystrophy (DMD), 1047, 1050–1051, 1053, 1099
  acute respiratory deteriorations, management of, 1058
  corticosteroid therapy of, 1058
  daytime noninvasive respiratory aids, usage, 1058
  exon skipping of, 1058
  natural history of, 1056
  obesity, frequency, 1057
  prognosis of, 383
  respiratory care in, consensus on, 1057*b*
  respiratory disability, long-term management of, 1056–1057
  treatment, perspectives on, 1058
Duct ligation, 1103
Dupilumab, 754
Duplications, 41
Dutch Generation R study, in asthma, 654–655
Dynamic airway compression, 80
Dynein, 1038–1039
Dyskeratosis congenita (DC), 823, 823*f*
Dyskinesia, primary ciliary, 1034–1043
Dysphagia, 860
Dyspnea, 21
  long-term risk for, 878
Dystrophin gene, location of, 1047

**E**

Early antigen responses, 692
Early onset sarcoidosis (EOS), 863
Early-onset pneumonia, 352–353, 353*f*
Early-onset scoliosis, 384
  classification of growth-friendly spine implants for, 1059*b*

EBB, Endobronchial biopsy

EBC, Exhaled breath condensate

EBV, Epstein-Barr virus

Echinocandins
- for candidiasis, 519–520
- for pulmonary mycoses, 508

Echinococcosis (hydatid disease), 538–543
- clinical features of, 539–540, 540*f*–541*f*
- diagnosis of, 540–541, 541*f*
- differential diagnosis of, 540–541
- epidemiology of, 538
- etiology of, 538
- management for, 541–543
- pathology/pathogenesis of, 538–539, 538*f*
- prognosis for, 543
- sylvatic Alaskan-Canadian variant of, 543
- treatment of, 537*t*, 541–543

Echocardiography, 333–334
- monitoring, 375
- in pediatric pulmonary arterial hypertension, 570–571
- in pulmonary hypertension, 621

Echogenicity, increase, 289–290

Economic impact, of asthma, 648

Ectopia, 320–322

Edema, 860
- formation of, opposition in, factors in, 583
- pathophysiologic consequences of, 585–586
- presence of, 585–586

Edwards syndrome, 1005*t*–1006*t*

Efferocytosis, 133

Effusions, in Down syndrome, 999

EGFR, Epidermal growth factor receptor

Ehlers-Danlos syndrome, 312

EIB, Exercise-induced bronchoconstriction

E-ILO, Exercise-induced laryngeal obstruction

Elastance, in respiratory resistance, 193

Elastic pulmonary arteries, 68

Elastin, in interstitium, 69–70

Electrocardiogram QT intervals, prolongation, sudden infant death syndrome and, 1139

Electrolyte imbalances, in nonpulmonary sequelae, 635–636

Electronic noses, 697

Electrostatic attraction, 260

Embolization, 319

Embryo

- anterior-posterior (A-P) axes, formation of, 26
- organization of, principles in, 26

Embryonic period, 27–29, 27*t*, 28*f*

Embryonic phase, 248

Embryonic pleural space, 1007

Embryonic stage, of fetal lung, 70

Emergent airway, 301

Emotional factors, asthma and, 693

Emphysema, 290

- gene mutations and, 38–39
- in hydrocarbon aspiration, 626
- pulmonary interstitial, 359–360

Empyema, 287, 1014–1021

- bacterial causes of, 1016*b*
- chest drain, 1019, 1020*f*

clinical manifestations of, 1016
    complications of, 1021
    diagnosis of, 404
    epidemiology of, 1015
    etiologic agents with, 398*t*
    etiology of, 1014–1015
    follow-up of, 1021, 1021*f*
    hemithorax opacity and mediastinal deviation, 435*f*
    investigations, 1016–1019, 1017*f*–1018*f*
    management of, 1019–1021
    microbiology of, 1015–1016
    monitoring progress, 1021
    pleural effusion, relationship, 435–436

EMTU, Epithelial-mesenchymal trophic unit

ENaC, Epithelial sodium channel

Encapsulated pneumonia, 911
    chronic granulomatous disease and, 912*f*

ENCODE (Encyclopedia of DNA elements) project, 33–34

End organ involvement, assessment, 772

End-expiratory lung volume, 77

Endobronchial biopsy (EBB), usage of, 866

Endobronchial lesions, biopsy for, 143

Endobronchial ultrasonography, 170

Endoderm, 26

Endoplasmic reticulum (ER)
    CFTR polypeptide translation, 759
    stress, 843
    surfactant, synthesis, 344

Endothelial basement membranes, epithelial membranes and, fusion of, 581*f*

Endothelial cell injury, assessment of, 587–588

Endothelial dysfunction, in pulmonary arterial hypertension, 567–568

Endothelial nitric oxide synthase (eNOS), 696–697

Endothelin receptor antagonists, in pulmonary arterial hypertension, 576–577

Endotoxin, in asthma, 659–660

Endotracheal aspirates, 400

Endotracheal intubation

- recorded, 3
- in smoke inhalation, 632

Endotracheal tube diameter, in Down syndrome, 1004*t*

eNOS, Endothelial nitric oxide synthase

Enterogenous cysts, 314

Enterovirus D68 (ED68), 466

- infection
  - characteristics of, 467*t*
  - clinical features of, 466
  - diagnosis of, 467
  - differential diagnosis of, 467
  - epidemiology of, 466
  - etiology of, 466, 467*t*
  - imaging of, 467
  - laboratory findings on, 467
  - management and treatment of, 467
  - pathology/pathogenesis of, 466
  - physical findings on, 466–467
  - prevention of, 467
  - prognosis of, 467
  - pulmonary function tests for, 467
  - symptoms of, 466

Enthesitis-related arthritis (ERA), development of, 850–852

Entrainment or breath-enhanced nebulizers, 268, 268*f*

Environment, maternal, on asthma, 654

Environmental exposures

- adverse
  - in home environment, 50*t*
  - increased disease risk in, mechanism of, 50–54
  - vulnerability of children in, 49–54, 50*t*
- asthma and, 715

Environmental modification, 454

Environmental tobacco smoke (ETS), effects, 444

Enzyme immunoassay (EIA), for histoplasmosis, 510

Enzyme-linked immunosorbent assays (ELISA), in hypersensitivity pneumonitis, 949

EOS, Early onset sarcoidosis

Eosin, stains with, 844

Eosinophilia, 105
- asthma and, 696
- control of, 966–967
- drug-induced, 958–959

Eosinophilic esophagitis, 1116, 1120
- diagnosis of, 1116
- endoscopic features of, 1116
- symptom from, 1116
- treatment of, 1116

Eosinophilic granuloma, 961–962
- characteristics of, 961*t*

Eosinophilic granulomatosis with polyangiitis, 962–964
- characteristics of, 963*b*

Eosinophilic inflammation
- activate, 101
- in preschool wheeze
  - inception, 672
  - persistence, 672–673
- in school age allergic asthma, 670
  - noninvasive biomarkers of, 670
  - stability of, 670

Eosinophilic lung diseases, 944–967
  drugs that cause, 958*t*
  etiology of, 952, 952*b*
  helminth associated, 955*b*
Eosinophils, 105–106, 128–129, 750–751
  adhesion of, 105
  airway, asthma and, 686–687
  biology of, 953–955
  in pediatric allergic asthma, 665–667, 667*b*
  recruitment, 105
Epidemiologic approaches, to asthma, study of, 640–641
Epidemiology and Natural History of Asthma: Outcomes and Treatment Regimens study, 650
Epidermal growth factor receptor (EGFR), gefitinib, 880–881
Epigenetics, 46–47, 47*f*
  of asthma, 652–653
Epigenome-wide association studies (EWAS), in asthma, 652–653
Epiglottitis, 412–414
  clinical features of, 413, 413*f*
  diagnosis of, 404
  epidemiology of, 412
  etiologic agents with, 398*t*
  etiology of, 412
  management of, 413–414
  pathology of, 412–413
  swollen, 413*f*
Epiglottoplasty, 1121
Episodic viral wheeze (EVW), 103, 649–650
Epistaxis, in bronchoscopy, 145
Epithelial cell
  injury in, by inflammatory mediators, 60–61

- surface of, hydration of, 26

Epithelial membranes, endothelial basement membranes and, fusion of, 581*f*

Epithelial sodium channel (ENaC), 777
- CFTR control, 762–763

Epithelial-mesenchymal interactions, lung morphogenesis and, 35

Epithelial-mesenchymal trophic unit (EMTU), formation of, 954–955

Epithelium, reduction of, 65*f*

Epoprostenol (intravenous prostacyclin), 575

Epstein-Barr virus (EBV), 418

ERA, Enthesitis-related arthritis

Ergosterol, for pulmonary mycoses, 507–508

Erythrocytes, transit time of, 18

Erythromycin, 1115
- for pertussis, 532

Esophageal atresia, 322–324, 1003

Esophageal cysts, 314
- duplication of, 1083–1085
- location of, 1083
- types of, 1084

Esophageal dysmotility, 1115

Esophageal perforation, management in, 1070

Esophageal surgery, 1121

Esophageal tube injection, 334

Esophagitis, eosinophilic, 1116

Esophagogastroduodenoscopy, 1119

Esophagus
- injuries to, 1069–1070
- motility disorders, treatment, 1115

  - plain chest radiographs, usage, 1070
- Estrogens, females receiving, pulmonary embolism and, 888
- Ethambutol
  - for nontuberculous mycobacterial infections, 504*t*
  - for tuberculosis, 493*t*
- Ethnicity, in prevalence of asthma, 645–646
- Etiologic agents, 396

- treatment of, 221, 222*f*

Exercise-induced bronchospasm, 693

Exercise-induced laryngeal obstruction (E-ILO), 228*f*, 726

  - diagnosis, 228
  - mechanism of, 228
  - research, 228
  - therapeutic modalities, 228
- Exercise-induced laryngomalacia, 691–692
- Exhaled breath condensate (EBC), 117–118, 697
- Exhaled gases, 116–118
- Exhaled nitric oxide
  - for asthma, 696–697, 697*t*
  - for eosinophilic inflammation, 670
- *Exophiala* spp., 526
- Expiratory muscles
  - contraction of, in coughing, 15
  - effective contraction, 283
- Expiratory wheezing, 11
- Expulsive phase, 121
- Extensive drug resistance, 494
- External PEEP valve, use of, 388
- External stents, 310
- Extracellular matrix
  - amount, increase of, 30
  - role of, 36–37
- Extracorporeal life support, in pediatric acute respiratory distress syndrome, 613–614
- Extracorporeal membrane oxygenation (ECMO) therapy, 330–331
  - in pediatric intensive care, 598
- Extrapulmonary nontuberculous mycobacterial disease
  - clinical manifestations of, 502–503
  - management and treatment of, 505
- Extrapulmonary tuberculosis

    clinical features of, 482–483, 483*f*
    in human immunodeficiency virus–infected children and adolescents, 968
    treatment of, 494
Extrathoracic airways, 16–17
Extrathoracic regions, inspection of, 6
Extrathoracic tuberculosis, 483–484, 483*f*
Extravascular lung water (EVLW)
    measurement of, 588
    mortality function of, 589*f*
Extrinsic allergic vasculitis, clubbing in, 19
Extubation, mechanical ventilation in, 554
Eyelids, heliotrope rash over, 857

**F**

Factor V Leiden, factor II 20210A variant, 572–573
FADS, Fetal akinesia deformation sequence
Failed extubation, 302, 303*f*
Familial hypereosinophilic syndrome, 966*b*
Familial pulmonary arterial hypertension (FPAH), 556
Family history
    asthma and, 691
    inquiry of, 3
Famine exposure, 249
Farming studies, in asthma, 659–660
FAST, Focused Assessment with Sonography in Trauma
Fast-twitch fibers, in muscles of respiration, 84
Fatty acid oxidation deficiencies, 1138–1139
Fecal pancreatic elastase-1, test, 790
Feeding

- behavioral issues, 1113
- conditions, 1108–1109
- development of, 1107–1108, 1107*t*
- neurologic conditions, 1109
- treatment strategies, 1112–1113

Feeding and swallowing disorders, 1106–1113
- epidemiology of, 1106

FEES, Fiberoptic endoscopic evaluation of swallowing

$FEF_{25\text{-}75}$, airway obstruction and, 695

Females (women), chest radiograph for
- with cystic fibrosis, 765*f*
- with juvenile dermatomyositis, 858*f*

Fentanyl, for pulmonary hypertension, 621

Fetal akinesia deformation sequence (FADS), 1005*t*–1006*t*

Fetal breathing activity, importance of, 338

Fetal echocardiography, 293–294

Fetal endoscopic tracheal occlusion (FETO), 293–294, 294*f*

Fetal growth, on asthma, 654–655

Fetal hemoglobin, oxygen-binding curve of, 18

Fetal lung
- abnormalities, prenatal detection, 291
- embryonic stage of, 70
- fluid, of newborn infants, 346
- liquid secretion, 71
- polarized epithelium lining in, 72*f*

Fetal oxyhemoglobin dissociation curve, 91

FETO, Fetal endoscopic tracheal occlusion

FGF, Fibroblast growth factor

FHA, Filamentous hemagglutinin

Fiberoptic endoscopic evaluation of swallowing (FEES), 1100, 1110–

1112, 1110*t*, 1112*f*

pediatric, 1110*t*

videofluoroscopic swallow studies *versus*, 1100*t*

Fiberoptic nasoendoscopy (FNE), 300–301, 301*f*

Fibrinogen, 60–61

Fibrinous septations, empyema and, 1014*f*

Fibroblast growth factor (FGF), 314

in lung morphogenesis, 26–27

mutations in, 38

Fibroblasts, in interstitium, 70

Fibrosing colonopathy, 790

treatment of, 790

Ficolins, 125

Filamentous hemagglutinin (FHA), in *Bordetella* pertussis, 530*t*

Fimbriae 2, in *Bordetella* pertussis, 530*t*

Fimbriae 3, in *Bordetella* pertussis, 530*t*

Finger clubbing, measurement of, 20*f*

FISH, Fluorescent in situ hybridization

Flail chest, 5–6, 1063–1064

action, diagram of, 1063*f*

paradoxical respiratory excursions with, 1064

Flexible bronchoscopes, 134–135

in contrast to rigid bronchoscopes, 135

Flexible bronchoscopy, 136, 136*t*, 941, 1118

Flexible nasoendoscopy, 305

Flow limitation, 182–183

Fluconazole

for candidiasis, 519–520

for coccidioidomycosis, 513

  for pulmonary mycoses, 507–508
Flucytosine, for pulmonary mycoses, 508
Fluid accumulation, sequence of, schematic representation of, 585*f*
Fluid dynamics, laws of, 406
Fluid filtration rate, reduction in, 592–593
Fluid leakage rate, reduction in, 592
Fluid management, mechanical ventilation in, 554
Fluid movement, factors for, 581–583
Fluid restriction, 376
Fluid-exchanging membranes, fluid equilibrium across, 581
Fluid-exchanging vessels, vascular permeability in, increase in, 584
Flunisolide, 705
Fluorescence-based screening assays, 913
Fluorescent in situ hybridization (FISH), 41, 45*t*
Fluoroscopic technique, 156–157, 157*f*
Fluoroscopy, of atelectasis, 1029–1030, 1029*f*
Fluticasone furoate, for asthma, 704
Fluticasone propionate, for asthma, 704
Flutter, 275*f*, 278*f*, 280*f*
FNE, Fiberoptic nasoendoscopy
Focal biliary cirrhosis, 792
Focal bronchopneumonia, in hydrocarbon aspiration, 626
Focal lung densities, 153, 154*f*
Focused Assessment with Sonography in Trauma (FAST), 1067
Food allergy, asthma and, 725
Forced expiration, huffing, 279
Forced expiration measurement, 182–189

- assessment of bronchodilator response and, 189, 190*f*
- flow and volume
  - cooperative subjects, 184–185
  - in infants, 185–189
- physiological principles and assumptions of, 182–184, 183*f*
- quality control, acceptability criteria, and limitations of, 184–185
- raised volume-rapid thoracoabdominal compression in, 185–186, 186*f*–187*f*
- rapid thoracoabdominal compression in, 185–186

Forced oscillation technique, 199–205, 199*f*, 201*f*
- asthma and, 695

Forced vital capacity (FVC), measurement, sitting position, 1046–1047

Foregut
- duplication cysts, 1081
- embryologic maldevelopment, 1081*f*
- structure of, 1081

Foregut cysts, 313, Bronchogenic cysts

Foregut patterning, 27*f*

Foreign bodies
- in atelectasis, 1027
- removal of, therapeutic bronchoscopy for, 143–144

Forkhead box A2 (FOXA2)
- in gene expression, 26
- as transcription factor, 32

Forkhead box transcription factor 1 (FOXF1), coding sequence (heterozygous mutations) of, 825

Formoterol
- for asthma, 707
- combined with inhaled corticosteroids, 709

FOXF1, mutations in, 38

FPAH, Familial pulmonary arterial hypertension

F protein, 407–408

Fraction exhaled nitric oxide, measurement of, in asthma, 650
Fractional nitric oxide, 696–697, 697*t*, 701
Fractures, sternal, 1063
Frameshift variant, 40, 41*f*
Fraser syndrome, 298
FRC, Functional residual capacity
Frequency dependence, 194
Functional electrical stimulation, 286*f*
Functional residual capacity (FRC), 76, 120
  formation of, 338
  maintained, 60–62
  volume of, 581
Functional surfactant, alveolar pool of, 58
Fungal infection, in human immunodeficiency virus–infected children and adolescents, 973–975
Fungal pulmonary infections, 923–924
Fungal spores, asthma and, 692
Funnel chest deformity, change, 6*f*
*Fusarium* spp., 525–526

**G**

Galactomannan antigen assay, 928–929
  for invasive aspergillosis, 517
Gallstones, occurrence of, 794
Gamma-aminobutyric acid (GABA), importance of, 342
Ganciclovir
  availability of, 984
  for CMV pneumonia, 973
Ganglioneuroblastoma, 1081

Ganglioneuroma, 1081

Gas dilution technique, 176–180, 179*f*

Gas exchange, 85–86, 85*f*

- breath-by-breath analysis, 215
- HR variables, relationships, 215
- measurement, 214–215
- occurrence of, 67–68
- protocol, 215

Gas humidification, mechanical ventilation in, 554

Gas mixing, measurement of, 205–210

- multiple breath washout technique, 205–207, 206*f*–210*f*

Gasdermin B (GSDMB), in asthma, 653*t*

Gases

- in barriers, 88
- definitions and symbols in, 73–74
- diffusing, amount of (Q), 88
- diffusion rate of, 88
- exhaled, 116–118
- flow of, 79
- in physical solution, 74
- pressure, measurement of, 74
- properties of, 74

Gastric contents, reflux, 1097

Gastric emptying

- in cystic fibrosis, 796
- disorders, 1115

Gastric pepsin, elevation of, 1101–1102

Gastroenteric cysts (duplication cysts), 314, 1085

Gastroesophageal reflux (GER)

- aspiration of, 1101–1103
- asthma and, 693, 725

  - GERD *versus*, 1114
  - in newborn infants, 343, 366
  - role of, 1127–1128
  - treatment considerations for, 1102–1103

Gastroesophageal reflux disease (GERD), 1114–1115, 1120
  - coexist, 447–448
  - diagnosis, 1115
  - in Down syndrome, 1003
  - management for, 1115
  - medical therapy, 1115
  - reconstructive airway surgery and, 1114–1115
  - symptoms, 1114
  - weight gain and obesity, association, 1114

Gastrografin enemas, usage of, 796

Gastrointestinal (GI) cancers, 797

Gastrointestinal disease, 766–767
  - in Down syndrome, treatment of, 1005

Gastrointestinal-respiratory interactions, in Down syndrome, 1003

GATA-3 transcription factor, 112–113

GATA-binding protein 6 (GATA6), in gene expression, 26

Gaucher disease, 821
  - chest radiograph in, 822*f*
  - clinical features of, 821
  - epidemiology of, 821
  - etiology of, 821
  - management of, 821
  - pathobiology of, 821
  - prognosis of, 821
  - treatment of, 821

Gefitinib, as tyrosine kinase inhibitors, 880–881

Gender
  - in asthma prevalence, 645–646

- pulmonary arterial hypertension and, 559–560
- switch, in asthma, 645–646

Gene
- by environmental interactions, 50–53
- therapy, HPAH gene, identification of, 577

Gene environment interactions, of asthma, 652, 653*t*

Gene expression
- cis-regulatory networks controlling, 33–34
- control of, 31*f*
- exercise, 229*f*
- transcriptional mechanisms in, 31–34

Gene regulatory networks, 31–33

Gene therapy, cystic fibrosis, 805–810, 805*b*
- lungs and, 806
- outstanding questions on, 808–810
- recent progress in, 806–808, 807*f*
- vector development and upcoming clinical trials of, 808, 808*f*–809*f*
- viral *versus* nonviral, 806

Generalized pulmonary underinflation, 148

Generic HRQoL instruments, 232

Genetic ablation, 26

Genetic abnormalities (identification), of surfactant production disorders (impact), 845

Genetic anomalies, in Down syndrome, 1005–1006

Genetic susceptibility, 371

Genetic variation
- interpretation of, 43
- research study designs to, 44–46, 45*t*
- risk for respiratory disease, 50
- technologies to identify, 41–43
- type of, 40–41, 41*f*, 43*t*

Genetics, of asthma, 651–652
Genome-wide approaches, in asthma, 651–652
Genome-wide association studies (GWAS), 40, 46
Genome-wide interaction study (GEWIS), in asthma, 652
Genotype-phenotype associations, 47–48
Genotype-phenotype correlations, 760–762, 774–775
Gentamicin, for early onset septicemia, 346
GERD, Gastroesophageal reflux disease
Germ cell tumors, nonseminomatous, 1078–1079
Ghon focus, 478
Gibson and Cooke technique, 770
Girls, Females
    chest diameters of, mean values of, 8*f*
    with SLE, chest radiographs in, 856*f*
Gland excision, 1103
Globulin, 60–61
Glottic closure, 121
    in coughing, 15
    intact bulbar function, requirement, 283
Glottic openness, in coughing, 15
(1-3)-b-D-glucan (BDG), 517
Glucocorticoid response element (GRE), 705
Glucocorticoids, in pediatric allergic asthma, 667
Glutathione-S-transferase Mu 1 (GSTM1), in asthma, 653*t*
Glutathione-S-transferase Pi 1 (GSTP1), in asthma, 653*t*
Glutathione-S-transferase Theta 1 (GSTT1), in asthma, 653*t*
Glycerol-phosphorylcholine backbone, 57
Glycine, importance of, 342

Glycocalyx, 68

Glycoproteins, 121–122

Glycosaminoglycans, in interstitium, 69–70

GM-CSF, Granulocyte-macrophage colony-stimulating factor

Goblet cells, 66*f*

- replacement of, 65

Gomori-Grocott (methenamine-silver) stain, for bronchoalveolar lavage, 142

Goodpasture syndrome, 894–895

Gorham-Stout disease, 819

Gottron's papules, presence of, 857

G-protein-coupled receptors, transmembrane receptor superfamily of, 110

Graft-*versus*-host disease (GVHD), pediatric intensive care and, 604–605

Gram stain appearance, of bacterial respiratory pathogens, 398*t*

Granulocyte-macrophage colony-stimulating factor (GM-CSF)

- impact of, 836–837
- lung/serum biomarkers, 846
- production of, genetically determined primary defects in, 840
- serum autoantibody testing for, 846

Granulocyte-macrophage colony-stimulating factor deficiency, 58

Granulocytes, in pulmonary endothelium, 70

Granulomatosis with polyangiitis, 869–872, 895–896, 895*f*–896*f*

- airways of, bronchoscopic photographs of, 873*f*
- clinical manifestation of, 869–870
- CT scan in, 872*f*
- diagnosis of, 871
- epidemiology of, 869
- HRCT scan in, 870*f*

- induction therapy for, 872
- lung biopsy, photomicrograph of, 869*f*
- pathogenesis of, 869
- prognosis of, 872
- pulmonary involvement in, 870–871
- pulmonary symptoms of, 870
- pulmonary-renal syndrome and, 871
- soft tissue radiograph in, 871*f*
- treatment of, 871–872

Granulomatous lesions, occurrence of, 864

Granulomatous lung lesions, progression of, 865

Grass pollen, asthma and, 692

Gravitational sedimentation, aerosol, 259–260

GRE, Glucocorticoid response element

Great arteries, transposition of, 18

Green zone, preventive management of, in preschool asthma, 680, 681*f*

Group A *Streptococcus*, 427

Group B *Streptococcus* clearance, 61

Group O Rh-negative blood, administration of, 339–341

Growth, exercise (relationship), 213*f*

Growth factors, 111, 112*f*
- in pulmonary arterial hypertension, 568

Guillain-Barré syndrome, 1046

GWAS, Genome-wide association studies

**H**

*Haemophilus influenzae*, 396
- in asthma, 659
- clearance, 61

*Haemophilus influenzae* b (Hib)
  vaccine, 427
    in bacterial pneumonia, 969–970
    in HIV-infected ART-naïve children, 970
Hamartomas, 1072
Hamman-Rich disease, 944
HAPE, High-altitude pulmonary edema
HapMap project, in asthma, 651–652
HEADSS (Home Education Activities Drugs Sexuality Suicide) framework, 244*b*
Health, exercise and, 213*f*
Health-related quality of life (HRQoL)
  assessment, 233
  children, 232
  clinical utility, 233–234
  errors, reduction, 232–233
  feedback, impact, 233–234
  integration, feasibility, 234
  measures, 231–232
    development, 232
    developmental considerations, 232–233
    PRO type, 231–232
  proxy-respondent, usage, 233
Heart
  primary sarcoma of, 1086
  primary tumors of, 1086
Heart rate, increase, 391
Heart-lung transplantation, 983
  success in, 578–579
Heated humidified high-flow nasal cannula (HHHFNC), 347
Heavy nocturnal snoring, clinical symptoms of, 17*b*
Heliox, for acute episode of asthma, 719

Helium dilution technique, 179*f*

Helminth associated eosinophilic lung disease, 962

Helminth larvae, 962

Hemagglutinin, in influenza virus, 460

Hemangiomas, 307–309

Hematopoietic stem cell transplantation

- pulmonary complications of, 935–940, 935*t*
  - early noninfectious posttransplant complications, 936–937, 936*f*
  - late noninfectious posttransplant complications, 938–940
  - pretransplant factors, 935–936
- special pulmonary considerations in pediatric patients with, 604–605, 605*t*

Hemianomalous pulmonary venous drainage, 298

Hemiplegia, 1046

Hemodynamics, in pediatric pulmonary arterial hypertension, 571–572

Hemoglobin

- reduced, 18*f*
- in transport of carbon dioxide, 94

Hemoglobin A, 903

Hemoptysis, cystic fibrosis and, 781

Hemorrhage

- in hydrocarbon aspiration, 626
- pulmonary, as complication of mechanical ventilation, 603

Hemosiderosis, in Down syndrome, 999*f*

Hemothorax, 1065–1066

- bleeding sources, abundance, 1065–1066
- children, 1025
- clotting/loculation/infection, 1066
- management of, 1066

Hepatic engorgement, 21

Hepatic function, abnormality of, 540

Hepatic steatosis, 792

Hepatobiliary disease, 791–794, 791*f*

- blood test, usage of, 791
- clinical presentation of, 791
- diagnosis of, 792, 792*f*
- management of, 793–794
- ultrasound in, 792

Hepatopulmonary syndrome (HPS), following solid-organ transplantation, 933

Hereditary clubbing, 19

Hereditary SP-B deficiency, recognition of, 837

Hering-Breuer reflex, 69, 185–186

- lung inflation stimulation, 342–343

Heritable pulmonary arterial hypertension (HPAH), 564

- epidemiology of, 564
- gene identification of, 577
- incidence and prevalence of, 560
- natural history of, 564–565

Hermansky-Pudlak syndrome (HPS), 823

Herpes simples virus (HSV), 926

Herpesvirus type 6, 926

HES, Hypereosinophilic syndrome

Heterotaxia, 1041

Heterotaxy, 1041

Heterotaxy syndrome, in single ventricle physiology, 624–625

HFCWO, High-frequency chest wall oscillation

HFJV, High-frequency jet ventilation

HFOV, High-frequency oscillatory ventilation

HFV, High-frequency ventilation

HGVS, Human Genome and Variome Society

HHHFNC, Heated humidified high-flow nasal cannula

HIES, Hyper IgE syndromes

High altitude (HA), 226
  asthma, 226–227
  bronchopulmonary dysplasia, 227
  chronic exposure, 227
  cystic fibrosis, 227
  muscle performance, 226

High-altitude pulmonary edema (HAPE), 590–591, 1003

High-frequency chest wall oscillation (HFCWO), 281*f*
  usage, 281, 284

High-frequency jet ventilation (HFJV), randomized trials, results, 376

High-frequency oscillatory ventilation (HFOV)
  in acute respiratory distress syndrome, 611
  randomized trials, results, 376

High-frequency ventilation (HFV), 550–551
  gas-transport mechanisms during, 597, 598*f*

High intensity interval training (HIIT), 224–225

High-permeability pulmonary edema, 584

High pressure pulmonary edema, 584, 588–589
  distinguishing low pressure from, 587–588

High-resolution computed tomography (HRCT), 165, 165*f*
  interpretation, 165–168, 166*f*–167*f*
  sensitivity, 1103–1104
  for severe problematic asthma, 724

HIIT, High intensity interval training

Hilar adenopathy, in pulmonary tuberculosis, 479*f*

Hilar bronchogenic cyst, esophagram of, 1083*f*

Hilar expansion, 151

Hippocratic fingers, 18–19

Hirschsprung disease, 1150

Histamine, 220

- in asthma, 667
- direct bronchoprovocation testing and, 695
- presence, 739

Histones, 47

*Histoplasma capsulatum*, 508

Histoplasmosis, 508–512

- diagnosis of, 509–510, 511*f*
- differential diagnosis of, 510
- disseminated, 509
- epidemiology of, 508, 508*f*
- etiology of, 508
- imaging of, 509, 510*f*
- laboratory findings on, 509
- management and treatment of, 510–511
- pathology/pathogenesis of, 508–509
- prevention of, 511
- prognosis of, 511–512
- pulmonary, 509
- pulmonary function testing for, 509
- pulmonary infection and, 929–930
- symptoms and physical findings of, 509

Historical cohort study, in asthma, 640–641

History, 2–25

- in diagnosis of preschool asthma, 677–678
- pediatric, 2–4
- principles of, 2

HIV, Human immunodeficiency virus

HMPV, Human metapneumovirus
HOA, Hypertrophic osteoarthropathy
Hoarseness, 305
Hodgkin disease, relapsing, 878
Holding chambers, for asthma, 714, 714*t*
Home care, considerations for, 385–386
Home mechanical ventilators, 389–390
Home positive pressure mechanical ventilators, 390
Home visit, adherence and, 727
*Homeobox 2B (PHOX2B)* gene, 384–385
Homeostasis, in type II alveolar epithelial cells, 67
Hookworms, 962
Hoover sign, 5
Horner's syndrome, 1080–1081
Hospital
  admission to, severe asthma and, 729–730, 730*b*
  management of asthma in, 719
Hospitalization, in asthma, 646–647
Host defense functions, of surfactant, 59–60
House dust mites, pet sensitization and, 728–729
How Are You? (HAY), 236*t*–237*t*
HP, Hypersensitivity pneumonitis
HPAH, Heritable pulmonary arterial hypertension
HPS, Hermansky-Pudlak syndrome
HRQoL, Health-related quality of life
HS, Hyperinfection syndrome
HSV, Herpes simples virus
Human genome, sequencing, 229

Human Genome and Variome Society (HGVS)
- CFTR guidelines, 758

Jugular venous distention, 21

Juvenile dermatomyositis (JDM), 857–860
- asymptomatic pulmonary function abnormalities in, 859
- chest radiograph in, 858*f*
  - posteroanterior/lateral view of, 859*f*
- clinical manifestations of, 857
- diagnosis of, 857–858
- epidemiology of, 857
- pathogenesis of, 857
- prognosis of, 860
- pulmonary involvement in, 858–859, 858*f*
- treatment of, 859–860

Juvenile idiopathic arthritis (JIA), 850–854
- classification of, 852
  - International League of Associations for Rheumatology (ILAR) criteria for, 852
- clinical manifestations of, 852
- diagnosis of, 852

    epidemiology of, 850
    etiology of, 850–852
    intraarticular corticosteroid injections for, usage of, 854
    macrophage activation syndrome (MAS) and, 852
    mortality of, 853
    nonsteroidal anti-inflammatory drugs (NSAIDs) for, usage of, 854
    pathogenesis of, 850–852
    prognosis of, 854
    pulmonary function in, studies of, 853–854
    pulmonary involvement in, 853–854
    pulmonary manifestations with, 853
    subtypes of, 852*t*
    systemic onset, HRCT scan in, 853*f*
    treatment of, 854
Juvenile myasthenia gravis, 1047, 1050, 1053, 1056
Juvenile scoliosis, 1059
Juxtacapillary (J) receptors, distribution of, 581

**K**

Kartagener syndrome, 63–65
Karyotype, 41, 45*t*
Kasukawa's criteria, 863
KCO, 88
Kenny-Caffey syndrome, 312
Keratoconjunctivitis sicca, 872
Kerley B lines, 958
Kerley lines, 586
    example of, 587*f*
KL4 polypeptide, 346–347
Kreisler (mouse) MAF-related leucine zipper homolog, 1144

Kyphoscoliosis, 1048–1049, 1052, 1054, 1058–1060, 1085
  classification of, 1048
  respiratory effects of, 1048–1049
  respiratory function testing in, 1052
Kyphosis
  onset, 274*f*
  severe, 384

**L**

Labile asthma, 690
Lactoferrin, 126
LAM, Lymphangioleiomyomatosis
Lamellar bodies, 67, 838
  absence, 61
LAQ, 234–235
LAR, Laryngeal adductor reflex
Larsen and Fryn syndrome, 312
Larsen syndrome, 1005*t*–1006*t*
Laryngeal adductor reflex (LAR), adequacy, 1111
Laryngeal agenesis, 291
Laryngeal atresia, 304–306
Laryngeal chemoreflex apnea (LCRA), 1126
  feeding infants with exaggerated, 1129–1130
  in infant, 1127*f*
Laryngeal cleft, 306
  type 1, 306, 306*f*
  type 2, 306
  type 3, 306
  type 4, 306
Laryngeal closure, prevention of, 121

Laryngeal disorders, 121, 1118–1124
    operative assessment, 1118–1119
Laryngeal electromyography, 306–307
Laryngeal function, impaired, 1097
Laryngeal mist airway (LMA), 346–347
Laryngeal obstruction, 227–228, 228*f*
Laryngeal receptor reflex, 98–99
Laryngeal webs, 304–306, 305*f*, 1122
Laryngoceles, 307
Laryngoesophagotracheal cleft, evaluation of, 1105*f*
Laryngomalacia, 16, 302–304, 726, 1121
    in Down syndrome, 993–994
    presentation of, 304*f*, 317*f*
Laryngotracheal reconstruction (LTR), 308
Laryngotracheobronchitis (LTB), viral, 406–409
Laryngotracheoesophageal cleft (LTEC), 1100
Larynx, 1106
    abnormalities of, congenital, 300*t*, 302–306
        laryngeal atresia, 304–305
        laryngeal cleft, 306
        laryngeal webs, 305
        laryngomalacia, 302–304
    congenital conditions above, causing neonatal airway obstruction, 299*t*
LAS, "Lung Allocation System"
Laser diffraction, aerosol, 262–263
Late-onset pneumonia, 353–354
Late preterm infants, autonomic instability, 1132–1133
Late pulmonary hypertension, mortality, 374*f*
Lateral chest
    diameters, mean values of, 8*f*

  - inspiratory indrawing of, 5

Lateral neck radiograph, 414

Laterality defects, 1041

LCRA, Laryngeal chemoreflex apnea

Lecithin to sphingomyelin ratio (L:S ratio), 344

Leflunomide, 883

Left atrial (LA) pressure, differences in, 582

Left hemidiaphragm, blunt traumatic rupture of, 1070*f*

Left hilar bronchogenic cyst, 1082*f*

Left lower lobe
  - bronchus, obstructive emphysema (chest radiograph), 1087*f*
  - inflammatory stricture of, 1088*f*
  - total atelectasis, chest radiograph of, 1088*f*

Left mediastinal outline, semicircular left convex distortion of, 149*f*

Left-sided pneumothorax, 1011*f*

Left-sided primary spontaneous pneumothorax, 1013*f*

Left ventricular hypertrophy (LVH), 374

*Legionella pneumophila*, 931

Leigh disease, 384–385

Lesions, parenchymal, 313–320

Lethal pterygium syndrome, 1005*t*–1006*t*

Leukemia, chlorambucil, 879

Leukocytes, in pulmonary endothelium, 70

Leukotriene antagonists, 884
  - for asthma, 709–710

Leukotriene receptor antagonist, 708

Levalbuterol, for asthma, 702–703

Levetiracetam, 882

LHR, Lung-to-head ratio
Life measures, health-related quality, 231–232
Ligand-binding alpha chain (CD116), 836–837
Lights Criteria, pleural fluid, 1014*t*
Line probe assays, for tuberculosis, 491
Linezolid, for nontuberculous mycobacterial infections, 504*t*
Lipid-containing macrophages, elevation of, 1101–1102
Lipid-laden macrophage index (LLMI), 1101
  bronchoalveolar lavage across studies *versus*, 1102*f*
Lipid mediators, 102, 110
Lipid stains, for bronchoalveolar lavage, 142
Lipoblastoma, 1079–1080
Lipopolysaccharide-induced expression, inhibition of, 60
Lipoxin (LX), 114
Lipoxin $A_4$ ($LAX_4$), 102
Liver biopsy, for non-CF-related liver disease, 792
Liver disease
  clinical presentation of, 791
  diagnosis of, 792, 792*f*
  fat-soluble vitamin dosage, 798*t*
  management of, 793–794
Living donor lobar lung transplantation, success with, 983–984
LKLF, Lung Kruppel-like factor
LLMI, Lipid-laden macrophage index
LMA, Laryngeal mist airway
Load compensation, 1131
Lobar overinflation, 149–150, 150*f*
Lobar pneumonia, 287, 353*f*

Lobectomy, 316–317

Local breath sounds, absence or presence of, 12

Localized thoracic neurogenic tumors, primary therapy for, 1081

Loculation, 435

Loeffler's-like syndrome, 958

Löffler syndrome, 962

Lomustine (CCNU), 879

Long-acting b-agonists
  for asthma, 706–709
  overuse of, 708

Long-acting b-2 agonists, role, 454

Long-acting muscarinic antagonists, for asthma, 710

Long-chain polyunsaturated fatty acids, in asthma, 654

Long-term injection medialization, 1121

Long-term mechanical ventilation, 392

Long-term pulmonary fibrosis, hydrocarbon aspiration, 1097

Loop diuretics, effects of, 379

Low-affinity IgE receptors (Fce:RII), 105

Low contrast volume bronchography, 335

Low dose carbon dioxide, 343

Low lung function
  environmental exposures in, 53, 54*f*
  risk for respiratory disease, 50

Low oxygen saturation, 907

Low pressure pulmonary edema, distinguishing high pressure from, 587–588

Lower airway
  bronchoscope in, 140
  histamine, presence, 739

  - nasal inflammation, systemic effects, 739
  - systemic disease, 765–766
  - upper airway disease on, influence of, 737–746
- Lower cranial nerve function, impact, 1099–1100
- Lower respiratory tract infection (LRTI)
  - in Down syndrome, 996–999
    - clinical presentation of, 998
    - epidemiology of, 996–998
    - etiology of, 996
    - histopathology of, 996
    - imaging of, 999–1000
    - prevention of, 1004–1005
    - rare diseases of, 999
    - severity of, 998
    - treatment of, 1004–1005
  - in human immunodeficiency virus–infected children and adolescents, 968–969
  - outcome, chest radiographs (impact), 429
  - signs/symptoms, 428–429
- Low-viscosity periciliary gel layer (PCL), 121–122
- LRTI, Lower respiratory tract infection
- LTEC, Laryngotracheoesophageal cleft
- LTR, Laryngotracheal reconstruction
- Lucinactant (Surfaxin), 346–347
- Ludwig angle, 9*f*
- Lung(s)
  - abnormalities of, 374
  - adaptive defense of, 70
  - airway
    - branching of, 65*f*
    - resin cast of, 64*f*
  - alveoli-containing gas-exchanging area, 63
  - biomarkers of, 846
  - biopsy of, usage of, 816
  - at birth, 71, 72*f*

capacities of, determined, 77
cellular characteristics of, 67*t*
changes in, 71
circulation, early injury, 373–374
closing volume in, 77
compliance of, 75–76
congenital abnormalities of, 71
congenital malformations, epidemiology of, 290
cystic fibrosis gene therapy and, 806
cystic hydatidosis of, occurrence of, 539–540
cysts, detection of, 539
development, relationship of, 371*f*
distal, 75*f*
dried human, 64*f*
dynamic (flow-resistive) properties of, 78–81
elastic recoil of, 75, 75*f*–76*f*
  increased, 75
  responsibility of, 75
elasticity of, 75
in excretion of acids, 94
fibrous network of, structure of, 80
fibrous support of, 69*f*
fluid movement in, 594*f*
fluke disease in, 545–546
function decline, acceleration (determinants), 452
growth of
  abnormal, 829*f*
  deficient, conditions associated with, 828*t*
  and development, 70–71, 71*f*
  optimization, 318
hila of, 69
histopathology of, 846–847
hyperinflation of, 67–68
inflation, degree of, 148
innate defense of, 70

- innervation of, 69
- interstitial matrix of, 69–70
- lesion, cystic, 292*t*
- lymph flow in, pulmonary microvascular pressures and, relationship of, 593*f*
- mechanics, modifications, sleep (impact) of, 1044
- metabolic functions of, 99–100, 100*t*
- microvascular pressures in, changes in, 592
- multisystem congenital disorders that affect, 332
- new and emerging infections of, 466–474
- normal
  - anatomy of, 63
  - mechanical ventilation in, 551
- in number, 67*t*
- parenchyma, acinus in, 66–67
- perfusion, regional differences in, 83
- post pneumonectomy, 73
- pressure-volume curve of, 75–76, 75*f*–76*f*, 79*f*
- recoil of, 80
- resistance, measurement of, 79
- sensory nerves from, 69
- shape, 63
- stabilization of, methods in, 75
- structural features of, 580
- total lung compliance, changes in, 76
- ventilation of, 73

Lung abscess, 154, 155*f*, 436–437
- clinical presentation, 437
- diagnosis of, 404
- etiologic agents with, 398*t*
- parenteral antibiotic, usage, 437

"Lung Allocation System" (LAS), 981–982

Lung biopsy, 1091*f*
- in hypersensitivity pneumonitis, 950–951, 951*f*
- for invasive aspergillosis, 517

Lung bud morphogenesis, 27*f*

Lung clearance index, 206, 209*f*–210*f*

Lung compliance, reduction, 383

Lung defense, 120–133
  adaptive, 129–132
  innate, 121–129
  intrinsic, 120–121

Lung densities, focal and multifocal, 153, 153*f*

Lung development, 254
  adverse effects
    across the life course, 248–249
    operating antenatally, 249–251
  aging, 254
  antenatal, 248
  antibiotics, 254
  asthma and, 252–253
  atopy and, 252–253
  birth weight, and gestational age, 251
  delivery, long-term effects of events, 251
  early viral infections, 254
  environmental pollution, 252
  in health and disease, 248–255
  microbiome, 254
  molecular mechanisms directing, 31–37
  morphogenetic periods of, 27*t*
  nutrition on life course of, 252
  postnatal lung growth, 251–252, 251*b*
  stages of, 28*f*
  stress and outcomes, 253
  wheeze, acute attack and, 252–253

Lung diseases
  associated with disruption, of pulmonary surfactant homeostasis, 836–849
    diagnosis and differential diagnosis of, 845–847

        - epidemiology of, 836–838
        - etiology of, 838–840
        - management, treatment, and prognosis of, 847–849
        - pathology/pathogenesis of, 840–844
    - CF expression, 765
    - due to NKX2.1, incidence of, 838
    - eosinophilic, 944–967
        - drugs that cause, 958*t*
        - etiology of, 952, 952*b*
        - helminth-associated, 955*b*
    - pulmonary function/gas exchange impairment in, 874*t*

Lung epithelial cell
    - development, 32*f*
    - morphogenesis and differentiation of, 33*f*

Lung function
    - abnormalities, 905–906
    - child health and disease, 212–230
    - in chronic lung disease, 979
    - low, environmental exposures in, 53, 54*f*
    - tests, for asthma, 695

Lung growth, 70–71, 71*f*
    - postnatal, 71–73, 72*f*–73*f*
    - prenatal, 70–71
    - reduced, environmental exposures in, 53
    - and relationship to disease outcomes, 252–254

Lung growth abnormalities, 826–828
    - clinical features of, 827–828
    - diagnosis of, 829
    - differential diagnosis of, 829
    - epidemiology of, 826–828
    - etiology of, 826–827
    - histologic findings in, 828–829
    - management of, 829
    - pathogenesis of, 826–827
    - prognosis of, 829–830

    radiologic findings in, 828–830, 828*f*
    treatment of, 829
Lung injury
    chronic aspiration, impact, 1104*f*
    evaluation, aspiration, 1103–1104
    ventilator-induced, 600–601
Lung Kruppel-like factor (LKLF), 102, 113–114
Lung morphogenesis, 26–31
    autocrine-paracrine signaling in, importance of, 37
    epithelial-mesenchymal interactions and, 35
    gene transcription in, regulating, 32
    molecular determinants of, 26–39
    *Nkx2-1* in, ablation of, 32–33
    nontranscriptional mechanisms regulating, 34–35
    reciprocal signaling during, 29*f*
    secreted growth factors influencing, 36*b*
Lung opacities, 151–153, 151*f*–153*f*
Lung proliferation, control of, 36
Lung sounds, 10
    asymmetry of, 10–11
    nomenclature, 13*t*
    objective acoustic measurements of, 11
Lung tissue, 401
    compression, 1027
    granuloma of, 912*f*
Lung transplantation
    in cystic fibrosis, 786
    dependence, 61
    pediatric, 981–991
        acute rejection after, 986
        antimicrobial regimen for, 984
        benefit of, 990
        bronchiolitis obliterans in, 988

        - bronchiolitis obliterans syndrome in, 988
        - chronic lung allograft dysfunction in, 988–989
        - complications after, 985–989, 985*f*
        - contraindications to, 982–983, 983*t*
        - death, causes of, 990, 991*f*
        - early phase of, 986–987
        - functional outcome after, 990
        - future directions in, 990–991
        - ganciclovir, availability of, 984
        - hyperacute rejection after, 986
        - immediate posttransplant phase of, 985–986
        - immunosuppressive regimen for, 984
        - indications for, 981–982, 982*f*
        - infection in, 986–987
        - late phase of, 987–989
        - Liou study in, 990
        - management issues in, 984–985
        - medication side effects in, 987
        - outcomes of, 989–990
        - posttransplant lymphoproliferative disease in, 987–988
        - posttransplant management for, 984
        - quality of life in, 990
        - referral of, timing of, 981
        - rejection after, 985–987
        - somatic growth after, 990
        - surgical technique for, 983–984
        - survival after, 989, 989*f*
        - timing of, 981–982
        - viral infections in, 986
    - in pulmonary arterial hypertension, 578–579
- Lung volumes, 76–78
    - asymmetrical lung volumes, 148–149, 150*f*, 150*t*
    - and capacities, 179*f*
    - definition of, 76–77, 77*f*
    - determined, 77
    - interpretation of, 78
    - measurement of, 78, 176–181
        - gas dilution technique for, 178–180, 179*f*–180*f*
        - whole body plethysmography for, 177–178, 177*f*
    - -pressure relations, changes in, 76

- regional, 78, 79*f*

Lung-gut axis, 47–48

Lung-protective ventilatory strategies, usage of, 593

Lung-to-head ratio (LHR), 292–293

LVH, Left ventricular hypertrophy

Lymph node disease, complicated, in tuberculosis, 480–483, 481*f*

Lymph nodes, biopsy of, 1090

Lymphadenitis, 910

Lymphadenopathy, isolated, in tuberculosis, 479, 479*f*

Lymphangiography, 1023–1025

Lymphangioleiomyomatosis (LAM), 819–820
- gene mutations and, 38–39

Lymphangioma, 819

Lymphangiomatosis, 819

Lymphatic capillaries, 68–69

Lymphatic clearance, 582–583

Lymphatic system, 68–69, 1021–1022
- development of, 1009*f*
- respiratory disorders of, 817–819

Lymphatic tree, congenital disease of, 329

Lymphatic vessels, 68–69
- location, 1007

Lymphocytic interstitial pneumonitis, 850

Lymphoid cells, in pediatric allergic asthma, 667–669

Lymphoid interstitial pneumonitis, in human immunodeficiency virus–infected children and adolescents, 977, 977*f*

Lymphomas, 1074

Lymphosarcoma, 1075

Lymphoscintigraphy, 1023–1025

Lysozyme, in airway, 125

**M**

MAb338, for HMPV infection, 470

MAC, *Mycobacterium avium* complex

Macro malnutrition, impact, 443–444

Macrolide antibiotics
- for pertussis, 532–533
- for severe therapy-resistant asthma, 734

Macrophage activation syndrome (MAS), 852

Macrophage inflammatory protein (MIP)-1a, 947

Macrophages, 104–105, 127

Magnesium sulfate (MgSO4)
- for acute episode of asthma, 717–719
- for preschool asthma, 685

Magnetic resonance imaging (MRI), 169–170, 169*f*–170*f*, 334
- for atelectasis, 1030–1031, 1031*f*
- for cystic fibrosis, 792
- for Down syndrome, 995, 995*f*
- for pediatric pulmonary arterial hypertension, 572
- for pulmonary edema, 587
- for pulmonary embolism, 890–891
- for vascular rings, 619

Main pulmonary artery, dilation of, 19–21

Major bronchi, lumens (lesions), 1088*f*

Male, hypereosinophilic syndrome in, 965

Malignancy, special pulmonary considerations in pediatric patients with, 604–605

Malignant teratoid tumors, 1077–1078

Malinosculation, 289

Malnutrition

- in chest circumference, 6
- predisposition, 443–444

Mannitol, as indirect bronchoprovocation agent, 695–696

Manual hyperinflation, 286*f*

Manual techniques, 286*f*

MARS, Medication adherence rating scale

MAS, Macrophage activation syndrome

Mass lesions, therapeutic bronchoscopy for, 144

Mass median aerosol diameter (MMAD), 258

Mast cells, 103–104

- in asthma, 667

Maternal antibiotic, 250

Maternal exposures, in respiratory disease, 55

Maternal factors, on asthma, 653

Maternal hypertension, 250

Maternal lifestyle, on asthma, 654

Maternal malnutrition, 249

Maternal obesity, 249

- on asthma, 653

Maternal smoking, in respiratory disease, 50–51

Matrix protein inhibitors, for influenza, 463

Matrix proteins, in influenza virus, 460

Matthew-Wood syndrome, 1005*t*–1006*t*

Mature lung, injured, 60–61

Maximal exercise tests, 214

Maximal expiratory flow, cough spikes, superimposition, 283*f*

Maximum intensity projection, 158–159

MCTD, Mixed connective tissue disease

mDCs, Myeloid dendritic cells

Measles virus infection, antibiotic treatment of, 970*t*

Mechanical insufflation-exsufflation (MI-E), 599

- NIV, combination, 284

Mechanical ventilation, 548–555

- adjuvants to, 612–614
  - beta-adrenergic agonists, 613
  - corticosteroids, 612
  - extracorporeal life support, 613–614
  - inhaled nitric oxide, 612–613
  - neuromuscular blocking agents, 613
  - prone positioning, 612
  - surfactant, 613
  - tracheostomy, 614
- chronic dependency, causes of, 382
- complications of, 554
- composition of, 548, 549*f*
- external monitors use of, 390–391
- hemodynamic effects of, 551, 552*f*
- history of, 548
- indications for, 548
  - in pediatric intensive care, 596, 597*t*
- management during, 553–554
  - comfort and, 553
  - in fluid management, 554
  - in gas humidification, 554
  - in monitoring, 553
  - in neuromuscular blockade, 554
  - suctioning and, 553
  - synchronization and, 554
  - weaning and extubation, 554
- modes of, 548–550, 549*f*
- in pediatric intensive care, complications of, 598–605
  - air leak syndromes as, 601, 601*f*
  - atelectasis as, 599–600

        - intensive care unit neuromyopathy as, 603–604
        - lung injury as, 600–601
        - mucus plugging as, 598–599
        - pneumonia as, 601–603, 602*t*, 603*f*
        - pulmonary hemorrhage as, 603
    - reduction, 391
    - in specific conditions, 551–553
        - in acute respiratory distress syndrome, 551–552
        - in bronchiolitis, 553
        - in congenital heart disease, 553
        - in neonate, 553
        - in normal lungs, 551
        - in status asthmaticus, 552–553
- Mechanically ventilated patients, devices for, 269–270
- Meconium aspiration syndrome, 58, 349–351
    - clinical features of, 350, 350*f*
    - epidemiology of, 349–350
    - management of, 350–351
    - pathophysiology of, 350
    - prevention of, 351
    - prognosis of, 351
- Meconium ileus (MI), 794–795, 795*f*
    - nonoperative management of, 794–795
    - operative management of, 795
- Meconium-stained amniotic fluid (MSAF), 349–350
- Mediastinal bronchogenic cyst, 313–314, 313*f*–314*f*
- Mediastinal chemodectomas, 1081
- Mediastinal cysts
    - primary, 1081–1086
    - vertebral anomalies, presence of, 1085
- Mediastinal dermoid cyst (benign cystic teratoma), 1075–1076
- Mediastinal distortion, 150–151, 151*f*
- Mediastinal lipoma, 1079–1080
    - presence, reports of, 1079–1080

Mediastinal shift, 294–295

Mediastinal tumors, 1074–1086

- neurogenic, 1080–1081, 1080*f*

Mediastinum

- CT scan of, 1089*f*
- mobility of, 1062
- posterior gastroenteric foregut cysts of, 1085
- vascular-lymphatic abnormalities of, 1079, 1079*f*

Mediators, 109*f*

- antiinflammatory mechanisms of, 113–114
- multiplicity and redundancy of, 108–109

Medical history

- health status, impression of, 3
- use of, 2

Medical Research Council (MRC), in epidemiologic studies of asthma, 641–642

Medical stability, criteria for, 386*t*

Medical treatment, compliance, 4

Medication adherence rating scale (MARS), 727

Medication toxicity, following solid-organ transplantation, 932

Medication-induced pulmonary edema, 591

Medium-chain acyl-CoA dehydrogenase (MCAD) deficiency, 1139

Medulla oblongata, serotonin (5HT) neurons importance of, 342

Melbourne Children's Asthma Study, 646

Membranous subglottic stenosis, 308

Mendelian randomization studies, in asthma, 641*f*

Mendelian susceptibility, to nontuberculosis mycobacterial disease, 499, 500*t*

MSSA, Methicillin-sensitive *Staphylococcus aureus*

Mucin gel, properties of, 122

Mucoactive agents, 453–454

Mucociliary clearance

  disruption, airways dehydration (impact), 762–763

  measurement of, 122, 1040

  in pulmonary host defense systems, 37

Mucociliary system, disorders of, 122

Mucociliary transport system, 63–65

Mucoepidermoid, 313

Mucoid impaction, 955

*Mucor*, pneumonia due to, 929

*Mucorales*, 522

Mucormycosis, 522–523

Mucosal edema, asthma and, 688

Mucosal function, impairment, 739–740, 740*f*

Mucus, 121–122

  airway, 121

  clearance, cilia-dependent, 122

  layer, cilia and, 121

  water contents of, 122

Mucus plugging

  as complication of mechanical ventilation, 598–599

  therapeutic bronchoscopy for, 144

Multichannel intraluminal impedance plus pH-metry (MII-pH), 1115

Multidisciplinary coordinated care, 1094

Multi-drug resistant tuberculosis, 494, 495*t*, 972

Multifocal lung densities, 153, 153*f*–154*f*

Multilobular biliary cirrhosis, 792

Multi-omics approaches, for genotype-phenotype associations, 47–48

Multiplanar reconstruction, 158, 158*f*

Multiplanar volume reconstruction, 158–159, 159*f*

Multiple aortopulmonary collateral arteries, reperfusion pulmonary edema in, 622–624

Multiple breath washout technique, 205–207

- clinical applications in infants and young children, 209–210
- feasibility in older children
  - quality control, acceptability criteria, and limitations of, 207–209
- main outcome measures of, 206–207, 207*f*–208*f*
- physiological principles and assumptions in, 205–206, 206*f*

Multiplex ligation-dependent probe amplification (MLPA), 40–41, 45*t*

Multitrigger wheeze (MTW), 649–650

Munchausen syndrome by proxy, 1139–1140

Muscarinic antagonists, long-acting, 710

Muscle fiber, in muscles of respiration, 84

Muscles, of respiration, 83–85

Muscular dystrophy, 121

Muscular pulmonary arteries, 68

Muscularization, of arteries, 68

Mutation, 40

Myasthenia gravis, 1047

Mycobacteria, 930*f*, 931

Mycobacterial disease, nontuberculous, 498–506

- acquisition and potential for transmission of, 500–501
- alternative drugs for, 506
- drug toxicity and clinical response of, 505–506

  - environmental risk factors and spatial clusters of, 499–500
  - epidemiology of, 499–500
  - extrapulmonary
    - clinical manifestations of, 502–503
    - management and treatment of, 505
  - with human immunodeficiency virus infection/acquired immune deficiency syndrome, 499

Mycophenolate mofetil (MMF), 984

Mycoplasma organism, 106

Mycoses, 507–527

Myeloid dendritic cells (mDCs), 105

Myeloid malignancies, classification of, 964*b*

Myeloproliferative variants HES (M-HES), 966*b*

Myer-Cotton grading scale, 1119*f*

Myocardial contusions, blunt trauma of, 1067–1068

Myocardial failure, 589

Myopathies, 1046
    clinical features of, 1050–1051
    diagnosis of, 1053
    management of, 1056–1058
    pathogenesis of, 1047–1048

Myositis-specific antibodies, presence of, 857–858

Myotonic dystrophy, 40–41, 1051, 1053
    congenital, 1051
    management of, 1058
    muscular, 1099

Myxoma, commonness, 1086

**N**

Nail fold capillary abnormalities, 860–861

Naloxone, use of, 339–341

Narcotic-induced pulmonary edema, 591

Nasal cavity, anatomic abnormalities in, 1108–1109

Nasal congestion, 1041
    NIV high flow, impact, 387

Nasal continuous positive airway pressure (NCPAP), methylxanthine response, failure, 1133–1134

Nasal discharge, 4

Nasal flaring, presence of, 345

Nasal inflammation, systemic effects, 739

Nasal interfaces, 389

Nasal mask, 285*f*

Nasal nitric oxide, usage, 1040

Nasal obstruction, 4

Nasal passageways, inspection of, 16

Nasal polyps

- asthma and, 691
- frequency of, 6

Nasal potential difference (PD), 773*f*

Nasal-bronchial reflex, 740

Nasogastric lavage, for hydrocarbon aspiration, 627–628

Nasopharyngeal airway (NPA), 301

Nasopharyngeal specimens, 400

Nasopharyngeal swab, 396–397

National Asthma Education and Prevention Program (NAEPP) guidelines, 711

National surveillance surveys, in asthma deaths, 647

NATs, Nucleic acid detection tests

Natural killer (NK) cells, 129

- increased, 948

NCPAP, Nasal continuous positive airway pressure

ncRNA, Non-coding RNAs

Near-obligatory nasal breathers, 1144

Nebulization, 410

Nebulized epinephrine, 410–411

Nebulizers, 264, 267–269

Neck, adenoid tissue enlargement/OSA, lateral roentgenogram, 1153*f*

Necrosis, in smoke inhalation, 630

Necrotizing bronchitis, pertussis and, 529, 529*f*

Negative intrathoracic pressure, 1008

Negative pressure breath, supply of, 387–388

NEHI, Neuroendocrine cell hyperplasia of infancy

Neonatal airway obstruction, 299*t*

- examination of a child with, 300–301

Neonatal hyperoxia, neoalveolarization and, 254

Neonatal intensive care unit

- apnea episodes, 1130
- pediatric pulmonologists, basis of, 1134

Neonatal myasthenia gravis, 1047, 1050, 1053, 1056

Neonatal pulmonary hypertension, 560–561

Neonatal respiratory distress syndrome, pulmonary edema and, 590

Neonates

- acute airway compromise, 1123
- breathing, nasal/oral route change, 1144–1145
- bronchopulmonary anatomy of, 63
- chylothorax, 1024*f*
- community-acquired pneumonia (CAP), treatment, 433
- mechanical ventilation in, 553
- reflexes, potentiated, 1144

NERD, Nonerosive reflux disease

Nerve growth factor (NGF), 112

Neural mechanisms, in inflammatory airways, 111–112, 112*f*

Neurally adjusted ventilator assistance, 551

  in acute respiratory distress syndrome, 611–612

Neurally mediated bronchospasm, 740

Neuraminidase, in influenza virus, 460

Neuraminidase inhibitors, for influenza, 463

Neurilemomas, pediatric rarity, 1080

Neuroblastoma, 1080–1081

  boys, presence of, 1081*f*

Neuroendocrine cell hyperplasia of infancy (NEHI), 425, 832–834

  characteristic radiographic and pathologic findings in, 833*f*

  clinical features of, 832

  diagnosis of, 833–834

  differential diagnosis of, 833–834

  epidemiology of, 832

  etiology of, 832

  histologic findings in, 833

  management of, 834

  pathogenesis of, 832

  prognosis of, 834

  radiologic findings in, 832–833

  treatment of, 834

Neuroendocrine cell prominence, small airway obstruction severity (correlation) and, 832

Neuroepithelial bodies, oxygen-sensing functions of, 65

Neurofibromatosis, 822–823

Neurofibromatosis type 1 (NF-1), 822–823

  CT sagittal section in, 822*f*

Neurogenic mediastinal tumors, 1080–1081, 1080*f*

Neurogenic pulmonary edema, 590

Neurogenic tumors, radiographic examination in, 1081

Neurokinin A, 112

Neurologic arch, 1108

Neurological injury, 1097

- outcome prediction of, 637

Neuromuscular blockade, mechanical ventilation in, 554

Neuromuscular blocking agents, for acute respiratory distress syndrome, 613

Neuromuscular disease (NMD), 283–284

- inadequate pump out, 383–384
- physical therapy, 273
- respiratory function testing in, 1051
- special pulmonary considerations in pediatric patients with, 603
- spine deformities in, 1059

Neuromuscular junction diseases

- clinical features of, 1050
- diagnosis of, 1053
- management of, 1056
- pathogenesis of, 1047

Neuromyopathy, intensive care unit, as complication of mechanical ventilation, 603–604

Neuroprotection, following drowning, in induced hypothermia, 636

Neutrophilic airway inflammation, sputum markers, 447

Neutrophil-mediated proteolytic activity, in smoke inhalation, 631

Neutrophils, 106

- bronchospasm, 220–221
- characterized, 128
- dysfunction (Job's syndrome), 102
- in pediatric allergic asthma, 669

Newborn infants

- acute respiratory distress syndrome, 351–352

  - clinical presentation of, 351
  - management of, 351–352
  - pathophysiology of, 351
- airway muscles of, bronchoconstriction of, inadequate, 66
- apnea, 343

    - pharmacodynamics, 751
    - pharmacokinetics, 751
    - pharmacology, 751
    - safety, 751–752
    - for severe therapy-resistant asthma, 733
- Omics, 229–230
- Open, sucking thoracic wall injury, 1065*f*
- "Open tube" bronchoscope, 134

Open-lung biopsy, 942

Opitz-Frias syndrome, 306

Opportunistic infections (OIs), in human immunodeficiency virus–infected children and adolescents, 968

  fungal, 975

Optical coherence tomography, 170

OPTN, Organ Procurement and Transplantation Network

Oral contraceptive pill, asthma and, 694

Oral corticosteroids, for preschool asthma, 684–685

Oral endotracheal tube, tracheostomy techniques, 1064*f*

Oral glucose tolerance test (OGTT), 794

Oral H1 antihistamines, usage, 741–742

Oral motor development, 1107*t*

Oral secretions, aspiration of, 1103

ORCC, Outwardly rectifying chloride channel

Organ Procurement and Transplantation Network (OPTN), 981–982

Organ systems, review of, 4

Organ-restricted hypereosinophilic syndrome, 966*b*

ORM1-like protein 3 (ORMDL3), in asthma, 653*t*

Oronasal interfaces, 389

Oropharyngeal swabs, culturing, 772

Oropharynx, inspection of, 6–7

Orthopnea, existence of, 5

OSA, Obstructive sleep apnea

OSAS, Obstructive sleep apnea syndrome

Oscillatory positive expiratory pressure, 279–281

Oscillatory ventilation, conventional *versus*, in pediatric intensive care, 596–598, 598*f*

Oseltamivir, for influenza, 463, 463*t*

OT, Ocular toxocariasis

Ouchterlony double immunodiffusion, 949*f*

Outdoor air pollution, in asthma, 661–663

Out-of-hospital cardiac arrest, 637–638

Outwardly rectifying chloride channel (ORCC), chloride transportation, 758–759

OVA-induced eosinophil, 218

Ovalbumin (OVA), 218

Ova/parasites, in stool examination, 537

Overexpansion, 320–322

Overlap hypereosinophilic syndrome, 966*b*

Overlap syndrome, 689–690

Oxaliplatin, 880

Oxidants, in smoke inhalation, 630

Oxidative stress, 111

Oxygen

- administration of, 93
- for bronchiolitis, 425
- delivery, to tissues, 92
- desaturations, 1157–1158
- in diffusing capacity, 88
- humidified, for asthma, 719
- mixtures, hazards of, 93–94
- in pulmonary arterial hypertension, 577–578
- in sensory feedback system, 99
- therapy, 92–94
- toxicity, 372
- transport, 89–91, 90*f*, 91*t*
- treatment, 3

Oxygen radical production, 61

Oxygenation

  inhaled nitric oxide (iNO), 377–378

  ventilation index and, contrast to, 609

Oxyhemoglobin dissociation curves, 90*f*

**P**

Paclitaxel, 880

PAH, Pulmonary arterial hypertension

Paired-like homeobox 2B (PHOX2b), 1150

Palivizumab, 426

  use of, 379

Pallister-Hall syndrome, 306

Pallor, BRUE definition and factors for inclusion and exclusion, 1126*t*

Palpable lymph nodes, biopsy of, 1090

Palpation, 8–9

  order, 8

PAM, Pulmonary alveolar microlithiasis

Pancreatic disease, 788–799

  enzyme supplements, 790

  fibrosing colonopathy, 790

    treatment of, 790

  pathobiology of, 788

  pathophysiology of, 789*f*

Pancreatic enzyme replacement therapy (PERT), 790

Pancreatic enzymes, 793

  CF produces, 789

  release of, 788, 794

Pancreatic function

  - assessment of, 790
  - fecal pancreatic elastase-1 test, 790
  - testing, 772
- Pancreatic insufficiency (PI), 788
  - management of, 790
  - mutations, impact, 761*f*

- Paranasal sinusitis, 14

Parasites
  extirpation of, 542
  in stool examination, 537
Parasympathetic nerves, 69
Paratracheal nodes, in pulmonary tuberculosis, 480–481
Parenchymal lesions, 313–320
Parental reporting, of wheeze, 677–678
Parental supervision, adherence and, 727
Pari PEP device, 281*f*
Parietal pleura, 1007
Paroxysmal coughing, 1028–1029
Paroxysmal supraventricular tachycardia, 21
Partial SP-B deficiency, 847
Partially muscular pulmonary arteries, 68
Particle size, 258–259
  aerosol, 258*t*
PAS staining, Periodic acid-Schiff staining
Passive smoking, 252
  severe asthma and, 729
Patau syndrome, 1005*t*–1006*t*
Patent ductus arteriosus (PDA), 18, 361–363
  clinical features of, 362, 362*f*
  clinical importance of, 346–347
  epidemiology of, 361–363
  etiology of, 361
  management of, 362–363
  pathogenesis of, 361–362
  prevention of, 362
  prognosis of, 363
  repair, 1121

Patient/provider discussion (facilitation), HRQoL (usage), 233

Patient-related variables, 258*t*, 260–261

Patient-reported outcomes (PRO), 231–240

- definition, 231
- development, 231
- importance, FDA recognition, 231
- psychometric criteria, 232*t*
- utilization, 231

Pattern-recognition receptors, 123–125

PAVM, Pulmonary arteriovenous malformation

PCD, Primary ciliary dyskinesia

PCR, Polymerase chain reaction

PCV, Pneumococcus conjugated vaccine

PDA, Patent ductus arteriosus

PDH, Progressive disseminated histoplasmosis

Peak expiratory flow, 183–184

- rate
  - handheld devices for, 715
  - monitoring of, for asthma, 714–715
  - zones for, 715

Peak flow meter, asthma and, 695

Pectus excavatum, 1048, 1051–1052, 1058

Pediatric acute respiratory distress syndrome, 607*t*

- extracorporeal life support in, 613–614

Pediatric asthma

- allergic, cells, molecules, and cytokines involved in, 665–669
- NO measurement for, 117

Pediatric Asthma Caregiver's Quality of Life Questionnaire, 235, 236*t*–237*t*

Pediatric Asthma Quality of Life Questionnaire (PAQLQ), 234, 236*t*–237*t*

Pediatric blunt chest trauma, 1062

Pediatric care models, differences, 242

Pediatric chest radiology, 147

Pediatric deaths, occurrence, 1062

Pediatric fiberoptic endoscopic evaluation of swallowing, advantages and disadvantages, 1110*t*, 1111

Pediatric history, structure of, 2–4

Pediatric Index of Mortality (PIM2), 637

Pediatric intensive care unit (PICU)
  history of, 596
  intubation in, 596
  mechanical ventilation in
    complications of, 598–605
    indications for, 596, 597*t*
  respiratory complications of, 596–605
  special pulmonary considerations in
    in patients with congenital heart disease, 604
    in patients with malignancy or hematopoietic stem cell transplantation, 604–605, 605*t*
    in patients with neuromuscular disorders, 603
  transfer, 386
  ventilation strategies in, 596–598
    conventional *versus* oscillatory ventilation, 596–598, 598*f*
    extracorporeal membranous oxygenation, 598

*Pediatric Laryngology and Bronchoesophagology*, 406

Pediatric lung transplantation, 981–991
  antimicrobial regimen for, 984
  benefit in, 990
  causes of death after, 990, 991*f*
  complications after, 985–989, 985*f*
  contraindications to, 982–983, 983*t*
  early phase in, 986–987
  future directions in, 990–991
  immediate posttransplant phase in, 985–986

  - immunosuppressive regimen for, 984
  - indications for, 981–982, 982*f*
  - issues in, 984–985
  - late phase in, 987–989
  - outcomes of, 989–990
    - functional, 990
  - posttransplant management for, 984
  - quality of life in, 990
  - somatic growth after, 990

Penicillamine, 882–883

PEP, Positive expiratory pressure

Percussion, 9–10

  subjective assessment of, 10

Perfusion scanning, 333

Pericardial coelomic cysts, 1085

Pericardial cyst, location (posteroanterior/lateral chest radiographs), 1086*f*

Pericardial tumors, 1086

Pericardioperitoneal canals (primorial pleura cavity), 1008*f*

Pericardium, primary neoplasms of, 1086

Pericyte, in interstitium, 70

Peri-Engraftment respiratory distress syndrome, 936–937

Periodic acid-Schiff (PAS) staining

  for bronchoalveolar lavage, 142

  usage of, 844

Periodic breathing, 4–5

  definition, 1145

  epochs, 1131

  newborn infants, 343

Periodic leg movements, 1155*f*

Periostosis, 448

Peripheral blood mononuclear cells (PBMCs), methylation, 229–230

Peripheral chemoreflexes, 1146–1147

Peripheral cyanosis, 17

Peripheral edema, 21

Peripheral interlobular septal thickening, HRCT scan in, 861*f*

Peripheral vascular disease, 860–861

Peritonsillar abscess, 417–418

Permanent medialization laryngoplasty, 1121

Persistent airflow limitation, severe asthma and, 732–733

Persistent bacterial bronchitis, inflammation and, 101

Persistent pulmonary hypertension of newborn (PPHN), 354–357, 560, 1001–1002
  clinical presentation of, 355
  diagnosis and differential diagnosis of, 355–356
  management of, 356–357
  mechanical ventilation in, 553
  mortality and morbidity of, 357
  pathophysiology of, 355
  treatment of, 577

Persistent rhinitis, diagnostic testing, 741

PERT, Pancreatic enzyme replacement therapy

Pertactin, in *Bordetella* pertussis, 530*t*

Pertussis, 287, 528–534
  clinical features of, 530–531
  diagnosis of, 532
  differential diagnosis of, 532
  epidemiology of, 528, 529*t*
  etiology of, 528
  imaging of, 531–532
  incidence, 437
  laboratory findings of, 531–532
  management of, 532–533
  pathology/pathogenesis of, 528–530, 529*f*, 530*t*
  physical findings on, 531, 531*t*
  prevention of, 533
  prognosis of, 533
  pulmonary function testing for, 531–532
  symptoms of, 530–531
  treatment of, 532–533

Pertussis toxin (PTX), 530*t*

PET, Positron emission tomography

PFTs, Pulmonary function tests

PGD, Primary graft dysfunction

pH, alterations in homeostasis in, asthma and, 688

PHACES syndrome, 307

Phaeohyphomycosis, 526

Phagocyte function, defect in, 909

Pharmacologic agents, lung injury caused by, 876–885, 884*t*

Pharmacologic therapy, of chylothorax, 1025

Pharyngitis

- diagnosis of, 404
- etiologic agents associated with, 397*t*

Pharyngoconjunctival fever, in adenoviral infections, 473

Phase III slope (SIII) analysis, for washout curve, 207, 208*f*

Phenotype, 45

- genotype correlations, 760–762, 774–775

Phenotypic variation, of asthma, 648–651

- atopic and nonatopic asthma, 650
- inflammatory subtypes of, 650
- severe asthma, 650
- temporal progression of symptoms of, 648–650, 649*f*

Phonation, 1108

Phosgene gas, inhalation of, 591

Phosphatidylcholine (PC), presence of, 836

Phosphatidylglycerol (PG), requirement, 344

Phosphodiesterase inhibitors, in pulmonary arterial hypertension, 577

Phosphodiesterase type 5 (PDE5) inhibitors, 577

Phospholipids
    content of, 61
    phosphatidylcholine species of, 57
Physical activity
    in asthma, 660–661
    cystic fibrosis, 223–225
    insufficient, 230
    lung disease, 225
Physical examination, 4–14
    auscultation in, 10–14
        technique of, 12–14, 13*f*–14*f*, 13*t*–14*t*
        thoracic acoustics, 10–12, 10*f*–11*f*
    inspection in, 4–7, 5*f*–8*f*
    palpation in, 8–9
    percussion in, 9–10, 9*f*
    taste and smell in, 14
Physical fitness, 212–213
Physical irritation, occurrence of, 3
Physical therapy

  - formation, 1008–1010
  - Gram stain, 436
  - Lights Criteria, 1014*t*
  - microbiological testing, 436
  - ultrasonogram of, 1089*f*
- Pleural liquid excess, accumulation, 1008–1010
- Pleural space, 1007–1026
  - anatomy, 1007–1008
  - bacteria, entry, 435
  - embryology, 1007–1008
  - fluid, 1013–1025
  - physiology, 1008–1010
- Pleural tuberculosis, 482, 482*f*
- Pleuroperitoneal shunt, chylothorax, 1025
- Pleuropulmonary blastoma, 1073
- Pleximeter, placement of, 9
- pMDIs, Pressurized metered dose inhalers
- PMN, Polymorphonuclear leukocytes
- Pneumatoceles, association, 435
- Pneumococcal pneumonia, 430*f*
  - presumptive diagnosis, 434*f*
- Pneumococcus conjugated vaccine (PCV)
  - in bacterial pneumonia, 969–970
  - in HIV-infected children, 969–970
  - impact, 437
- *Pneumocystis jirovecii*, 927–928
- *Pneumocystis jirovecii* pneumonia, in human immunodeficiency virus–infected children and adolescents, 973–975
  - antibiotic treatment of, 970*t*

Pneumomediastinum, 358, 359*f*

Pneumonectomy, 316–317

Pneumonia

- in children, 427–438
- definition of, 427
- diagnosis of, 404, 431
- in Down syndrome, 1003*f*
- environmental contributions to, 55
- etiologic agents with, 397*t*
- in human immunodeficiency virus–infected children and adolescents, 968–969
  - antibiotic treatment of, 970*t*
  - associated with *Bordetella pertussis*, 969
  - bacterial, 969–970
  - cytomegalovirus in, 973
  - *Pneumocystis jirovecii*, 973–975, 974*f*
  - prevention of, strategies for, 975*b*
  - varicella zoster, chest radiograph of, 973*f*
- hydrocarbon, 627*f*
- incidence, vaccines (impact), 427
- necrotizing pneumonia, 435
- prevention, 437
- prognosis, 437–438
- slowly resolving pneumonias, 433–435
- vaccine trials, efficacy estimates, 427
- ventilator-associated, 554, 601–603, 602*t*, 603*f*

Pneumopericardium, 359, 359*f*

Pneumothorax, 358, 358*f*–359*f*

- absence of, 148, 154–156, 156*f*
- cystic fibrosis and, 781
- flying and diving after, 1013
- left-sided, 1011*f*
- measurement of, 1012*f*
- pleural space, 1010–1013
- primary spontaneous, 1012*f*

    - quantify, methods, 1011*t*
    - secondary, causes of, 1010*t*
    - traumatic, 1064–1065
    - treatment of, 1011
- Pollen-sensitive asthma, exacerbations, 117
- Pollution, antenatal effects of, 249
- Polyclonal hypergammaglobulinemia, 911
- Polydrug resistance, 494
- Polyhydramnios, 291–292, 294–295
- Polymerase chain reaction (PCR)
    - CAP analysis, 431
    - for invasive aspergillosis, 517
    - for pertussis, 532
- Polymorphisms, 40, 61
    - in hospitalization, in asthma, 647
    - occurrence, 1137
- Polymorphonuclear leukocytes (PMN), 407–408, 590
- Polymyositis (morbidity/mortality), ILD (impact) of, 858
- Polyphonic wheezing, 17
- Poor adherence, in hospitalization, in asthma, 647
- Pores of Kohn, 66–67
- Portable suction machines, 390
- Portable ventilators, 388
- Portal hypertension, 791–793
- Porto-pulmonary hypertension (PPHTN), following-solid organ transplantation, 933
- Posaconazole
    - for mucormycosis, 523
    - for pulmonary mycoses, 507–508
- Positioning, 287*f*

Positive end expiratory pressure (PEEP)
  delivery of, 347–348
  intrinsic, offsetting, 388
Positive expiratory pressure (PEP), 279, 280*f*–281*f*
Positive pressure devices, 388–389
Positron emission tomography (PET), 173
Post-effort breath sound, 12
Posterior cricoid cartilage grafting, 1121–1122
Posterior gastroenteric foregut cysts, 1085
Posterior laryngeal clefts, 1123
Posterior mediastinal cyst, enteric characteristic of, 1085
Posteroanterior chest radiograph, overexposure, 1082*f*
Posteroanterior film, in children, 147
Postinfectious bronchiolitis obliterans, 447
Postmenstrual age, 1130–1131
  monitoring, 1134
Postnasal drip, inflammatory material, 740
Postnatal pulmonary vasculature, 69
Postoperative atelectasis, 1029
Postoperative pulmonary hypertensive crisis, 619–621
  background of, 619–620
  evaluation and monitoring of, 621
  pathophysiology of, 621
  risk factors for, 620–621
  treatment of, 621
Posttransplant lymphoproliferative disease, 932–933, 933*f*, 939
  in pediatric lung transplantation, 987–988
Posttraumatic atelectasis, 1067, 1069*f*
Postural drainage (PD), positions, ACBT (usage), 279–281

Postural hypotension, effect (minimization), 285
Potentiators, 803–804

Potts shunt, in severe pulmonary arterial hypertension, 578

PPHN, Persistent pulmonary hypertension of newborn

Practicalities and Perceptions Approach (PAPA), 727

Prader-Willi syndrome (PWS), 385

- sleep-related/breathing-related manifestations, 1151–1152

Praziquantel, for pulmonary paragonimiasis, 546

Pre-Bötzinger complex, 1144

Prednisolone, for severe therapy-resistant asthma, 733

Prednisone, in ABPA, 957

Preemptive inhaled corticosteroids, for preschool asthma, 682, 682*f*

Preemptive leukotriene receptor antagonists, for preschool asthma, 682

Preemptive oral corticosteroids, for preschool asthma, 682–683

Preemptive strategy, effective, for preschool asthma, 683

Pregnancy and childbirth, asthma on, 653–655

- fetal growth and birth size, 654–655
- maternal factors, 653–654
- maternal lifestyle and environment, 654
- mode of delivery, 655

Pregnant women, immunization of, in HIV, 973

Premature emphysema, tobacco exposure and, 249

Premature infants

- apnea, 1125, 1130–1134
  - spontaneous, 1133*f*
- home monitoring, 1134
- intercostal tone, loss, 1131

Premature neonates, quiet sleep, nonapneic controls, 1131

Premature termination, 184–185

Prematurity, 255–256, 255*b*, 826

  - chronic lung disease of, infant pulmonary function testing for, 814–815
  - lung disease, 225
- Prematurity and Respiratory Outcomes Program (PROP), 378*f*
- Prenatal exposures
  - pathway, 50*t*
  - in respiratory disease, 55
- Prenatal maternal stress, 250
- Prenatal onset pulmonary hypoplasia, 828–829
  - ranges of, 826–827
- Prenatal ultrasound, 291
- Prenatal (saccular) walls, in postnatal lung growth, 73
- Preoperative swallowing, 1119
- Preschool age child, asthma in, 677–685, Preschool asthma
- Preschool asthma, 677–685
  - clinical patterns of wheeze in, 679
  - diagnosis of, 677–678, 678*t*
  - environmental factors of, 679
  - epidemiology of, 677, 678*f*
  - natural history of, 679
  - pathology of, 679
  - treatment of, 680–685
    - future directions in, 685
    - initial management of exacerbations in, 683–685
    - nonpharmacological, 680
    - pharmacological, 680–683
- Preschool wheeze, 671–674
  - developing airway microbiome, 673
  - differential diagnosis of, 678*t*
  - eosinophilic inflammation on
    - inception, 672
    - persistence, 672–673
  - episodes of, 677
  - exacerbations

- during and in between, airway pathology in, 672, 672*f*
- infection associated, airway inflammation in, 671–672

- impact of immune maturation on, 673
- phenotypes of, 671
- progression to asthma of, 674
- protection from, 673
- response to antiinflammatory therapies, 671
- severity and frequency of, 674

Preschool-age children

- wheezing in, preventive strategy for, 681

Prescription records, adherence and, 727

Pressure control ventilation, 549, 549*f*

Pressure support ventilation, 549–550, 549*f*

Pressure-volume curves, 59

- of lung, 75*f*–76*f*

Pressurized metered dose inhalers (pMDIs), 257, 264–266, 265*f*

Preterm infants

- aspiration susceptibility, 1099
- periodic breathing, epochs, 1131
- with respiratory distress syndrome, 60

Preventive strategy, for specific wheezy children, 681

Primary cardiac tumors, 1086

- myxoma of, 1086

Primary ciliary dyskinesia (PCD), 63–65, 122, 256, 1034–1043

- classification of proteins mutated in, 1038*f*
- clinical features of, 1040–1042, 1040*t*
- diagnosis of, 1042
- epidemiology of, 1034
- etiology of, 1034–1036
- functional defects of, 1039–1040, 1039*f*
- gene mutations and, 38–39, 1037*t*
- genetic heterogeneity of, 1036

  - genetics, 1036–1038
  - HRQoL measure, 239
  - management of, 1042–1043
  - nasal nitric oxide, 1040
  - normal motile ciliary structure and function of, 1034–1036, 1035*f*–1036*f*
  - pathogenesis of, 1036–1040
  - pathology of, 1036–1040
  - primary ciliopathies, overlap, 1035–1036, 1042
  - prognosis of, 1043
  - pulmonary function tests of, 1041
  - recommendation, 240
  - respiratory physiotherapy, 274–283
  - specific ciliary defects causes, 1038*f*
  - surgical intervention of, 1043
  - treatment of, 1042–1043
  - ultrastructural ciliary defects, 1038–1039, 1039*t*
- Primary graft dysfunction (PGD), 986
- Primary intrathoracic malignancy, 318
- Primary mediastinal cysts, 1081–1086
- Primary pulmonary lesions
  - benign, 1072
  - malignant, 1072–1073
- Primary spontaneous pneumothorax, 1012*f*
- Prior pleurodesis, 982
- PRO, Patient-reported outcomes
- PROBIT trial, in asthma, 655–656
- Problematic severe asthma, 723*b*
  - initial evaluation of, 723–724
  - not asthma at all, 724
  - nurse-led assessments in, 727*t*
- Procarbazine, 880

Procaspase 8, 132–133
Progressive disseminated histoplasmosis (PDH), 509
Progressive primary infection, in tuberculosis, 479, 479*f*
Progressive right heart failure, in untreated IPAH, 564–565
Proinflammatory cytokines, 60
Proinflammatory transcription factors, 109–110
Prone positioning
  in acute respiratory distress syndrome, 612
  sudden infant death syndrome and, 1140
PROP, Prematurity and Respiratory Outcomes Program
Prophylactic caffeine, use of, 343
Propranolol therapy, for tracheal hemangioma, 308, 308*f*
Prostacyclin, inhaled, for pulmonary hypertension, 621
Prostacyclin analogues, 575–576
  inhaled, 575–576
  oral, 576
Prostaglandins (PG), 110
Protectin D1 (PD1), 102
Protein C/S deficiency, 572–573
Proteinase 3 (PR3), 869
Proteoglycans, in interstitium, 69–70
Protracted bacterial bronchitis, 439–440, 440*f*, 456–459
  bronchoscopic appearances, 456*f*
  children, outcomes, 456–457
  clinical features of, 457
  defining, 457–458
  diagnosis of, 457–459
  diagnostic criteria of, 458*b*
  differential diagnosis of, 457–459
  disease burden, 456

    epidemiology of, 456
    management of, 459
    pathology/pathogenesis of, 456–457
    prognosis of, 459
    treatment of, 459

Protracted hematogenous tuberculosis, 482

Proximal airway wall, T-lymphocytes in, 103

Proximal conducting zone (bronchial tree), 63

Proximal upper airway lesions, subcutaneous emphysema (presentation), 1066

Proxy-respondents, use of, 233

PS, Pancreatic sufficiency

*Pseudallescheria boydii*, 525–526

Pseudoglandular period, 28*f*, 29–30

Pseudoglandular phase, 248

Pseudoglandular stage, 70

*Pseudomonas aeruginosa*, 319, 777
    airways colonization, 757

Psychological stress, in hospitalization, in asthma, 647

Psychosocial development, quality of life and, 383

PTE, Pulmonary thromboembolism

Pubertal growth spurt, respiratory failure during, 384

Pulmonary agenesis, 321–322, 321*b*

Pulmonary alveolar microlithiasis (PAM), 820–821
    clinical features of, 820
    diagnosis of, 820
    differential diagnosis of, 820
    epidemiology of, 820
    etiology of, 820
    management of, 820–821

  - pathogenesis of, 820
  - prognosis of, 820–821
  - radiographic features of, 820*f*
- Pulmonary alveolar proteinosis (PAP), 939
  - autoimmune, 839
  - autosomal recessive *CSF2RA* mutations, impact, 839–840
  - autosomal recessive *CSF2RB* mutations, impact, 840
  - as surfactant homeostasis disorder, 836
  - syndrome, genetic disorders and, 840
- Pulmonary arterial hypertension (PAH), 850
  - assessment of, 570–572
  - atrial septostomy in, 578
  - childhood, 556–579
  - classification of, 556–557
  - clinical presentation of, 569
  - definition of, 556–557
  - diagnosis of, 570–572
  - epidemiology of, 557–560
  - etiology of, 557–560
  - genetics of, 560
  - impact of, 863
  - lung transplantation in, 578–579
  - management of, 572–577
    - anticoagulation in, 572–573
    - calcium channel blockade in, 573–575
    - endothelin receptor antagonists in, 576–577
    - general measures in, 572
    - phosphodiesterase inhibitors in, 577
    - prostacyclin analogues in, 575–576
  - pathogenesis and pathobiology of, 565–568
    - apoptosis in, 568
    - cell proliferation in, 568
    - endothelial dysfunction in, 567–568
    - growth factors in, 568
    - inflammation in, 568
    - pathways responsible for vasoconstriction in, 566–567, 566*f*

        - thrombosis in, 568
    - pathophysiology of, 568–569
    - pediatric
        - diagnostic workup for, algorithm illustrating, 570*f*
        - pharmacological approach to, algorithm illustrating, 574*f*
        - severity of disease in, 574*f*
    - physical examination findings of, 569–570
    - severe, Potts shunt in, 578
    - targeted therapy for, 573–575
    - targets for current or emerging therapies in, 566*f*
- Pulmonary arterial (PA) pressure, 582
- Pulmonary arterial tree
    - absent or small, 324–326, 325*f*–326*f*
    - arrangement, disorders of, 324–326, 325*f*

- Pulmonary arteriovenous malformation (PAVM), 298, 327–329
    - associated disorders of, 328
    - clinical features of, 327–328, 328*f*
    - clubbing in, 19
    - complications, 329
    - diagnosis of, 328
    - etiology of, 327
    - prevalence of, 327
    - screening, 328
    - treatment of, 328
- Pulmonary artery sling, 309, 309*f*, 615–619, 618*f*
    - clinical presentation of, 619
    - diagnosis of, 619
    - slide tracheoplasty for, 620*f*
    - treatment of, 619, 619*f*–620*f*
- Pulmonary atresia, reperfusion pulmonary edema in, 622–624
- Pulmonary blood

- flow
    - increased, 589
    - ventilation and, 214
- vessels, definition of, 580–581
- volumes, increased, 585

Pulmonary capillaries, endothelium in, continuity of, 580

Pulmonary capillaritis, isolated, 898

Pulmonary capillary bed, 68

- reduction of, 18

Pulmonary capillary pressure, 582

Pulmonary changes (evaluation), CT scanning (usage), 772

Pulmonary circulation, 81, 893

- methods of evaluating, 83
- physiology of, 568–569

Pulmonary compression injury (traumatic asphyxia), 1067

Pulmonary disease, 1120

- bleomycin and, 877–878
- cardiovascular signs of, 6–7
- in cystic fibrosis, 777–787
- presence of, 863

Pulmonary disease associated with congenital heart disease, 615–625

- with Fontan repair of single ventricle physiology, 624–625
- pulmonary hypertension and postoperative pulmonary hypertensive crisis, 619–621
    - background of, 619–620
    - evaluation and monitoring of, 621
    - pathophysiology of, 621
    - risk factors of, 620–621
    - treatment of, 621
- pulmonary vein stenosis, 621–622, 622*f*–623*f*
- related to cardiac surgery and cardiopulmonary bypass, 624–625
- reperfusion pulmonary edema, 622–624
- vascular rings and slings, 615–619, 616*f*–618*f*

        - clinical presentation of, 619
        - diagnosis of, 619
        - treatment of, 619, 619*f*–620*f*

Pulmonary edema, 287, 363–364, 363*f*, 580–595, 936
    - anatomic considerations in, 580–581
    - clinical disorders causing, 588–591
    - clinical presentation of, 586–588
    - in Down syndrome, 1001*t*
    - fluid clearance in, 584–585
    - fluid movement in, factors for, 581–583
        - interstitial forces, 582
        - lymphatic clearance, 582–583
        - microvascular filtration coefficient, 582
        - surface tension, 583
        - vascular forces, 582
        - vascular permeability, 582
    - following solid-organ transplantation, 931
    - formation of, opposition in, factors in, 583
    - high altitude, 590–591
    - high pressure, 584, 588–589
        - distinguishing low pressure from, 587–588
    - low pressure, distinguishing high pressure from, 587–588
    - mechanisms causing, 583–584
    - medication-induced, 591
    - narcotic-induced, 591
    - neurogenic, 590
    - pathophysiologic consequences of, 585–586
    - quantitation of, in patients, 588
    - reexpansion, 589–590
    - in smoke inhalation, 630
    - therapy for, 591–593

Pulmonary epithelium, in pulmonary immunity and asthma pathogenesis, 670–671

Pulmonary function tests (PFTs), 219, 586
    - abnormalities of, 854–855
    - asthma and, 691–692

- for children, 175–176, 176*f*
- for Churg-Strauss syndrome, 962–963
- cystic fibrosis and, 782
- for forced expiration measurement, 182–189
  - assessment of bronchodilator response and, 189, 190*f*
  - physiological principles and assumptions of, 182–184, 183*f*
  - quality control, acceptability criteria, and limitations of, 184–185
  - raised volume-rapid thoracoabdominal compression in, 185–186, 186*f*–187*f*
  - rapid thoracoabdominal compression in, 185–186
- for gas mixing measurement, 205–210
  - multiple breath washout technique, 205–207, 206*f*–210*f*
- for hypersensitivity pneumonitis, 950
- for infants, 174–175, 175*f*
- for lung volume measurement, 176–181
  - gas dilution technique for, 178–180, 179*f*–180*f*
  - whole body plethysmography for, 177–178, 177*f*
- for resistance and compliance measurement, 189–205
  - forced oscillation technique in, 199–205, 200*f*–201*f*, 203*f*–204*f*
  - general considerations for, 194, 194*f*–195*f*
  - interpretation of, 191–194, 191*f*–193*f*
  - measurement of interrupter resistance in, 196–198, 197*f*
  - physiological principles and assumptions in, 190–191
  - plethysmographic measurement of airway resistance and, 198–199, 199*f*
  - single-breath occlusion technique, 194–196, 195*f*

Pulmonary heart disease, 19–21

Pulmonary hemorrhage, 364–365, 364*f*, 893, 894*b*
- as complication of mechanical ventilation, 603
- rarity of, 855

Pulmonary host defense
- surfactant protein D (SP-D) in, 57
- systems, development of, 37–38

Pulmonary hypertension (PH), 19–21, 619–621, 905
- background of, 619–620
- bronchopulmonary dysplasia and, 357–358, 560–561
- classification of, evolution of, 556–557, 557*b*–559*b*, 557*t*
- decrease, 373

- evaluation and monitoring of, 621
- in human immunodeficiency virus infected children, 979–980
- management of, 907
- pathophysiology of, 621
- pediatric
  - clinical presentation of, 569
  - pharmacological therapy for, 561*t*–563*t*
- rarity of, 855–856
- risk factors for, 620–621
- treatment of, 621
- vascular changes in, pathologic mechanisms underlying, 565*f*

Pulmonary hypertensive vascular disease, pediatric

- broad schema of 10 basic categories of, 557*b*, 557*t*
- classification of, 558*b*–559*b*

Pulmonary hypoplasia, 291

- associated with oligohydramnios, 1005*t*–1006*t*

Pulmonary immunity

- altered, in asthma, 665, 666*f*
- structural airway cells in, 670–671

Pulmonary infections, in immunocompromised child, 923

- approach to, 940
- clinical presentation of, 923–924
- fungal pathogens, 927–930
- infectious agents in, 924–931
- invasive diagnostic studies for, 941–942
- noninvasive diagnostic studies for, 940–941
- parasitic agents, 931
- pathogens associated with, 924*t*
- prevention strategies for, 942
- pulmonary coinfections, 931
- radiographic testing for, 940, 940*t*
- viral pathogens in, 924–927

Pulmonary inflammation, exaggeration/persistence, 445–446

Pulmonary injury, 634–635
  - management of, 636
  - outcome of, 636–637
  - surfactant depletion, 634–635

Pulmonary interstitial emphysema, 154, 155*f*, 359–360, 360*f*

Pulmonary interstitial glycogenosis (PIG), 830–832, 999, 1000*f*
  - clinical features of, 830
  - diagnosis of, 830–832
  - differential diagnosis of, 830–832
  - epidemiology of, 830
  - etiology of, 830
  - histologic findings in, 830, 831*f*
  - management of, 832
  - pathogenesis of, 830
  - presentation of, 830
  - prognosis of, 832
  - radiologic findings in, 830
  - treatment of, 832

Pulmonary involvement
  - small vessel vasculitides with, 868*t*
  - vasculitis syndromes and, 867–869, 868*t*

Pulmonary Langerhans cell histiocytosis, 961–962

Pulmonary lesions
  - in hydrocarbon aspiration, 627
  - x-ray for, 911

Pulmonary lobes, projections of, 13*f*

Pulmonary lymphangiectasia (PL), 817–819
  - chest HRCT in, 818*f*
  - clinical features of, 817–818
  - epidemiology of, 817
  - etiology of, 817
  - imaging of, 818

  - management of, 818
  - pathogenesis of, 817
  - prognosis of, 818–819
- Pulmonary microstructure, forces on, 58–59
- Pulmonary microvascular pressures, lung lymph flow to, relationship of, 593*f*
- Pulmonary mycoses, 507–527
  - antifungal drugs for, 507–508
  - endemic, 508–515
  - in hosts with impaired immunity, 515–526
- Pulmonary parenchyma, tumor (presence) of, 1089*f*
- Pulmonary resistance, increased, 120–121
- Pulmonary sarcoidosis
  - decision to treat, 866
  - presenting symptoms of, 864–865
- Pulmonary sequestration, 319–320
- Pulmonary surfactant, 57, 836
  - homeostasis, lung diseases associated with disruption of, 836–849
    - diagnosis and differential diagnosis of, 845–847
    - epidemiology of, 836–838
    - etiology of, 838–840
    - management, treatment, and prognosis of, 847–849
    - pathology/pathogenesis of, 840–844
- Pulmonary thromboembolism (PTE), 887–892
  - clinical features of, 889
  - diagnosis of, 889–890
  - differential diagnosis of, 889–890
  - epidemiology of, 887
  - etiology of, 887–888, 888*t*
  - imaging for, 888, 890*f*
- Pulmonary toxicity, BCNU and, 879
- Pulmonary tuberculosis

  - in human immunodeficiency virus–infected children and adolescents, 968, 971
    - empiric therapy for, 971
  - treatment of, 493–494, 493*t*

Pulmonary tumors, in human immunodeficiency virus–infected children and adolescents, 977–978

Pulmonary vascular disease, 374, 565–566

Pulmonary vascular pressures, 81

Pulmonary vascular resistance, 82, 82*f*
  - in single ventricle physiology, 624
  - structural changes, impact, 373

Pulmonary vascular surface area, increased, 583–584

Pulmonary vascular system, 68, 68*f*
  - endothelium of, 68

Pulmonary vasculature, in Down syndrome, 1001–1003

Pulmonary vasodilation, for pulmonary hypertension, 621

Pulmonary veins, 68
  - misalignment of, 825–826

Pulmonary venous tree
  - abnormal, 326
  - congenital disease of, 326–327
  - veins, absence of, 326–327, 327*f*

Pulmonary vessels, physiologic classification of, 81

Pulmonary-renal syndrome, 867, 871

Pulse oximetry monitoring, 390–391

Pulsus paradoxus, 21

Pump failure, impact, 383

Pump output, inadequacy, 383–384

Purulent rhinitis, 909–910

pVHI, Pediatric Voice Handicap Index

PVOS, Pediatric Voice Outcome Survey

PVRQOL, Pediatric Voice-Related Quality of Life

Pyrazinamide, for tuberculosis, 493*t*

**Q**

Quadriplegia, 1045

Quality adjusted life years (QALYs), in asthma, 648

Quality of life (QOL)
  in asthma, 648
  measures, 453
    maximum, 452

Quiet sleep, 1143–1144

Quinsy, 417–418

**R**

Racial disparities, sudden infant death syndrome and, 1141

Radial spoke, primary ciliary dyskinesia and, 1034

Radiation fibrosis, 934, 934*f*

Radiographic swallow studies, value, 1100–1101

Radiography
  for asthma, 698, 699*f*
  chest, for tuberculosis, 484–485, 484*f*–485*f*

Radioimmunoassay (RIA), in hypersensitivity pneumonitis, 949

Radionuclide imaging, 172–173, 172*f*

Raised volume-rapid thoracoabdominal compression, 185–186, 186*f*–187*f*

Rales, 13–14

Randomized control trial (RCT), in asthma, 640, 641*f*

RANTES, Regulated on activation, normal T cell expressed and secreted

Rapid antigen tests, for influenza, 462

Rapid eye movement (REM)

  hypoventilation during, 384

  REM-associated obstructive apneic events, polygraphic tracing, 1153*f*

Rapid eye movement (REM) sleep, 1143

  neural sites and, 1143

  physiologic characteristics of, 1143

Rapid thoracoabdominal compression, 184*f*, 185–186

Rapidly adapting vagal (irritant) receptors, 69

RAR, Retinoic acid receptors

Rare childhood lung disorders, 817–824

Raster lines, projection of, 6

Rasterstereography, 6*f*

Raynaud phenomenon, 860–861

  vasodilating drugs for, 863

RDI, Respiratory disturbance index

RDS, Respiratory distress syndrome

Reactivation pulmonary tuberculosis, 481, 482*f*

Reactive oxygen species (ROS), production of, 372

Reactive thrombocytosis, 1018

Rebound tenderness, clinical signs of, 1071

Receptor molecules, localization of, 35

Receptor-mediated signal transduction, 35

Reciprocal signaling, during lung morphogenesis, 29*f*

Recombinant human CuZn superoxide dismutase (rhSOD), association, 372

Reconstructive airway surgery, GERD and, 1114–1115

Recruited cellular defenses, 127–129

Rectal prolapse, 796

Recurrent illness, 2

Recurrent laryngeal nerve palsy, in cardiac surgery, 1002*t*

Recurrent pneumonia, long-term risk of, 878

Recurrent respiratory infections, in Down syndrome, 993*t*

Recurrent syncope, 578

Reexpansion pulmonary edema, 589–590

Reflux aspiration

- biomarkers, 1101–1102
- evaluation, 1101
- treatment considerations for, 1102–1103

Regional lung volumes, 78, 79*f*

Regulated on activation, normal T cell expressed and secreted (RANTES), 947

Regulatory T cells (Tregs), 106–107

Rejection, after pediatric lung transplantation, 985–987

Relaxation phase, 121

Renal crisis, 860–861

Reproductive tissues, cystic fibrosis, 767

Resident cell defenses, 126–127

Residential mold contamination, 946–947

Residual pancreatic function, development, 767

Residual volume (RV), 76

- determining, 77

Resistance, 189–190

- forced oscillation technique in, 199–205, 200*f*–201*f*, 203*f*–204*f*
- general considerations for, 194, 194*f*–195*f*
- interpretation of, 191–194, 191*f*–193*f*
- measurement of interrupter resistance in, 196–198, 197*f*

- physiological principles and assumptions in, 190–191
- plethysmographic measurement of airway resistance and, 198–199, 199*f*
- single-breath occlusion technique, 194–196, 195*f*

Reslizumab, 754

Resolvin E1 (RvE1), 102

Resonant sounds, 10

Respiration

- initiation, birth, 338
- Lavoisier, stipulation, 1044
- muscles of, 83–85
- regulation of, 98, 98*f*
- tissue, 97–98

Respiratory activity, impact of, 342–343

Respiratory bronchiole (RB), light micrograph of, 66*f*

Respiratory compromise, risk, 1159

Respiratory control mechanisms, 1144–1147

Respiratory depression, at birth, 339

Respiratory disability, long-term management of, 1056–1057

Respiratory disease

- adventitious respiratory sounds, indication of, 11
- care, HRQoL/physiologic measures (integration feasibility), 234
- disease-specific aspects, 242
- in Down syndrome, 1001–1003
- environmental contributions to, in children, 49–56
  - epigenetic mechanisms in, 50–53
  - family tree of, 54*f*
  - pathways in, increased, 51*f*, 53–54
  - risk of, increased, 54*f*
  - vulnerability of children in, 49–54, 50*t*
- impact of, 2
- long-term consequences of, in children, 247–256, 248*b*, 248*t*
- of lymphatic system, 817–819

  - manifestations, description of, 3
  - in newborn, 338–366
  - progressiveness, 765
  - structural and physiologic basis of, 63–100
- Respiratory distress, 1080–1081
  - in pulmonary tuberculosis, 480*f*
- Respiratory distress syndrome (RDS)
  - acute, 351–352
  - alveolar surfactant pool sizes in, 58
  - clinical presentation of, 345, 349
  - diagnosis of, 345–346, 345*f*
  - differential diagnosis of, 345–346, 345*f*
  - epidemiology of, 344
  - management of, 346–348

Small intestine bacterial overgrowth (SIBO), 796–797

Small lungs
  bilateral congenital, causes of, 322*t*
  due to extrapulmonary mechanical factors, 322*t*

Small molecule cystic fibrosis transmembrane conductance regulator modulators, 800–801, 808
  candidate drugs, identifying, 800, 801*t*
  on protein expression, maturation, or function, 800–801, 802*f*
  protein with, 801, 802*f*
  restoration of, 809

Small primary pneumothorax, treatment of, 1012
Small volume liquid inhalers, 269
Small-cell carcinoma, CT scan of, 1089*f*
SMART regime, for severe therapy-resistant asthma, 733
SMN, Survival motor neuron
Smoke, 630
Smoke inhalation, respiratory complications of, 626–633
  carbon monoxide poisoning, 629, 629*f*
  clinical findings of, 631
  diagnosis and differential diagnosis of, 631
  epidemiology of, 628–629
  etiology of, 629
  management and treatment of, 631–632
  pathogenesis of, 629
  pathology of, 629–630
  pathophysiology of, 630–631
  prevention of, 633
  prognosis of, 633
  surface burns and, pulmonary complications of, 632–633
Smooth muscle cells, in interstitium, 70
Sneezing, as airway reflexes, 120–121
Sniffing, hydrocarbon, 628
Snoring, 905, 1147
SNPs, Single nucleotide polymorphisms
SNVs, Single nucleotide variants
Socioeconomic factors, in increase disease risk, 49–50
SOD, Superoxide dismutase
Sodium bicarbonate, use of, 339–341
Sodium channel, 122
Sodium transport model, alveolar epithelium (usage), 585*f*

Soft bedding, 1140–1141

Soft tissue, 148

Solid organ transplantation
  infectious risks in, 924, 925*f*
  pulmonary complications following, 931–934

Soluble extracellular pattern-recognition proteins, 125–126

Somatic gene therapy, 786

Somatic growth
  after lung transplantation, 990
  restriction, environmental exposures in, 53, 54*f*

Somatostatin, chylothorax, 1025

Sonic hedgehog (SHH), mutations in, 38

Sounds
  digital respirosonogram of, 10*f*
  pathways of, 10–11
  reflection of, 12
  transmission of, 12

Southern California Children's Health Study (CHS), in asthma, 660–661

SOX2
  in gene expression, 26
  mutations in, 38

SOX9, mutations in, 38

Spacer devices, for asthma, 714, 714*t*

Spatial variation, in prevalence of asthma, 644–645

SP-B protein, 344–345

Spear syndrome, 1005*t*–1006*t*

Specific airway resistance (sRaw), 198

Specific resistive loops, 199, 199*f*

Specific T helper cell phenotypes, 667*f*

Specimens
- blood, 401
- bronchoscopy, 400
- clinical, for respiratory pathogen diagnosis, 399–401
- throat and nasopharyngeal, 400

Spinal cord injury, 285
- pump output, inadequacy, 383–384

Spinal muscular atrophy (SMA), 121
- clinical features of, 1049–1050
  - type I, 1049
  - type II, 1049–1050
- diagnosis of, 1053
- drug therapy, perspectives, 1056
- management of, 1055–1056
  - type I, 1055–1056
- NIV/MI-E, combination, 284
- pathogenesis of, 1047
- prognosis of, 383
- severity, antenatal onset, 291
- type II, 1050*f*, 1056
- type III, 1050, 1056

Spinal muscular atrophy with respiratory distress type I (SMARD I), 1055–1056

Spirometric measurements of lung volumes in cooperative children, 178

Spirometry, 184
- for asthma, 695

Spondylocostal dysostosis, 1049

Spondylocostal dysostosis 1, 1005*t*–1006*t*

Spondyloepiphyseal dysplasia congenita, 1005*t*–1006*t*

Spondylothoracic dysplasia, 1049

*Sporothrix schenckii*, 523–524

Sporotrichosis, 523–524

Sputum, 396–397
  - in chest disease in children, 14–16
  - culturing, 772
  - cytologic examination of, asthma and, 696
  - induced, 116, 400
  - production, 14
  - samples, 402, 402*f*

Squawk, 11

SSEP, Short-latency somatosensory evoked potentials

Standard sweat test (Gibson and Cooke technique), 770

*Staphylococcus aureus*, 427–428
  - pneumonia, illness presentation, 427–428

Starling's equation, 592–593

“Static compliance” (Cst), 194

Statistical methods, usage, 231

Status asthmaticus, 719
  - mechanical ventilation in, 552–553

Stem cell transplantation
  - infectious risks in, 924
  - pulmonary function following, 937–938

Stenosis
  - cartilaginous congenital subglottic, 308
  - congenital tracheal, 310, 310*f*–311*f*
  - membranous subglottic, 308
  - pulmonary vein, 621–622, 622*f*–623*f*
  - subglottic, 298, 1122–1123
  - tracheal or bronchial, therapeutic bronchoscopy for, 144

Stents, for therapeutic bronchoscopy, 145

Sternocleidomastoid muscles, visible contraction of, 5

Sternum

- fractures of, 1063
- physical examination of, 1063

Steroid-resistant asthma, 312–313

Steroids

- assessment of responsiveness to, severe asthma and, 732, 732*t*
- for influenza, 463–464
- use of, 379

*Streptococcus pneumoniae*, 396, 427

- antibiotic resistance, 432–433
- in asthma, 659
- in bacterial pneumonia, 969
- empyema, 1022*f*
- pneumococcus serotypes, implications, 427

*Streptococcus pyogenes*, 427

- pharyngitis caused by, 396

Stress/inflammatory immune system, stimulant, 220–221

Stretch receptors, 69

Stridor, 12, 300

*Strongyloides stercoralis*, 543

Strongyloidiasis, 543–545

- clinical features of, 544
- diagnosis of, 544–545
- differential diagnosis of, 544–545
- epidemiology of, 543
- etiology of, 543
- pathology/pathogenesis of, 543–544
- treatment of, 537*t*, 545

Structural cell, 102

- as sources of mediators, 108, 108*f*

Structural changes and repair, 102–103

Subacute hypersensitivity pneumonitis, 949

Subacute illness, 2

Subcarinal nodes, in pulmonary tuberculosis, 480–481

Subcutaneous emphysema, 1067

Subcutaneous prostacyclin analogue (treprostinil), 576

Subglottic cysts, 303*f*

Subglottic hemangiomas, 307

Subglottic stenosis (SGS), 298, 1122–1123

- acquired, 1122
- in cardiac surgery, 1002*t*
- congenital, 308–309, 1122
- in Down syndrome, 995
- mechanical ventilation and, 554
- severity, levels of, 1122

Sublingual immunotherapy (SLIT), 747

- usage, 742

Submersion accidents, 635

Submersion events, 634–638

Subpleural cysts, in Down syndrome, 997*f*

Substance P, 112, 120–121

Sucking wound, occlusive chest wall dressing (application), 1066*f*

Suctioning, mechanical ventilation and, 553

Sudden infant death syndrome (SIDS), 1125–1142

- alveolar hemosiderin-laden macrophages, presence of, 1140
- arousal, abnormality, 1140
- bed sharing, 1141
- cardiac arrhythmias, lethality, 1139
- central nervous system, programmed cell death, 1137–1138
- circumstances of, 1139–1140

  - $CO_2$, increase concentration, 1140–1141
  - diagnostic shifting, scene data, 1140
  - electrocardiogram QT intervals, prolongation, 1139
  - epidemiologic findings, 1137
  - epidemiology, 1136–1137, 1136*f*–1137*f*
    - Back-to-Sleep campaign, 1140
    - success, 1141
  - fatty acid oxidation deficiencies, 1138–1139
  - metabolism, genetic diseases, 1138–1139
  - neural receptors, 1138
  - pathogenesis of, 1134–1135, 1135*f*
  - pathology and physiology, 1137
  - polymorphisms, occurrence, 1137
  - prone position in, 1140
  - racial disparities, 1141
  - serotonin binding, 1138
  - sleep practices, 1137
  - soft bedding, effect modifier, 1140–1141
  - sudden death, scene investigations, 1139–1140
  - ventilatory response, abnormalities, 1140–1141
- Sudden unexpected early neonatal death (SUEND), 1137
- SUEND, Sudden unexpected early neonatal death
- Sulfasalazine, 882
- Superficial gel layer, 63–65
- Superior left lower lobe
  - bilateral circumscribed densities in, 540*f*
  - fluid-filled cysts in, CT confirmation of, 541*f*
- Superior mediastinum, space-occupying structure in, 147
- Superoxide dismutase (SOD), mitochondrial, decrease in, 590
- Supplemental oxygen
  - chronic dependency, causes, 382
  - for hydrocarbon aspiration, 627–628

  - long-term risk, increase, 878
- Supraclavicular fossae
  - as horizontal reference points, 9*f*
  - indrawing of, 5
- Supraglottic airways, resonances from, 10
- Supraglottitis, 413
- Supraglottoplasty, 1121
- Surface burns, smoke inhalation and, 632–633
- Surface tension, 583
  - reduction of, 836
- Surfactant, 57–62
  - for acute respiratory distress syndrome, 613
  - alveolar life cycle of, 58, 59*f*
  - alveolar pool size of, 58
  - composition of, 57, 58*f*, 836–837
    - associated protein, 57, 58*f*
  - function, 58–59
  - genetic deficiencies in, 61
  - host defense functions of, 59–60
  - impairment of, with ARDS, 60–61
  - instillation of, 636
  - metabolism, 57–58, 836–837
    - kinetics, 58
  - phosphatidylcholine, 58
  - production of, 344
  - secretion, 58
    - basal rate, 58
  - static effects of, 59
  - surface tension decrease, 58–59
  - synthesis of, 58
  - therapy, 346–347
  - treatment, effect of, 60*f*
- Surfactant clearance

  - disorders of
    - epidemiology of, 838
    - etiology of, 839–840
    - pathology/pathogenesis of, 844
  - hereditary disorder of, features of, 849*t*

- Surfactant deficiency, 60–61
  - genetic testing of, 846
  - in preterm babies, 180
  - states, 57
  - surfactant treatment of, 61–62
- Surfactant-deficient lungs
  - surfactant effects on, 59
  - surfactant treatment on, 60*f*
- Surfactant dysfunction mutations, type II alveolar epithelial cells and, 67
- Surfactant homeostasis
  - disruption of, 836–849
    - genetic disorders, 841*f*
  - pulmonary, lung diseases associated with disruption of, 836–849
    - diagnosis and differential diagnosis of, 845–847
    - epidemiology of, 836–838
    - etiology of, 838–840
    - management, treatment, and prognosis of, 847–849
    - pathology/pathogenesis of, 840–844
- Surfactant production
  - disorders of
    - clinical features of, 844–845
    - epidemiology of, 837–838
    - etiology of, 838–839
    - imaging, pulmonary function testing, and laboratory testing in, 845
    - pathology/pathogenesis of, 840–844
    - presentation, symptoms, and physical findings in, 844–845
  - genetic testing of, 846
  - hereditary disorders of, features of, 849*t*
  - overview of, 837*f*
- Surfactant protein A (SP-A), 57, 125

- encoding, 57
- misfolding and trapping of, 61
- as pattern recognition molecule, 59
- polymorphisms of, 421

Surfactant protein B (SP-B), 57, 815

- deficiency
  - as autosomal recessive disorder, 838
  - ultrastructural findings associated, 842*f*
- hereditary deficiency, 837
- as hydrophobic surfactant proteins, 60
- as pattern recognition molecule, 59

Surfactant protein C (SP-C), 57

- deficient mice, 61
- gene, 57
- as hydrophobic surfactant protein, 60
- mutations of, lung incidence/prevalence and, 838

Surfactant protein D (SP-D), 57

- as 43-kD hydrophilic collectin, 57

Surgery, preoperative management, 285

Survival motor neuron (SMN), 1047

Susceptibility, individual, environmental exposures in, 50–53

Swallowing

- airway conditions, impact, 1109
- anatomy of, 1106–1108
- behavioral issues, 1113
- conditions, 1108–1109
- delayed initiation, 1098–1099
- development of, 1098
- dysfunction, 1098–1100
- endoscopic evaluation, 1100–1101
- esophageal phase, dysfunction, 1108*t*
- evaluation of, 1100–1101
- function, instrumental assessment of, 1109–1112

- neural control, 1106
- neurologic conditions, 1109
- oral phase, dysfunction, 1108*t*
- pharyngeal phase, dysfunction, 1108*t*
- phases of, 1107–1108
- physiology of, 1106–1108
- radiographic evaluation of, 1100
- treatment strategies, 1112–1113
- voice evaluations and, 1119

Sweat chloride concentration, 770

Sweat gland effects, 767

Sweat test, 769–771, 770*b*

- for asthma, 698
- chloride analyte, 770
- description, 769–770
- Gibson and Cooke, 770

Sylvatic Alaskan-Canadian variant, 543

Sympathetic nerves, 69

Symptomatic vascular compression, surgical management of, 1123

Synchronization, mechanical ventilation and, 554

Synchronized intermittent mandatory ventilation (SIMV) mode, 388

Syndromes, 396

- diagnostic approach by, 404

Synonymous variant, 40, 41*f*

Systemic corticosteroid, for asthma, 962

Systemic disease, characteristics, 765–767

Systemic gas transport, 89–92

Systemic hypertension, 374

Systemic inflammatory conditions, 874*t*

Systemic inflammatory disease, of childhood

  - acute respiratory deterioration in, causes of, 875*t*
  - pulmonary involvement in, 850–875
    - approach to, 874*b*
    - diagnosis/management of, 873–874
    - serologic test for, 851*t*
    - significant, 872–873
  - pulmonary manifestations of, 851*t*

Systemic lupus erythematosus (SLE), 850, 854–857
  - acute pneumonitis and, rarity, 855
  - antiphospholipid antibodies in, presence of, 856
  - chest radiographs, of, 856*f*
  - classification criteria (American College of Rheumatology) for, 855*b*
  - clinical features of, 854
  - epidemiology of, 854
  - pathogenesis of, 854
  - prognosis of, 857
  - pulmonary hemorrhage and, rarity, 855
  - pulmonary hypertension and, rarity, 855–856
  - pulmonary involvement in, 854–857
  - shrinking lung syndrome and, 856
  - treatment of, 857

Systemic onset juvenile idiopathic arthritis, HRCT scan in, 853*f*

Systemic scleroderma, 860

Systemic sclerosis (SSc), 860
  - classification of, 860–861
  - clinical features of, 860
  - pathogenesis of, 861
  - prognosis of, 862
  - pulmonary involvement in, 861
  - treatment of, 862

Systemic steroids, neoalveolarization and, 254

Systemic-to-pulmonary collateral vessels, development, 375

Systemic vascular pressures (reduction), diuretics/drugs (usage) in, 593

**T**

Tachypnea, 4
  usage, 429

TACQOL-Asthma, 234–235, 236*t*–237*t*

Tacrolimus, 984

TagSNPs, 41

*Talaromyces marneffei*, 525–526

TBB, Transbronchial biopsy

TBNA, Transbronchial needle aspiration

T-box family of transcription factors, in gene expression, 26

T cells
  in immune response to, *Mycobacterium tuberculosis*, 477
  regulatory, 106–107
    in lungs, 667–668

Technetium, 263

Technology dependence support, objectives of, 383, 383*t*

TEF, Tracheoesophageal fistula

Temporal progression of symptoms, in asthma, 648–650, 649*f*

Temporal variation, in prevalence of asthma, 642–644, 643*f*–644*f*

Tendon friction rub, 860–861

Tension pneumothorax, creation of, 1065

Teratoid mediastinal tumors, 1075–1079

Terbutaline
  for asthma, 702–703
  subcutaneous, for severe therapy-resistant asthma, 734

Terminal sac, 70

Tetralogy of Fallot, 311–312

  with absent pulmonary valve, 615–619, 618*f*
  reperfusion pulmonary edema in, 622–624
Th0 naïve T cells, 667*f*
$T_H$17 pathway, severe asthma and, 732
Thanatophoric dysplasia, 1005*t*–1006*t*
T-helper 2 (Th2) cells, 101, 667
  chemoattractant receptor of ($DP_2$-receptor), 110
  development of, 105
T-helper 2 (Th2) lymphocyte, 667–668, 668*f*, 668*t*
T-helper type 1(Th1) phenotypes, 123–124
T-helper type 2 (Th2) phenotypes, 123–124
Theophylline
  for asthma, 710
  low-dose, for severe therapy-resistant asthma, 733
Therapeutic bronchoscopy, 143–145
Thiabendazole, for strongyloidiasis, 545
Third-party payers, financial support, 386
Thoracentesis, empyema, 1019
Thoracic acoustics, 10–12
  signs, assessment of regional ventilation by, 12
Thoracic aorta, traumatic rupture of, 1068–1069
Thoracic cage, distortion of, 384
Thoracic diagnostic workup, MRI (usage), 1087–1088
"Thoracic insufficiency syndrome", 1049
Thoracic tumors, management and treatment of, 1090–1091
Thoracic wall, injury, 1065*f*
Thoracoabdominal injuries, 1070–1071
Thoracoscopy, usage, 1090

Thoracotomy, 1020–1021, 1020*f*
    usage, 1090
Thorax
    local sound generation of, 12
    sound transmission characteristics of, 12
Throat specimens, 400
Throat swab, 396–397
Thromboembolism, pulmonary, 887–892
    clinical features of, 889
    diagnosis of, 889–890
    differential diagnosis of, 889–890
    epidemiology of, 887
    etiology of, 887–888, 888*t*
    imaging for, 888, 890*f*
Thrombophilia
    acquired, 888
    inherited, 888
Thrombosis, in pulmonary arterial hypertension, 568
Thumbs, divergence of, 6
Thymic cysts, 1075, 1076*f*
Thymic shadow, size/shape, variation of, 1075
Thymic stromal lymphopoietin (TSLP), 110, 110*f*
    in pediatric allergic asthma, 668–669
Thymus
    and anterior mediastinum, widening of, 147
    chest radiograph for, 147, 148*f*
    enlargement, 1075*f*
    hyperplasia of, 1074–1075, 1075*f*
    neoplasms of, 1075
    teratoma of, 1075
Thyroid transcription factor 1 (TTF1), 836

Tidal volume (VT), 76

Tigecycline, for nontuberculous mycobacterial infections, 504*t*

Tiotropium, 710

  added to ICS and ICS and LABA, 710

TIPPV, Tracheostomy intermittent positive pressure ventilation

Tissue distribution, 759

Tissue-engineered tracheal transplantation, 310

Tissue resistance ($R_{ti}$), 192–193

Tissue respiration, 97–98

Tissues, boundary of, 12

TIVA, Total intravenous anesthesia

TLC, Total lung capacity

T-lymphocytes, 101, 106–107, 107*f*

  in pediatric allergic asthma, 667–668

  quiescence, LKLF, 113–114

T lymphocytes, and lung defense, 130

gd T lymphocytes, 130

T lymphocytic variant HES (L-HES), 966*b*

Tobacco exposure, in pregnancy, 249

Tobacco smoke, in hospitalization, in asthma, 647

Toll-like receptors (TLRs), 123–124, 124*f*

  interaction, 948

Tongue, oral cavity, 1106–1107

Tonsillectomy, usage, 1159

Torr unit, 74

Total atelectasis, chest radiograph revealing, 1088*f*

Total drug output, aerosol, 263

Total intravenous anesthesia (TIVA), 301

Total lung capacity (TLC), 76

Total obstruction, lesion persistence of, 1088*f*

Total respiratory resistance ($R_{rs}$), 192, 192*f*

Total respiratory system, compliance of, 195–196, 195*f*

Total surfactant pool size, 58

Toxic agents, inhalation of, 591

Toxic lung injury, induction of, 591

*Toxocara canis*, in helminth associated eosinophilic lung disease, 962

Toxocariasis, 535–538
  clinical features of, 536–537
  diagnosis of, 537
  differential diagnosis of, 537
  epidemiology of, 535
  etiology of, 535
  management for, 537
  pathology/pathogenesis of, 535–536
  prognosis for, 537–538
  treatment of, 537, 537*t*

*Toxoplasma gondii*, 930

tPAD (trans-Nasal Pulmonary Aerosol Delivery), 271

T-piece jet nebulizer, 267–268, 268*f*

Tracer concentration, 209*f*

Trachea
  congenital abnormalities of, 309–310
    congenital tracheal stenosis, 309*f*–311*f*, 310
    tracheomalacia, 309–310
  deviation of, 8
  kink, 147
  lacerations of, 1066
  position of, assessment of, 8
  resonances from, 10

    sounds, spectra of, 11*f*

Tracheal agenesis, 291

Tracheal airway disorders, operative assessment, 1118–1119

Tracheal atresia, upper respiratory tract, 298, 299*f*, 299*t*

Tracheal bronchus, in Down syndrome, 994, 1002*f*

Tracheal colonization, in *Bordetella* pertussis, 530*t*

Tracheal cytotoxin, in *Bordetella* pertussis, 530*t*

Tracheal hemangiomas, 307–309, 308*f*

Tracheal stenosis

    in Down syndrome, 995

    therapeutic bronchoscopy for, 144

Tracheal tug, examination of, 8

Tracheobronchial stenosis, 867

Tracheobronchial trauma, 1066

    chest radiographs, usage, 1066

Tracheobronchitis

    *Aspergillus*, 516

    in smoke inhalation, 630

Tracheoesophageal fistula (TEF), 291, 313, 313*f*, 322–324

    anatomic abnormalities, 1100

    associations of, 323

    condition, 1114

    etiology of, 322–323

    pathology of, 322–323, 323*f*

    postoperative care of, 324

    preoperative care for, 323–324

    presentation of, 323, 323*t*

    surgery for, 324

Tracheomalacia, 293–294, 309–310, 309*f*, 1124

    aortopexy, 310

    congenital tracheal anomaly, 1124

- in Down syndrome, 993–994
- surgery, 310
- technology dependence, 385
- tracheostomy, 310
- treatment of, 310

Tracheostomy, 310
- for acute respiratory distress syndrome, 614
- in chest wall injury, 1064
- complication, 1097
- operation, morbidity, 1064
- placement, 391
- presence of, 387
- techniques of, 1064*f*

Tracheostomy intermittent positive pressure ventilation (TIPPV), 285, 286*f*

Tracheostomy tube, presence of, 121

Traditional jet nebulizers, 257

Traffic-related air pollution, in asthma, 661

Transbronchial biopsy (TBB), 733

Transbronchial lung biopsy (TBLB), usage of, 866

Transbronchial needle aspiration (TBNA), 143

Transcription factors
- in gene expression, 31–33
- in inflammatory airways, 112*f*
- inflammatory airways and, 112–113

Transcriptional mechanisms, in gene expression, 31–34

Transepithelial potential difference measurements, 772

Transfer RNA (tRNA), 47

Transient hypoxemia, presence of, 346–347

Transient infant wheezers, 679

Transient tachypnea, of newborn, 349, 349*f*

Transition

- approach, 243–246
- barriers, 246
- definition, 241
- evidence base, 242–243
- importance, reasons, 241–243
- from pediatric to adult care, 241–246
- process, principles (development), 242
- readiness, checklist (sample), 245*b*
- Society for Adolescent Health and Medicine definition, 241
- transition, preparation, 243
- young adult preparation, 243

Transplacental transmission, 49

Transporter associated with antigen presentation (TAP) gene polymorphisms, 444

Transpulmonary pressure, 1008

- increase in, achievement of, 592

Transthoracic lung aspiration, 400–401

Transthoracic needle aspiration biopsy, 941–942

Trastuzumab, 883

Trauma

- in drowning, 636
- physiologic compensation to, 1062–1063

Traumatic asphyxia (pulmonary compression injury), 1067

Traumatic chylothorax, 1023

Traumatic pneumothorax, 1064–1065

Traumatic thoracic injury, 1062

Treatment-related lung damage, minimization of, 593

Treprostinil (subcutaneous/intravenous prostacyclin analogue), 576

Triamcinolone, intramuscular, for severe therapy-resistant asthma, 733

*Trichinella spiralis*, in helminth associated eosinophilic lung disease, 962

*Trichosporon* species, 524

Trichosporonosis, 524–525

Triclabendazole, for pulmonary paragonimiasis, 546

Tricuspid regurgitant jet velocity (TRV), 907

Triggers, of asthma, 692
- avoidance of, 715

Trimethoprim-sulfamethoxazole, for nontuberculous mycobacterial infections, 504*t*

Trinucleotide (CTG), instability (expansion), 1047–1048

Triple endoscopy, 1104–1105

Triple risk model, of sudden infant death syndrome, 1134–1135, 1135*f*

Tropical pulmonary eosinophilia, 962

True acidic GER, mucosal injury, 1114

True vocal folds (TVFs), 1106
- adduction, 1107–1108

Trunk, flexion of, splinting with, 5–6

TRV, Tricuspid regurgitant jet velocity

TSC, Tuberous sclerosis complex

TSLP, Thymic stromal lymphopoietin

Tuberculin skin test, for tuberculosis, 485–486, 486*b*, 488*f*, 489*t*

Tuberculins, 485

Tuberculosis (TB), 475–497
- acute pneumonia and, 481
- adult type, 481, 482*f*

bacillus Calmette-Guérin vaccination for, 496
bronchial disease in, 479–480, 480*f*–481*f*
CAP consideration, 431
chest radiography for, 484–485, 484*f*–485*f*
in children, 478, 478*t*, 479*f*
clinical features of, 478–484
complicated lymph node disease in, 480–483, 481*f*
control and prevention of, 496
diagnosis of, 484–485
diagnostic imaging for, 484
disease, 493–495
  adjunctive therapy for, 495
  follow-up for, 495–496
  treatment of, 493
drug-resistant, 494–495, 495*t*
epidemiology of, 475–477
exposure, treatment of, 491–492
extrapulmonary
  clinical features of, 482–483, 483*f*
  treatment of, 494
extrathoracic, 483–484, 483*f*
with human immunodeficiency virus
  clinical features of, 484
  epidemiology of, 476–477
in human immunodeficiency virus–infected children and adolescents, 970–972
  chest radiographs of, 971*f*
  extrapulmonary, 968
  IRIS, 978–979
  multidrug-resistant, 972
  pulmonary, 968, 971
incidence and prevalence of, 476
infection, treatment of, 492–493
interferon-gamma release assays for, 486–488, 488*f*, 489*t*
intrathoracic, 478–479
isolated lymphadenopathy in, 479, 479*f*
laboratory diagnosis of, 488–491, 489*t*
line probe assays for, 491

- pathophysiology of, 477–478
- pleural, 482, 482*f*
- progressive primary infection in, 479, 479*f*
- public health involvement for, 496
- pulmonary, treatment of, 493–494, 493*t*
- staining and microscopic examination of, 489–490
- transmission of, 475–476
- treatment of, 491–496
- tuberculin skin test for, 485–486, 486*b*, 488*f*, 489*t*

Tuberous sclerosis, 290

Tuberous sclerosis complex (TSC), 819–820, 819*f*

Tubular bones, periostosis, 448

Tubular myelin, 58

Tucson Children's Respiratory Study

- in asthma, 648–649
- in preschool wheeze, 679

Tumor necrosis factor (TNF), in asthma, 653*t*

Tumor necrosis factor-a (TNF-a), 123

- blocking, 109–110

Tumors

- benign, 1073–1074
- of chest, 1072–1092
- childhood, pulmonary complications of, 934–935
- of diaphragm, 1087
- malignant, 1074

Turbinates, edema of, from viral infections or allergies, 120

Turbuhaler, 265*f*, 266–267

Turner syndrome, 839–840

“Turnover” (TO), in multiple breath washout, 206

TVFs, True vocal folds

Twin studies, in asthma, 651

Type 2 innate lymphoid cells (ILC2), 668*t*

Type I alveolar epithelial cells, 67

Type II alveolar epithelial cells, 67, 67*f*

Type II cells
  in surfactant, 58
  ultrastructural abnormalities of, 58

Type III hypersensitivity response, 947–948

Type III secretion system (bsc), in *Bordetella* pertussis, 530*t*

Type IV hypersensitivity response, 947–948

**U**

UIP, Usual interstitial pneumonia

Ultrasonic nebulizers, 269

Ultrasonography, 170–172, 171*b*, 171*f*–172*f*, 333–334
  of atelectasis, 1031, 1031*f*

Ultrastructural ciliary defects, 1038–1039, 1039*t*

Uncomplicated fractures, treatment of, 1064

Uncontrolled asthma, 218

Undefined hypereosinophilic syndrome, 966*b*

Unfolded protein response (UPR)
  increased levels of, 843–844
  triggering, 843–844

Unilateral cord palsy, 307

Unilateral diaphragmatic paralysis, 384

Unilateral diseases, 5–6

Unilateral intrathoracic abnormalities, indication of, 8–9

Unilateral paralysis, management of, 1121

Unscreened populations, cystic fibrosis diagnosis (clinical features), 770*b*

Untreated idiopathic pulmonary arterial hypertension, progressive right heart failure in, 564–565

Upper abdominal tenderness, clinical signs of, 1071

Upper aerodigestive tract, 1108

Upper airway, 1147–1148
- congenital abnormalities of, 298–300
  - cough, 300
  - cyanosis, 300
  - neonatal intubation, 300
  - stridor, 300
  - voice/cry, 300
- control, 1147–1148
- in Down syndrome
  - anatomy of, 992–993
  - disease of, 992–995, 993*t*
  - obstruction of, 993*t*
- dysfunction, 1148–1149
- in muscles of respiration, 84
- partial obstruction of, 16
- reflexes, origination, 1144
- systemic disease, 765–766

Upper airway disease
- in human immunodeficiency virus infected children, 980
- on lower airway, influence of, 737–746

Upper airway endoscopy, requirements for, 302*b*

Upper airway infection, aspiration, relationship, 443

Upper airway obstruction, 365–366, 406–419, 407*f*
- acute, infectious and noninfectious causes of, 409, 409*b*
- diagnosis and differential diagnosis of, 409–412
- differentiation of principal infective causes of, 408*t*
- diphtheria, 415–416
- epiglottitis, 412–414
- load compensation, 1131

Upper mediastinal contour, chest radiograph, 148*f*

Upper respiratory tract atresias, 298, 299*f*

Upper respiratory tract disease, in Down syndrome

- clinical presentation of, 995
- treating, considerations when, 1004

Upper respiratory tract infection (URTI), posteroanterior chest radiograph of, 1084*f*

UPR, Unfolded protein response

Urbanization, in prevalence of asthma, 644–645

Urinary antigen testing, 414

Urine, 401

- bacterial antigens (detection), 430

Ursodeoxycholic acid (UDCA), in cystic fibrosis liver disease, 793

URTI, Upper respiratory tract infection

US National Health and Nutrition Examination Survey (NHANES), in asthma, 642–644

Usual interstitial pneumonia (UIP), 813

Usual interstitial pneumonia (UIP)-like pattern, 950–951

Uvulopharyngopalatoplasty, 1159

**V**

Vaccination, for influenza, 464, 464*t*

Vaccine-preventable infections, 396

Vagus nerve, and stimulation of afferent fibers, 120–121

VALI, Ventilator-associated lung injury

Value, in coordinated aerodigestive care, 1096

VAP, Ventilation associated pneumonia

Variceal bleeding, portal hypertension and, 793

Varicella zoster pneumonia, chest radiograph of, 973*f*

Varicella-zoster virus (VZV), 926

Vas deferens, congenital bilateral absence, 767–768

Vascular abnormalities, 298

Vascular cell adhesion molecule (VCAM), corticosteroids and, 705

Vascular cell adhesion molecule-1 (VCAM-1), 105

Vascular compliance, diuretics and, 589

Vascular compression, 1123

Vascular endothelial growth factor (VEGF), 18–19

Vascular endothelium, as source of locally active mediators, 567

Vascular engorgement, in hydrocarbon aspiration, 626

Vascular forces, 582

Vascular markings, preservation of, 148

Vascular permeability, 582

- increased, in fluid-exchanging vessels, 584

Vascular rings, 312–313, 615–619, 616*f*–617*f*

- clinical presentation of, 619
- diagnosis of, 619
- treatment of, 619, 619*f*–620*f*

Vascular trees, resin cast of, 64*f*

Vascular tumors, isolation, 1079

Vascularization, 35–36

Vasculitis, antineutrophil cytoplasmic antibody associated, 895–897

- treatment of, 897

Vasculitis syndromes, pulmonary involvement and, 867–869

Vasoconstriction, pathways responsible for, in pediatric pulmonary arterial hypertension, 566–567, 566*f*

Vasoconstrictive agents, 567

Vasodilator testing, response to, 571

Vasoproliferative substances, release of, 567

VATS, Video-assisted thoracoscopic surgery

VC, Vital capacity

VCD, Vocal cord dysfunction

VCD syndrome, 691–692

VEGF, Vascular endothelial growth factor

Veno-occlusive disease, 937

Venous thromboemboli (VTE), following solid-organ transplantation, 933–934

Ventilated patients, paralysis in, 613

Ventilation

- alveolar, 86
- for asthma, 720
- distribution of, 79*f*, 81
- mechanics and, of breathing, 73
- modalities of, 610–612
- support, CPAP (usage), 273
- via tracheostomy, 387

Ventilation associated pneumonia (VAP), 554

Ventilation index, oxygenation (contrast), 609

Ventilation/perfusion (V/Q)

- isotope study, 172*f*
- mismatch, 17–18, 385
- relationship, 89
- scanning
  - for pulmonary embolism, 890–891
  - usage, 320–321

Ventilator-associated lung injury (VALI), risk for, increase in, 609

Ventilator-dependent children, 382–383

Ventilator-induced lung injury (VILI), 372

Ventilators, dependency, HRQoL measure, 240
Ventilatory assistance, measure of, 609
Ventilatory drive, normalcy, 1147–1148
Ventilatory response, abnormalities, 1140–1141
Ventilatory support
  ancillary equipment, 389–391
  augmentation, 383
  devices, usage, 282
  options for, 387–389
  quality of life, 393
  survival, 392–393
  weaning from, 392
Ventricular dysfunction, in human immunodeficiency virus infected children, 979–980
Ventricular ectopic beats, 21
Venturi effect, 406
Venturi jet injector, 136
Very late antigen-4 (VLA-4), 105
Very long chain acyl-CoA dehydrogenase (VLCAD), 1139
Video-assisted thoracoscopic surgery (VATS), 436
  systematic review, 436
Videofluoroscopic swallow study, 1100, 1110, 1110*f*, 1110*t*
  fiberoptic endoscopic evaluation of swallowing *versus*, 1100*t*
VILI, Ventilator-induced lung injury
Vinca alkaloids (vinblastine and vindesine), 880
Viral gene transfer agents, 806
Viral infection
  in human immunodeficiency virus–infected children and adolescents, 972–973, 973*f*
  in pediatric lung transplantation, 986

Viral laryngotracheobronchitis, 406–409
  clinical features of, 408–409
  dosing regimen for, 410–411
  epidemiology of, 406–407
  etiology of, 407
  formulation for, 410–411
  management of, 409–411
  mild, 408
  moderate, 408
  other treatments for sever cases of, 411
  pathology of, 407–408
  prevention, 411
  prognosis and further evaluation of, 411–412
  route of administration for, 410–411
  sever, 408–409
Viral pathogens, 924–927
Viral pneumonia, respiratory syncytial virus-positive nasopharyngeal aspirate, presence, 431*f*
Viral shedding, bronchiolitis and, 421
Virtual bronchoscopy, 159–161, 160*f*–161*f*
Virulence-activated gene 8, in *Bordetella* pertussis, 530*t*
Visceral larva migrans, 535
Visceral pleura, 1007
  covering, 63
Visceral toxocariasis (VT), 535
Visual analysis, 143
Vital capacity (VC), 76
  reduction, 283–284
Vitamin D deficiency, asthma and, 694
VLCAD, Very long chain acyl-CoA dehydrogenase
VM-26, 880

VMD, Volume median diameter

Vocal cord, syndromes of dysfunction of, asthma and, 726

Vocal cord dysfunction (VCD), measures, 234
  - recommendation, 234

Vocal cord paralysis, 121, 306–309, 1121–1122
  - hemangiomas, 307–309
  - laryngoceles, 307
  - saccular cysts, 307, 307*f*

Voice
  - evaluations, 1119
  - mitigating factors, 1119–1120
  - optimization, 1120
  - patient selection, 1120

Voice-generated vibrations, 8–9

Volume control ventilation, 549, 549*f*

Volume median diameter (VMD), 261

Volume of carbon dioxide ($\dot{V}CO_2$), volume of oxygen ($\dot{V}O_2$) relationship with, 98

Volume of oxygen ($\dot{V}O_2$), relationship with volume of carbon dioxide ($\dot{V}CO_2$), 98

Volume-rendering technique, 159, 160*f*

Volutrauma, BPD development, 372

von Recklinghausen disease, 1085

von Willebrand factor, 68

Voriconazole
  - for invasive aspergillosis, 517–518
  - for pulmonary mycoses, 507–508

VT, Visceral toxocariasis

VZV, Varicella-zoster virus

**W**

Waking, neural circuitry, 1143

Wasserman gears, 214*f*

Water lily sign, 539

Weaning, mechanical ventilation in, 554

Weather, changes in, asthma and, 692

Weibel-Palade bodies, 68

Weight gain, gastroesophageal reflux disease and, 1114

WES, Whole exome sequencing

Westley scale, 409

“Wet lung”, 1067

WGS, Whole genome sequencing

Wheezes, 11, 13–14, 677

- in asthma, 648–649
- clinical patterns of, 679
- differential diagnosis of, 17*b*
- in Down syndrome, 993*t*, 998–999
- findings in, 18*f*
- parental reporting of, 677–678
- pitch of, 17

Wheezing, 16–17, 686–721

- associated with hyperreactive airway disease, 17
- causes of, in older children, 687*b*
- in children, preventive strategy for, 681
- defined, 686
- infections, association, 429
- inspiratory, 690–691
- natural history and prognosis of, 689–690
- pathology of, 686–687, 687*f*–688*f*
- pathophysiology of, 687–688
- patterns, in asthma, 648–649

- physical examination of, 691–692, 692*f*
- prevalence of, 649*f*

Whole exome sequencing (WES), 43, 45*t*

Whole genome sequencing (WGS), 43, 45*t*

Whole lung lavage (bronchopulmonary lavage), usage of, 842

Williams-Campbell syndrome, 65–66

WNT2/2b, in lung morphogenesis, 26–27

Work, of breathing, 80–81

Worrisome signs, 408–409

**X**

Xenobiotics, cytochrome P-450-dependent detoxification of, 65

Xerostomia, 872

X-linked CGD, carriers of, 913

Xpert, 490

**Y**

Young adults
- chronic illness, independence (inability), 241–242
- chronic respiratory disorder, transition, 241
- confidentiality, establishment, 243
- rarer conditions, ongoing care (identification), 245

Youth Quality of Life Instrument, 232

**Z**

Zafirlukast, 709

Zanamivir, for influenza, 463

Zileuton, 709

Z-scores, 176

Zygomycota, 522

Preface 51
Contributors 54
Video Contents 92
Section 1 General Basic and Clinical Considerations 96
- 1 The History and Physical Examination 98
  - The History 99
  - The Physical Examination 105
  - Common Signs and Symptoms of Chest Disease in Children 134
  - Conclusion 159
  - Suggested Reading 160
- 2 Molecular Determinants of Lung Morphogenesis 167
  - Introduction 167
  - Organogenesis of the Lung 168
  - Molecular Mechanisms Directing Lung Development 180
  - Development of the Pulmonary Host Defense Systems 198
  - Gene Mutations in Lung Development and Function 201
  - Summary 202
  - References 203
- 3 Basic Genetics and Epigenetics of Childhood Lung Disease 223
  - Types of Genetic Variation 227
  - Technologies to Identify Genetic Variation 229
  - Interpretation of Genetic Variation 232
  - When to Consider Clinical Genetic Testing 233
  - Research Study Designs to Attribute Genetic Variation to Disease 235
  - Epigenetics—Terminology and Technology 240
  - “Multi-Omics” Approaches to Refine Genotype-Phenotype

Associations 244

Websites 245

References 245

4 Environmental Contributions to Respiratory Disease in Children 254

Vulnerability of Children to Adverse Environmental Exposures 255

Environmental Contributions to Acute Respiratory Illness and Pneumonia 268

Environmental Contributions to Asthma 269

Summary 271

References 271

5 The Surfactant System 284

Surfactant Composition and Metabolism 284

Surfactant Metabolism and Secretion 287

Alveolar Life Cycle of Surfactant 289

Surfactant Function 290

Pressure-Volume Curves 291

Host Defense Functions of Surfactant 292

Surfactant Deficiency 294

Surfactant Treatment of Surfactant Deficiency 298

References 300

6 The Structural and Physiologic Basis of Respiratory Disease 309

Normal Lung Anatomy and Cell Function 309

Airways 311

Alveolar Region 318

Pulmonary Vascular System 323

Lymphatic System 326

Innervation of the Lung 326

Interstitium 328

Growth and Development of the Lung 330

The Lung at Birth 334

Postnatal Lung Growth 335

Ventilation and Mechanics of Breathing 339

Definitions and Symbols 339
Elastic Recoil of the Lung 343
Compliance of the Lung 346
Elastic Properties of the Chest Wall 348
Lung Volumes 349
Regional Lung Volumes 353
Dynamic (Flow-Resistive) Properties of the Lung 355
Distribution of Ventilation 360
Pulmonary Circulation 362
Pulmonary Vascular Pressures 363
Pulmonary Vascular Resistance 363
Distribution of Blood Flow 366
Methods of Evaluating the Pulmonary Circulation 367
Muscles of Respiration 368
Gas Exchange 373
Alveolar Ventilation 374
Dead Space 375
Diffusion 380
Shunt and Ventilation-Perfusion Relationships 383
Systemic Gas Transport 386
Oxygen Therapy 395
Carbon Dioxide Transport and Acid-Base Balance 399
Tissue Respiration 408
Regulation of Respiration 411
Sensory Feedback System 413
Metabolic Functions of the Lung 416
References 417
7 Biology and Assessment of Airway Inflammation 424
Introduction 424
Allergic Inflammation 425
Acute Inflammation 425
Chronic Inflammation 427
Inflammatory Cells 429
Structural Cells as Sources of Mediators 443

Inflammatory Mediators 445
Neural Mechanisms 453
Transcription Factors 455
Antiinflammatory Mechanisms 457
Direct Measurements of Airway Inflammation 459
Noninvasive Assessment of Airway Inflammation 463
Is AHR an Inflammatory Surrogate? 470
Other Potential Indirect Inflammatory Markers 470
Is There a Role for Assessing Inflammation in Pediatric Respiratory Disease? 471
Therapeutic Implications 472
Conclusion 472
References 473
8 Lung Defenses 492
Intrinsic Lung Defenses 492
Innate Lung Defenses 496
Adaptive Lung Defenses 519
Role of Programmed Cell Death and “Clearing the Garbage” in Lung Homeostasis 528
